16. Abstract <p>This report summarizes the work activity related to compatibility analysis in frontal collisions between passenger car and option 2 LTVs. This work involved both an overview analysis of structural interaction in frontal collisions between passenger cars and option 2 LTVs and the design of an over ride barrier for evaluating the secondary energy absorbing structure (SEAS) of the option 2 LTVs.</p> <p>Vehicle-to-vehicle frontal finite element simulations were conducted between compact passenger car (Neon) and option 2 LTV's (Ford F250 and Chevy Silverado). The Ford F250 has a cross-member type SEAS and the Chevy Silverado has a non cross-member type SEAS. The simulations were conducted with and without the SEAS. The effect of the SEAS on structural interaction between the two vehicles is evaluated based on the energy absorption and intrusions in the vulnerable vehicle.</p> <p>A parametric study was conducted with the option 2 LTV FE models to identify impact velocity, width and height of the ORB and the relevant assessment metrics to evaluate the strength of SEAS. Based on this study, an impact velocity of 25 mph was identified as an appropriate speed for the ORB test. A 1250 mm wide barrier with a top height aligned with the top of the Part 581 zone (508 mm) was identified as an appropriate barrier. Potentially, Kw400 could be used as an assessment metric for determining the strength of the SEAS structure.</p>

1 Introduction

As part of the planned research activities under the FHWA/NHTSA/NCAC co-operative agreement DTFH61-02-X-00076 and in consultation with NHTSA research staff, NCAC has conducted initial frontal compatibility studies between passenger car and LTVs. In addition, an over ride barrier design was evaluated based on the current Secondary Energy Absorbing Structure (SEAS) designs to evaluate the strength of the SEAS to promote improved structural interaction in frontal collisions. This report provides a summary and documentation for these two activities and identifies opportunities for further research.

Crash compatibility has attracted a lot of attention in recent years due to the proliferation of bigger, taller, and heavier SUV's. The inherent issue is the safety of the occupants in a smaller vehicle when involved in a collision with a larger vehicle. The three factors that contribute to crash incompatibilities are the differences in **mass, stiffness** and **geometry** between the colliding vehicles. Mass is difficult to control due to customer need for different class of vehicles ranging from small sub-compact cars to large pick-up trucks. Any proposal to control front-end stiffness should ensure that today's self-protection levels are not sacrificed to improve partner-protection. Though these three factors are increasingly difficult to define objectively, controlling front-end geometry presents a possible first step to improve the crash compatibility between passenger vehicles.

A first step toward improving geometrical compatibility was taken by the Alliance of Automobile Manufacturers (AAM) in the USA. The purpose of the voluntary agreement is to "align" the primary structural components for improved engagement in front-to-front crashes and to reduce the occurrence of underride and over-ride. The voluntary commitment was signed by all member manufacturers to begin designing light trucks in accordance with one of the following two geometric alignment alternatives (Figure 1-1), with the light truck at unloaded vehicle weight [1], no later than September 2009:

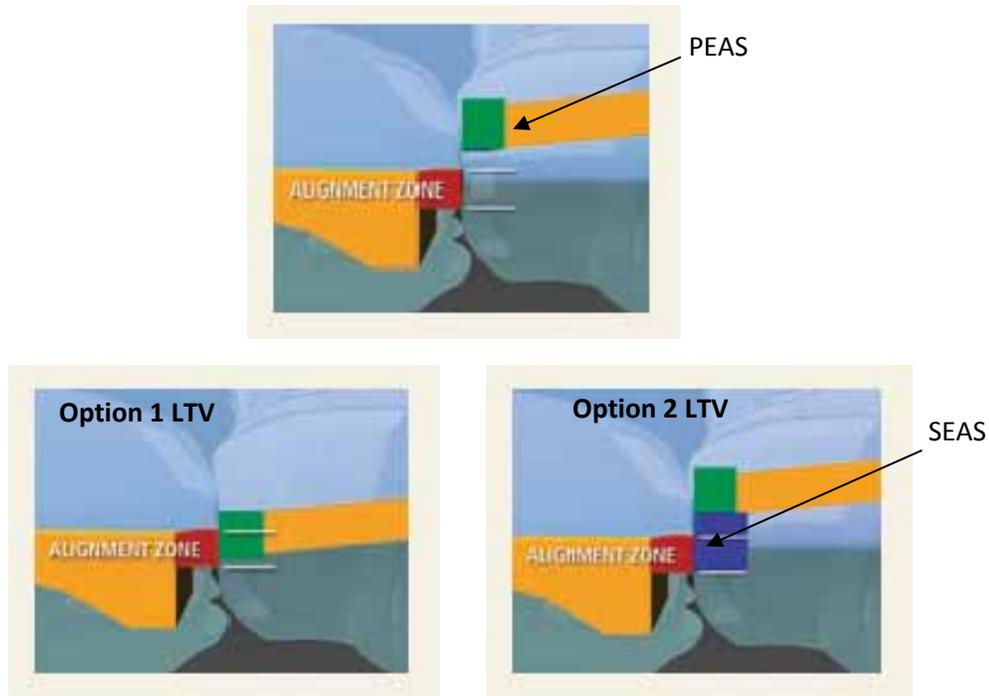

Figure 1-1: Structural Alignment, AAM Voluntary Commitment [1]

Option 1: The light truck’s primary frontal energy absorbing structure (PEAS) shall overlap at least 50% of the Part 581 zone (as defined in 49 CFR 571.3 [2]) AND at least 50% of the light truck’s PEAS shall overlap the Part 581 zone (if the primary frontal energy-absorbing structure of the light truck is greater than 8 inches tall, engagement with the entire Part 581 zone is required) [1].

Option 2: If a light truck does not meet the criteria of Option 1, there must be a SEAS, connected to the primary structure whose lower edge shall be no higher than the bottom of the Part 581 zone. This secondary structure shall withstand a load of at least 100 KN exerted by a loading device, before this loading device travels 400 mm as measured from a vertical plane at the forward-most point of the significant structure of the vehicle [1].

The objective of this study was to characterize the structural interaction between passenger cars and option 2 LTV’s in frontal crashes¹. NCAC/GWU has developed a fleet of virtual vehicles which are used to evaluate the effectiveness of static geometric alignment on structural interaction. The following vehicle pairs are used in this study:

- 1996 Neon – 2006 Ford F250 (Option 2 LTV, cross-member type SEAS)
- 1996 Neon – 2007 Chevy Silverado (Option 2 LTV, SEAS without a cross-member)

¹ Under this contract, the Structural Interaction between passenger cars and option 1 LTV’s was also investigated. The results from this study have been documented in a Doctoral Dissertation titled “Development of Objective Metrics to Improve Compatibility in Frontal Crashes” by Pradeep Mohan at the NCAC/GWU [3].

In addition, a laboratory test method was developed to evaluate the strength of the SEAS. An over ride barrier (ORB) was developed based on a test conducted at VRTC and optimized for the SEAS designs of the 2006 Ford F250 and 2007 Chevy Silverado LTV models.

2 Vehicle Models

NCAC/GWU has been developing a fleet of virtual vehicles which could be used in studies of this nature to gain further insight into structural interaction in many impact scenarios. The vehicle FE models range from a small sub-compact car (1997 Geo Metro) to a full size pick-up truck (2006 Ford F250). The vehicle models chosen for this study are based on the 1996 Dodge Neon, 2006 Ford F250 and the 2007 Chevy Silverado (Figure 2-1). These models have been validated to a full frontal NCAP test [Appendix A].

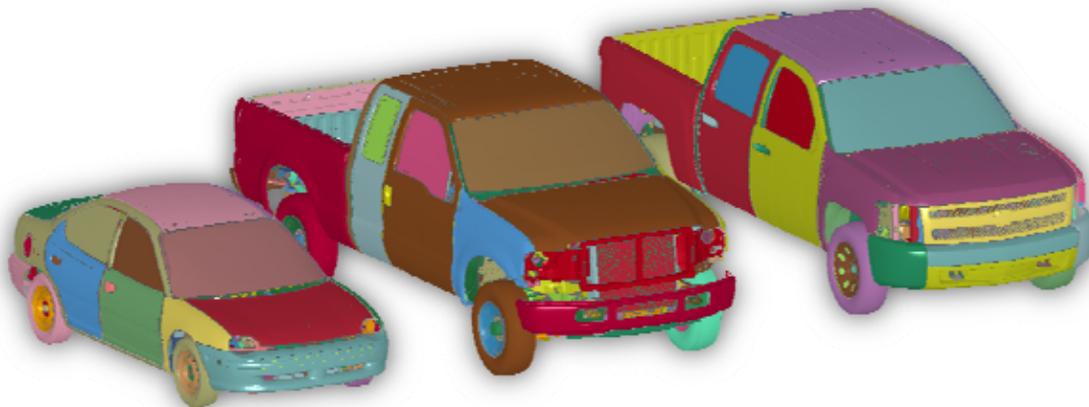

Figure 2-1: Vehicle FE Models Used in this Study (Neon, F250 and Silverado)

The frontal Force-Deformation (F-D) characteristics for the Neon, F250 and Silverado in a full frontal rigid barrier impact are shown in Figure 2-2. True AHOF400² and Kw400³ were calculated for each of the vehicles. Table 2-1 summarizes the difference in mass, geometry and stiffness between the target vehicle (Neon) and the two bullet vehicles (F250 and Silverado). From the F-D curves, it is evident that the frontal structure of the F250 and the Silverado are much stronger than that of the Neon. Consequently, the energy required to crush 400 mm of the front end of the F250 and the Silverado is much higher than the Neon as reflected by their respective Kw400 measures. Vehicle-to-vehicle full frontal simulations were conducted between Neon-F250 and Neon-Silverado. The closing speed was chosen such that the Neon experiences a Delta-V similar to that in a Frontal NCAP simulation.

² AHOF400 is defined as a metric to quantify vertical geometric alignment of a vehicle. The True AHOF400 is calculated from a full frontal impact into a rigid wall instrumented with load cells that can measure both Forces and Moments [3].

³ Kw400 (Crush-work stiffness) is defined as a metric to quantify front-end stiffness of the vehicles. The area under the F-D curve between 25 and 400 mm of front-end crush is equated to ideal spring energy. The resulting “K” value is termed Kw400 [3].

Table 2-1: Mass, AHOF400 and Kw400 for Neon, F250 and Silverado

		Target Veh.	Bullet 1	Bullet 2
		Neon	F250	Silverado
Mass	kg	1335	2998	2622
<i>Mass Ratio</i>			2.25	1.96
True AHOF400	mm	448	704	584
<i>AHOF Ratio</i>			1.57	1.30
Kw400	N/mm	1251	2940	2550
<i>Kw400 Ratio</i>			2.35	2.04
Approach Velocity	mph	35	15.59	17.8
<i>Closing Speed</i>	mph		50.59	52.80

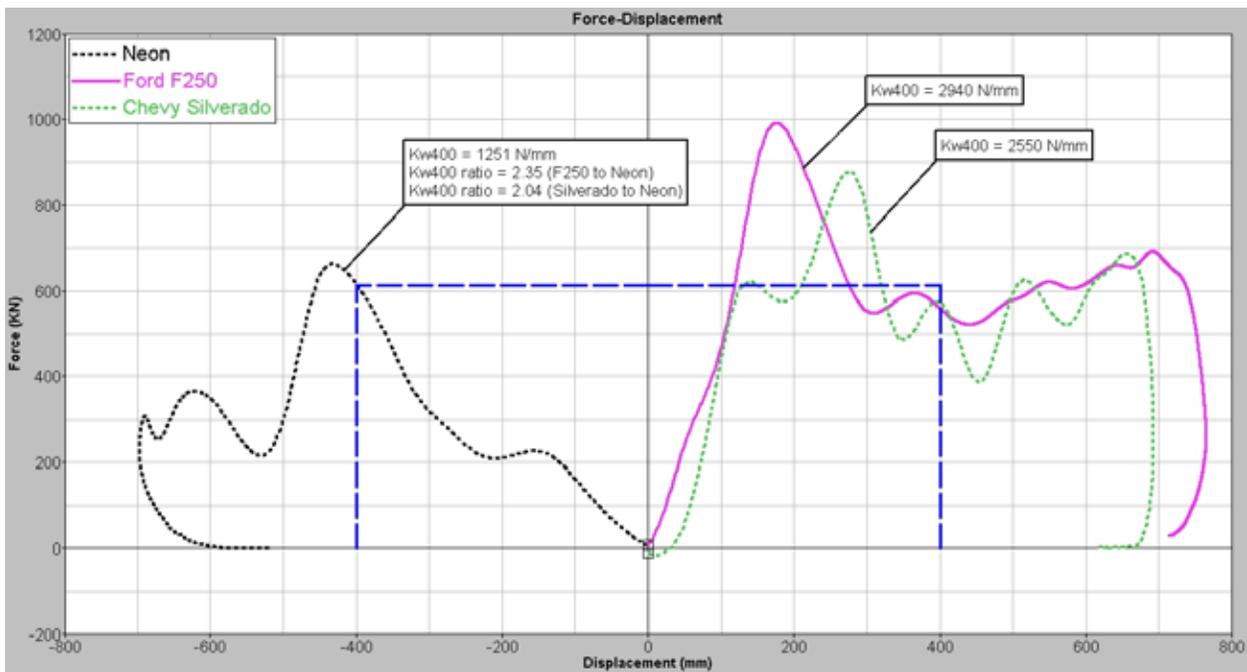

Figure 2-2: Force Deformation Comparison of Neon, F250 and Silverado

The structural alignment between Neon-F250 and Neon-Silverado is shown in Figure 2-3 and Figure 2-4, respectively. There is a significant vertical geometric mismatch between the PEAS of the Neon and F250. The SEAS positioned below the PEAS of the F250 overlaps 50% of the Neon PEAS as required by the AAM voluntary commitment to improve compatibility in frontal impacts for Option 2 LTV's. Based on the location and dimensions of the Silverado PEAS, it comes very close to being classified as an Option 1 LTV. Geometrically, the vertical mismatch of the PEAS is much lower between Neon-Silverado when compared to Neon-F250.

The lateral overlap of the PEAS in full frontal impact between Neon-F250 and Neon-Silverado is shown in Figure 2-5 and Figure 2-6. The results from these simulations are presented in the next chapter.

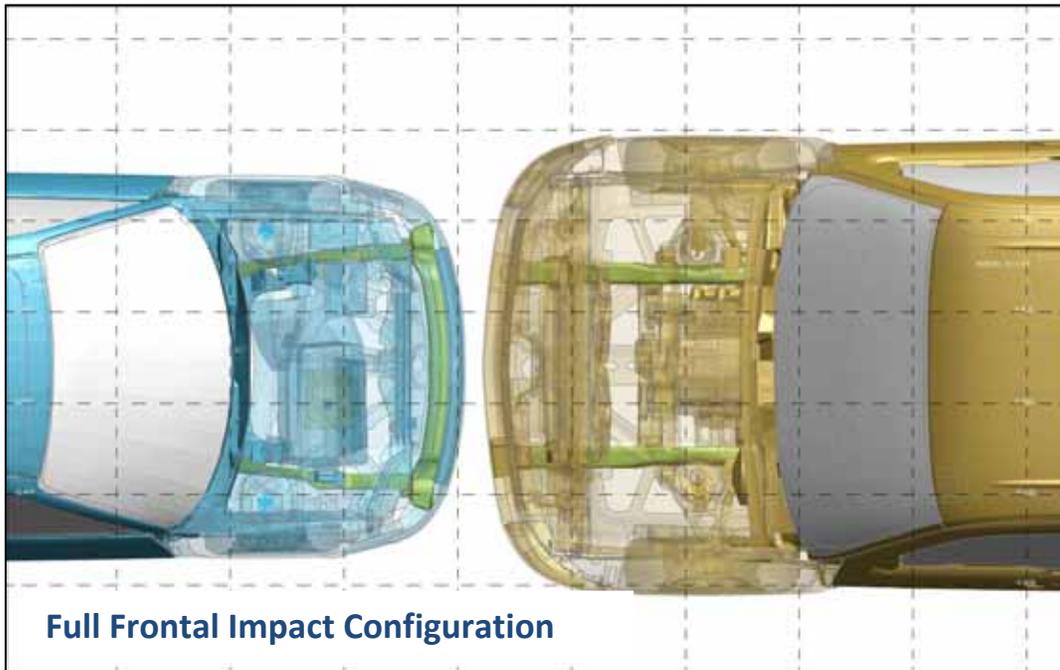

Figure 2-6: Lateral Overlap of PEAS, Neon and Silverado

3 Vehicle-to-Vehicle Simulation Results

3.1 Neon-F250

Full frontal and 40% offset frontal simulations were conducted between Neon and F250. Each of these simulations was conducted with and without the SEAS of the F250 to evaluate the influence of the SEAS on structural interaction between the two vehicles. The interaction between the PEAS of the Neon and the F250 is illustrated in Figure 3-1 (with SEAS) and Figure 3-2 (without SEAS). The SEAS on the F250 prevents the Neon from completely under riding the F250. The front of the Neon PEAS interacts with the F250 SEAS and crushes axially in the beginning, but as the SEAS starts to fail the Neon PEAS starts to bend towards the ground. Without the SEAS on the F250, the structural interaction is significantly reduced resulting in notable under riding of the Neon front end.

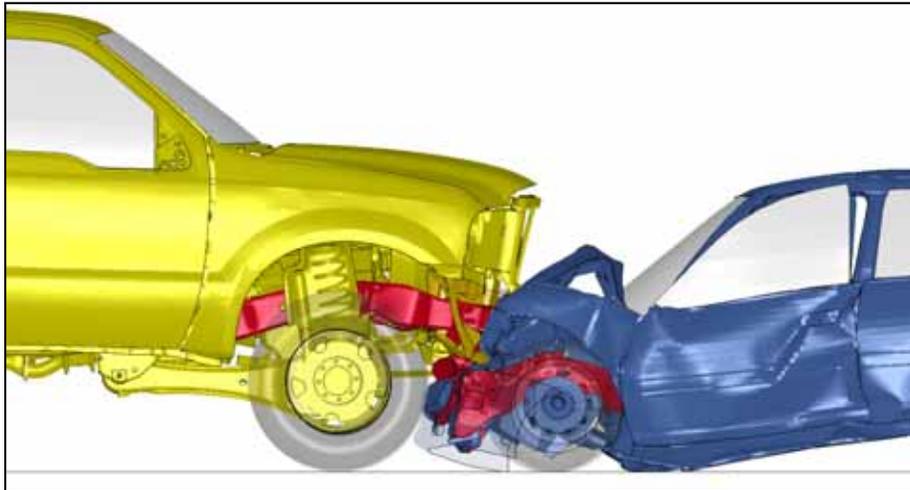

Figure 3-1: Structural Interaction between Neon and F250 (with SEAS)

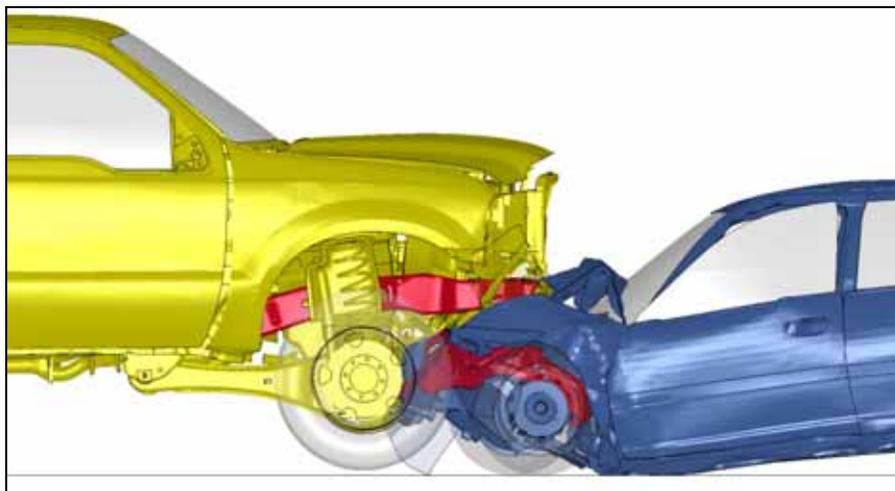

Figure 3-2: Structural Interaction between Neon and F250 (without SEAS)

The change in structural interaction was primarily investigated based on the amount of crash energy absorbed by the vehicles involved in the crash. In addition to the crash energy, the amount of structural intrusion into the occupant compartment of the vulnerable vehicle was compared.

The crash energy absorbed by the vulnerable vehicle (Dodge Neon in this research) is further divided into two groups:

- Front engine compartment energy
- Occupant compartment energy

The front engine compartment energy is the energy absorbed by the components that are designed to absorb the crash energy. This includes the longitudinal frame rails, upper rails and the sub-frame etc., as shown in the front section of the Neon (picture of front section in Figure 3-3). The occupant compartment energy is the energy absorbed by the occupant compartment, which is primarily designed to prevent any structural collapse into the occupant compartment. This includes the A, B and C pillars, roof rail, doors, fire wall etc., as shown in the occupant compartment of the Neon (picture of occupant compartment in Figure 3-3). The internal energy absorbed by each of the components as a function of time, in the two groups was summed from the simulation results.

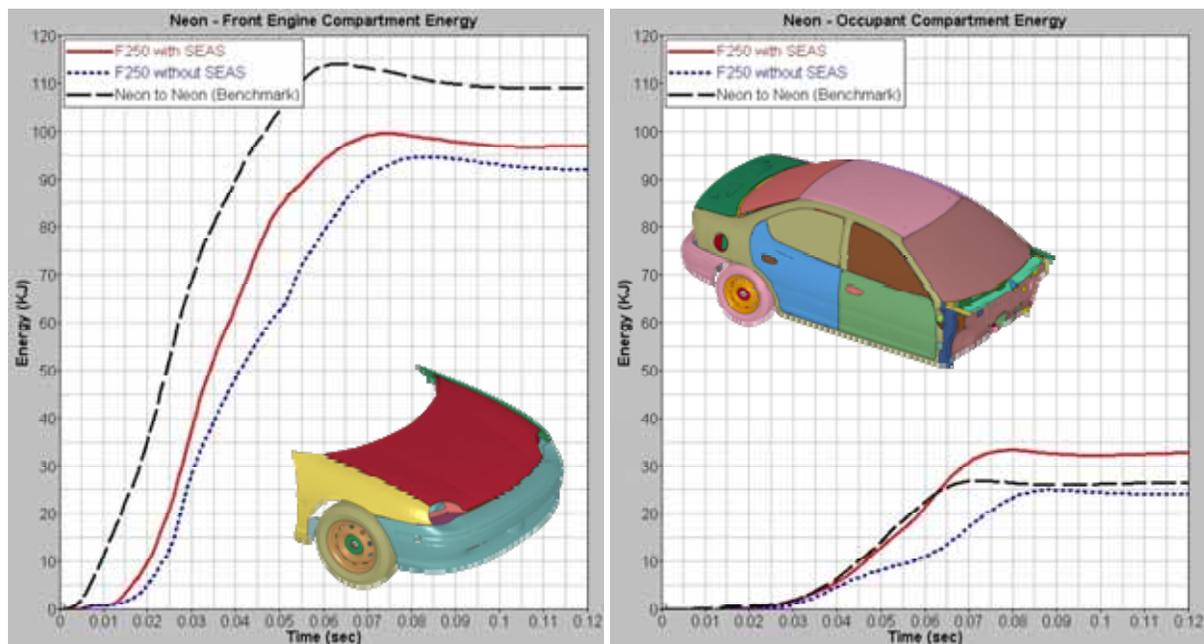

Figure 3-3: Energy Distribution, Neon-F250 Full Frontal Impact

The benchmark for energy comparison is a full frontal simulation between identical Neon's. The mass ratio, the AHOF400 ratio, and the Kw400 ratio are all equal to one. The energy distribution between the front engine compartment and occupant compartment for full frontal impact between Neon-F250 (with SEAS), Neon-F250 (without SEAS) and Neon-Neon is shown in Figure 3-3. "Due to significant mismatch between the Neon PEAS and the F250 PEAS, the Neon frontal structures do not deform as observed in the Neon-Neon benchmark simulations".

Consequently, the energy absorbed by the Neon front engine compartment is lower compared to the benchmark simulation between identical Neon's. The presence of the SEAS shows that the occupant compartment energy initially follows the benchmark simulation, but due to taller, stiffer and heavier F250 the Neon occupant compartment continues to crush and absorb more energy to satisfy the conservation of energy principle. On the other hand, without the SEAS, there is significant underride of the Neon frontal structures and hence, the energy absorbed by the Neon occupant compartment converges to the benchmark simulation. This cannot be conceived to offer better protection to the Neon occupants. Though structural mismatch is desired in low severity crashes to reduce compartment accelerations, the problems associated with geometrical mismatch outweigh their benefits. Typically, crash sensors are positioned on the PEAS and the bumper structure to trigger air bags and pretensioners in the event of a crash. A frontal crash resulting in underride may not trigger these countermeasures. This may reduce their effectiveness in reducing risk of serious injuries to the occupants. This phenomenon was observed in a laboratory test between Ford F250 with and without the SEAS and the Ford Focus. The probability of injuries increased for the Ford Focus driver in a frontal impact with the Ford F250 without the SEAS [4].

Neon Intrusions

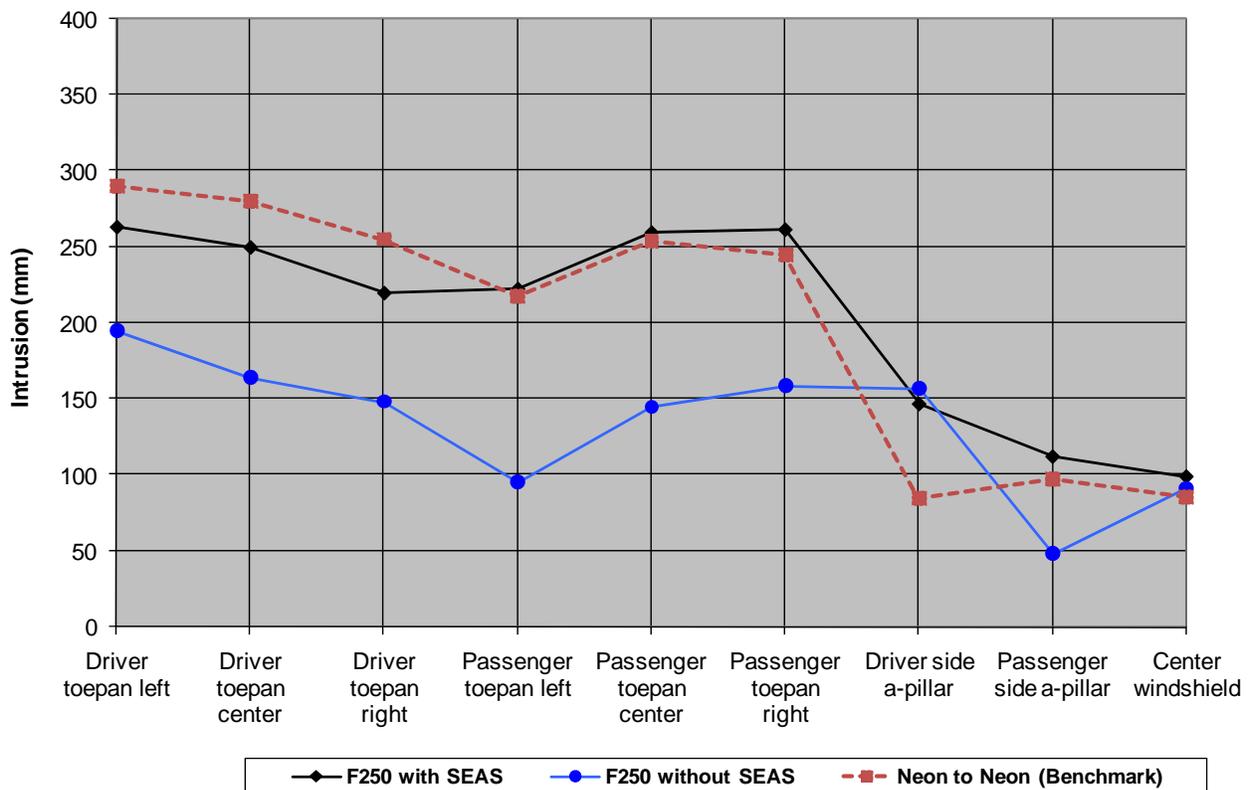

Figure 3-4: Neon Intrusions, Neon-F250 Full Frontal Impact

The energy comparison won't be conclusive without evaluating the resulting intrusions into the occupant compartment of the vulnerable vehicle. The intrusion into the Neon occupant compartment in full frontal impact with F250 (with and without SEAS) and Neon is shown in Figure 3-4. The structural underride between Neon and F250 without the SEAS results in lower

toe pan intrusions compared to impact between Neon and F250 with the SEAS. This is expected as the lower load path is not initiated due to the geometrical mismatch of the structures without the SEAS on the F250. The toe pan intrusions in the case of Neon to F250 with the SEAS are very similar to the benchmark impact between identical Neon's. However, in both cases (Neon to F250 with the SEAS and without the SEAS) the driver side A-pillar intrusions are nearly twice that of the benchmark impact between identical Neon's.

3.2 Neon-Silverado

The structural interaction between the PEAS of the Neon and the Silverado is illustrated in Figure 3-5 (with SEAS) and Figure 3-6 (without SEAS). The SEAS in the Silverado is laser welded to the PEAS and cannot be easily separated as in the Ford F250, where the SEAS is a bolted structure to the PEAS. However, separating the SEAS from the Silverado PEAS is possible in computer simulations. The simulation results showed that the presence or absence of the SEAS on the Silverado has negligible effect in the overall crush kinematics of the Neon frontal structures. This is because of the vertical geometric overlap between the PEAS of the Neon and Silverado (Figure 2-4).

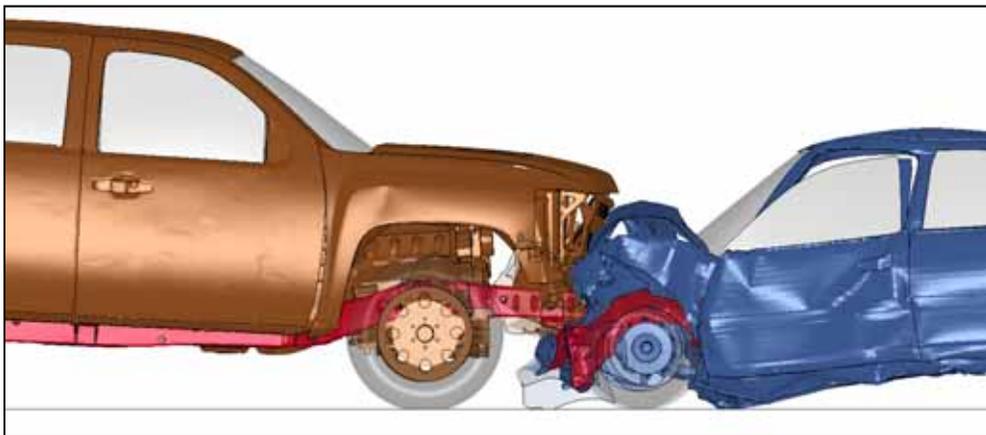

Figure 3-5: Structural Interaction between Neon and Silverado (with SEAS)

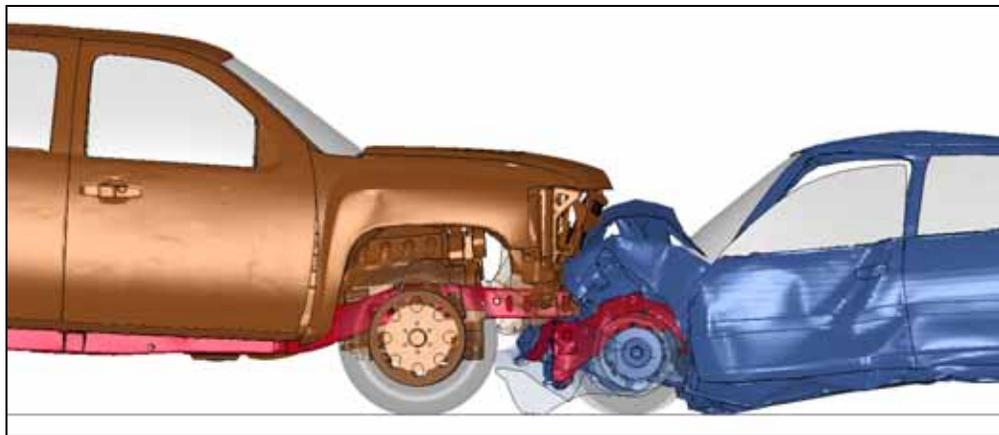

Figure 3-6: Structural Interaction between Neon and Silverado (without SEAS)

The energy distribution between the front engine compartment and occupant compartment of the Neon for full frontal impact between Neon-Silverado (with SEAS), Neon-Silverado (without SEAS) and Neon-Neon is shown in Figure 3-7. The energy absorbed by the Neon frontal structures in a frontal impact between Neon-Silverado is similar to the benchmark simulation between identical Neon's. The Neon frontal structures deformed, primarily, in axial compression which is consistent with full-width barrier tests. However, the energy absorbed by the occupant compartment is significantly higher when compared to the benchmark simulation. Since, the Silverado is much heavier and stiffer than the Neon; the Neon structure has to absorb the remainder of the crash energy to satisfy the conservation of energy principle.

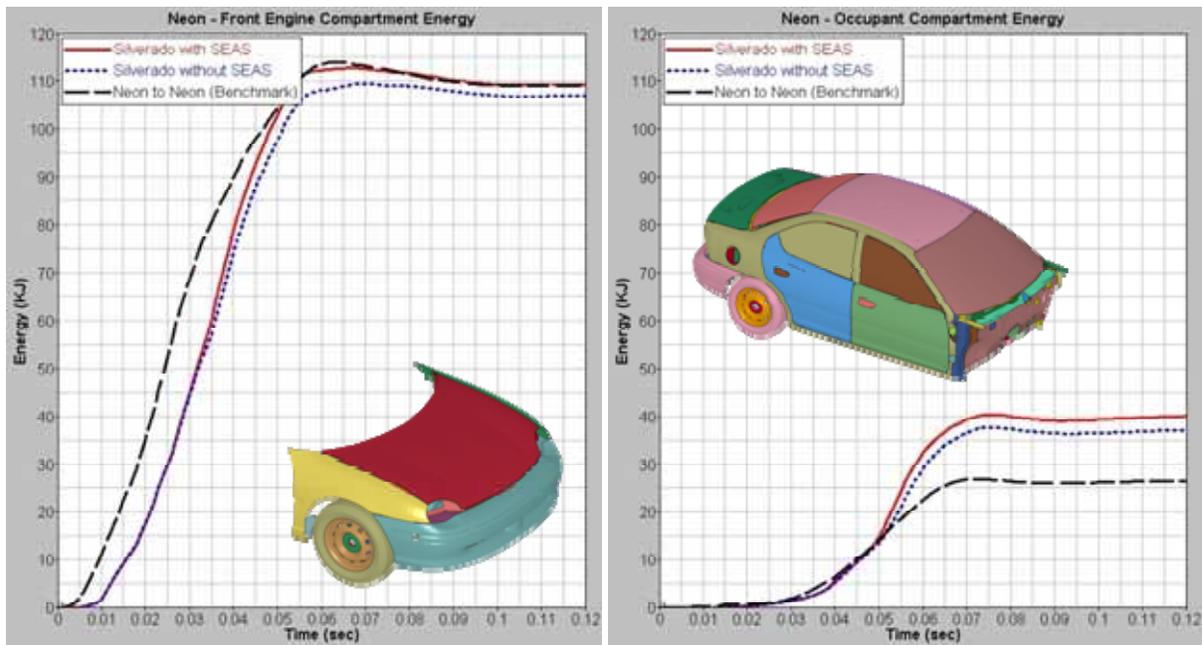

Figure 3-7: Energy Distribution, Neon-Silverado Full Frontal Impact

One interesting observation is the front engine compartment and occupant compartment energies of the Neon are only marginally lower when impacted by the Silverado without the SEAS compared to the Silverado with the SEAS simulation. The design and placement of the SEAS makes the Silverado PEAS stiffer and reduces its contribution to energy absorption in a frontal impact with Neon. When the SEAS is removed, there is slightly higher energy absorption by the Silverado PEAS and this lowers the amount of energy to be absorbed by the Neon frontal structure. Since the Silverado PEAS without SEAS absorbed more energy than the Silverado PEAS with SEAS, the Neon frontal compartment and the occupant compartment had to absorb less energy in the Neon-Silverado without SEAS compared to Neon-Silverado with SEAS.

The resulting Neon compartment intrusions complement the observation above on energy distribution. The resulting toe pan and A-pillar intrusions are higher for the Neon-Silverado (with and without SEAS) simulation compared to the benchmark simulation Figure 3-8. Without the SEAS, the intrusions at the toe pan are lower as some of the crash energy is absorbed by the Silverado PEAS.

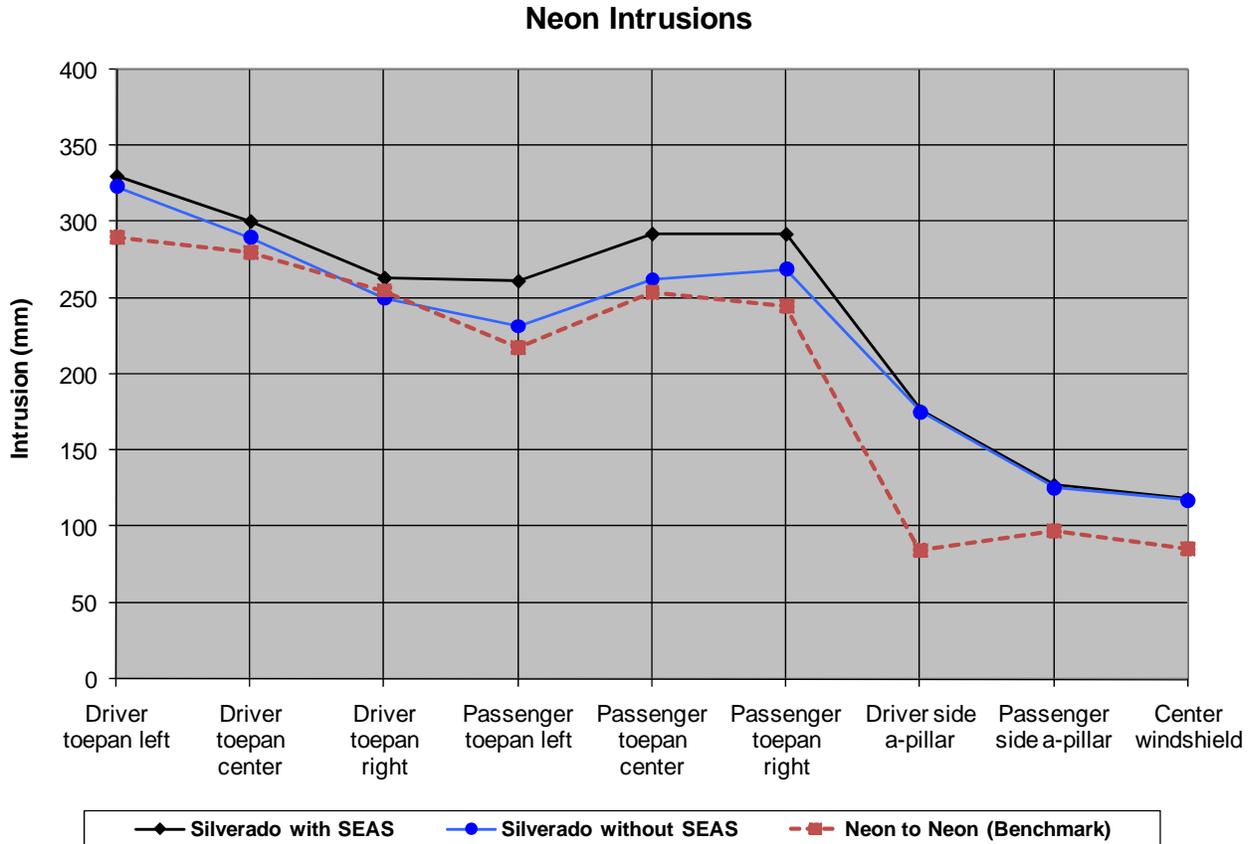

Figure 3-8: Neon Intrusions, Neon-Silverado Full Frontal Impact

3.3 Summary

The observations from the Neon-F250 simulations demonstrate that the cross-member type SEAS design helps prevent under-riding of the Neon frontal structures. Under-riding of Neon structures was not observed in the structural interaction (Figure 3-5 & Figure 3-6) between Neon and Silverado with and without SEAS. The SEAS in the Silverado was a non-contributing factor in the overall crush kinematics of the Neon frontal structures, mainly because of the vertical overlap of the PEAS structures of the Neon and Silverado. The Neon intrusions and occupant compartment energy were higher than the benchmark simulations between identical Neon's.

This preliminary analysis was limited to understanding the structural interaction in full frontal and offset frontal impacts. Other frontal and oblique impact conditions and impact locations and their effect on structural interaction were not considered in this preliminary analysis. The effect of these impacts on occupant injury was also not considered in this study at this time. A validated occupant compartment model with the necessary restraints required for this analysis is not available at this time. Future passenger car models planned to be developed can be used to extend this study to evaluating injury risks.

4 Over Ride Barrier Development

4.1 Overview

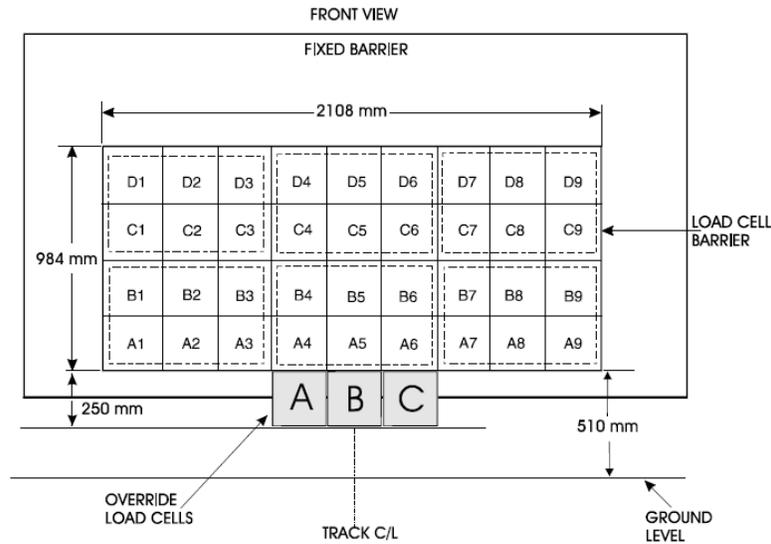

The Compatibility Technical Working Group (TWG) proposed that the SEAS withstand a load of at least 100 KN exerted by a loading device, before this loading device travels 400 mm as measured from a vertical plane at the forward-most point of the significant structure of the vehicle [1]. The TWG investigated and recommended a dynamic over ride barrier (ORB) test to evaluate the proposed SEAS strength requirements. The various SEAS designs on option 2 LTVs posed a unique challenge in developing a robust test procedure to evaluate the strength of SEAS.

NHTSA developed a concept ORB to study the emerging SEAS designs and its effect on structural interaction in frontal collisions [5]. A 2006 Ford F250 (cross-member type SEAS) and 2007 Chevy Silverado (non cross-member type SEAS) (Figure 4-1) were used in this series of tests. Since the vertical location of the SEAS and the SEAS differed for the LTV's, two different ORBs were used in these tests. The Ford F250 impacted into 750 mm wide ORB with 510 mm of ground clearance while, the Silverado impacted into 1250 mm wide ORB with 431 mm of ground clearance (Figure 4-2). In both tests, there was extensive damage to the SEAS and its connecting brackets.

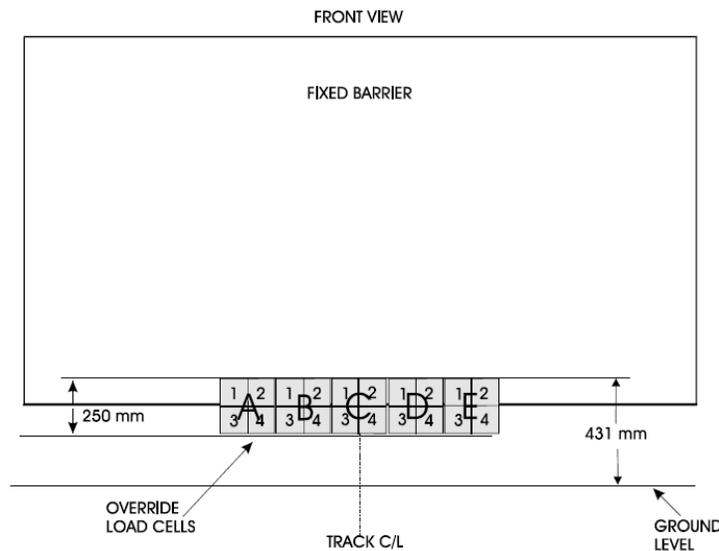

The objective of this task was to develop a laboratory test procedure, based on and building upon the tests conducted at VRTC, for evaluating the strength of SEAS to promote structural interaction in frontal collisions between option 2 LTV's and passenger cars. A simulation based parametric study was conducted to identify the barrier construction, impact velocity and assessment metrics to evaluate the strength of the SEAS.

Figure 4-1: Different Type of Secondary Energy Absorbing Structure (SEAS)

(a) 750mm wide ORB with 510mm of ground clearance

(b) 1250mm wide ORB with 430mm of ground clearance

Figure 4-2: Different ORB used in Tests

4.2 Model Validation

The Ford F250 and Chevy Silverado FE models were validated to the ORB tests conducted at VRTC. Figure 4-3 shows the time history comparison for the Ford F250 test and simulation. In the physical test, there was extensive deformation of the SEAS and its brackets primarily by metal rupture and bolt failures. The failure and rupture in the physical vehicle was a continuous process while it was discontinuous in the simulation because of element size limitations. Several different modeling approaches were examined to capture the deformation mode observed in the ORB test. Reasonable correlation was achieved for the acceleration and

velocity signals between the test and simulation (Figure 4-3). However, matching the forces on the ORB was extremely difficult due to bolt separation and failure during loading of the SEAS. Figure 4-4 shows the deformation of the SEAS structure for the test and simulation. Overall, the model was deemed adequate to capture the response of the ORB test and sufficient enough for the objective of this task (parametric study).

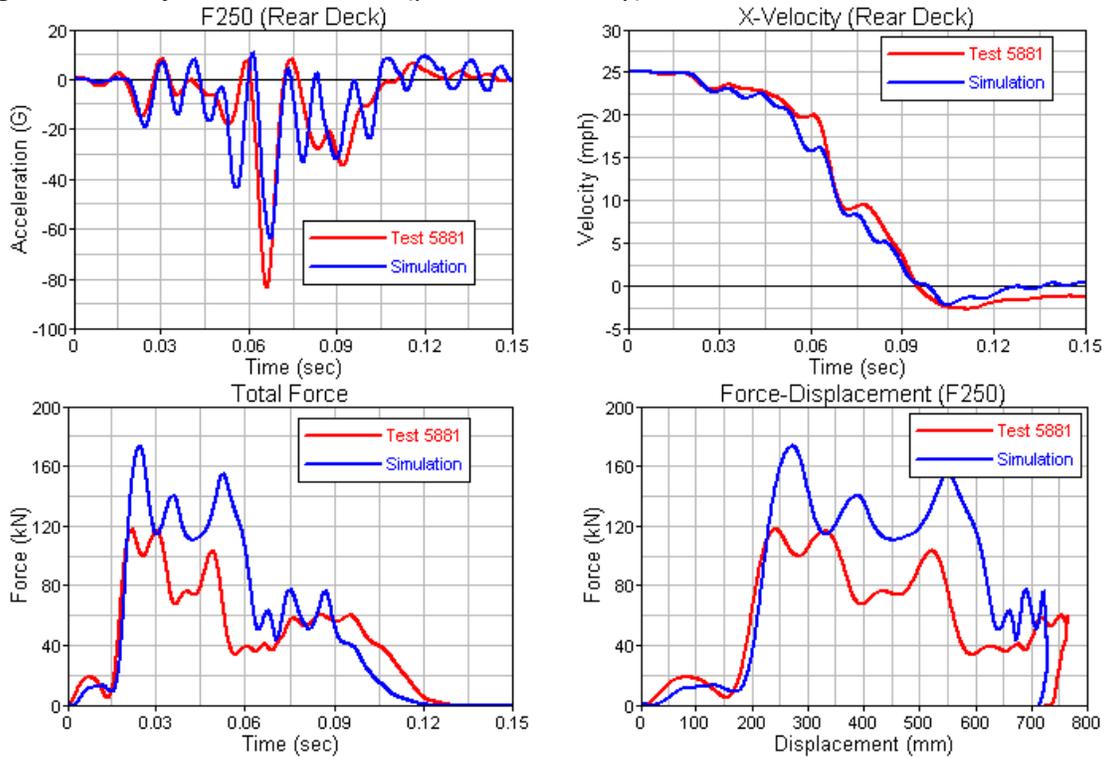

Figure 4-3: Validation of F250 ORB Test

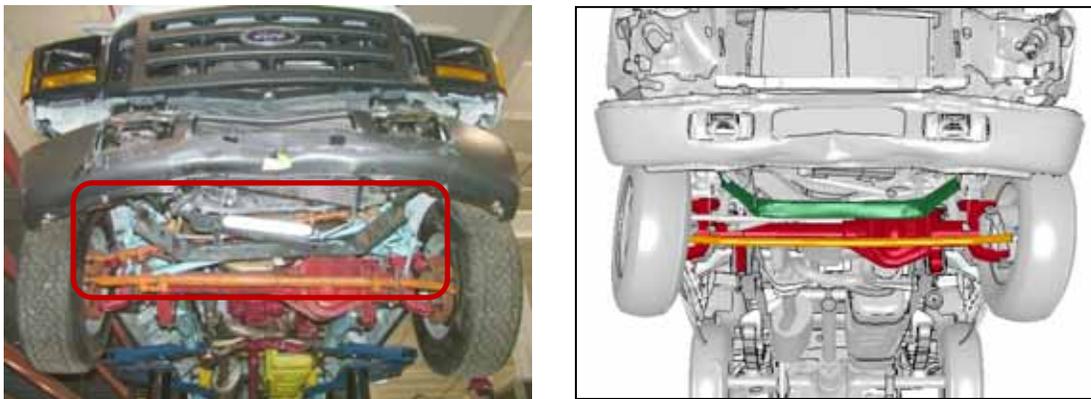

Figure 4-4: Comparison of the SEAS Deformation of F250

Figure 4-5 presents the correlation of Silverado ORB test and simulation. The model showed reasonable correlation for the acceleration and velocity at vehicle rear deck and total wall force. Similar deformation modes were observed between the test and simulation for the Chevy Silverado (Figure 4-6). The PEAS bends upwards as the SEAS loads the ORB. Once the

load exceeds the failure limit, the SEAS shears off by tearing the bottom section of the PEAS. This is followed by the suspension components loading onto the ORB.

The rupture observed in the PEAS and the SEAS in the physical test was again the limiting factor to effectively correlate the model. The first peak in the ORB wall force was generated by the impact of SEAS and the second peak was generated by the subsequent impact of the suspension components into the ORB. This essentially means that the SEAS of the Silverado reached its failure load quickly and did not absorb crash energy as the SEAS in the F250. Even though the peak force levels are similar between the F250 and Silverado, the Silverado SEAS did not sustain the force once it reached the failure load which led to relatively lower energy absorption compared to the F250 SEAS.

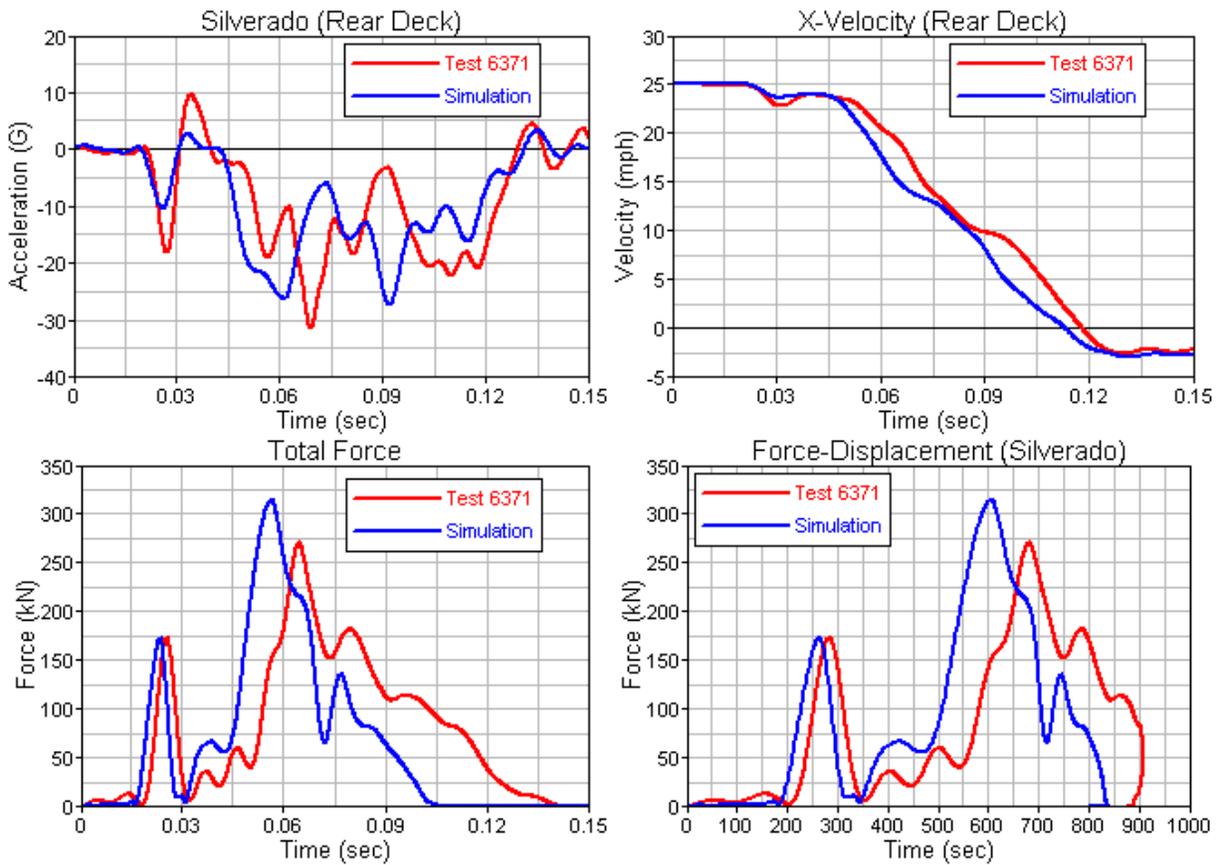

Figure 4-5: Validation of Silverado ORB Test

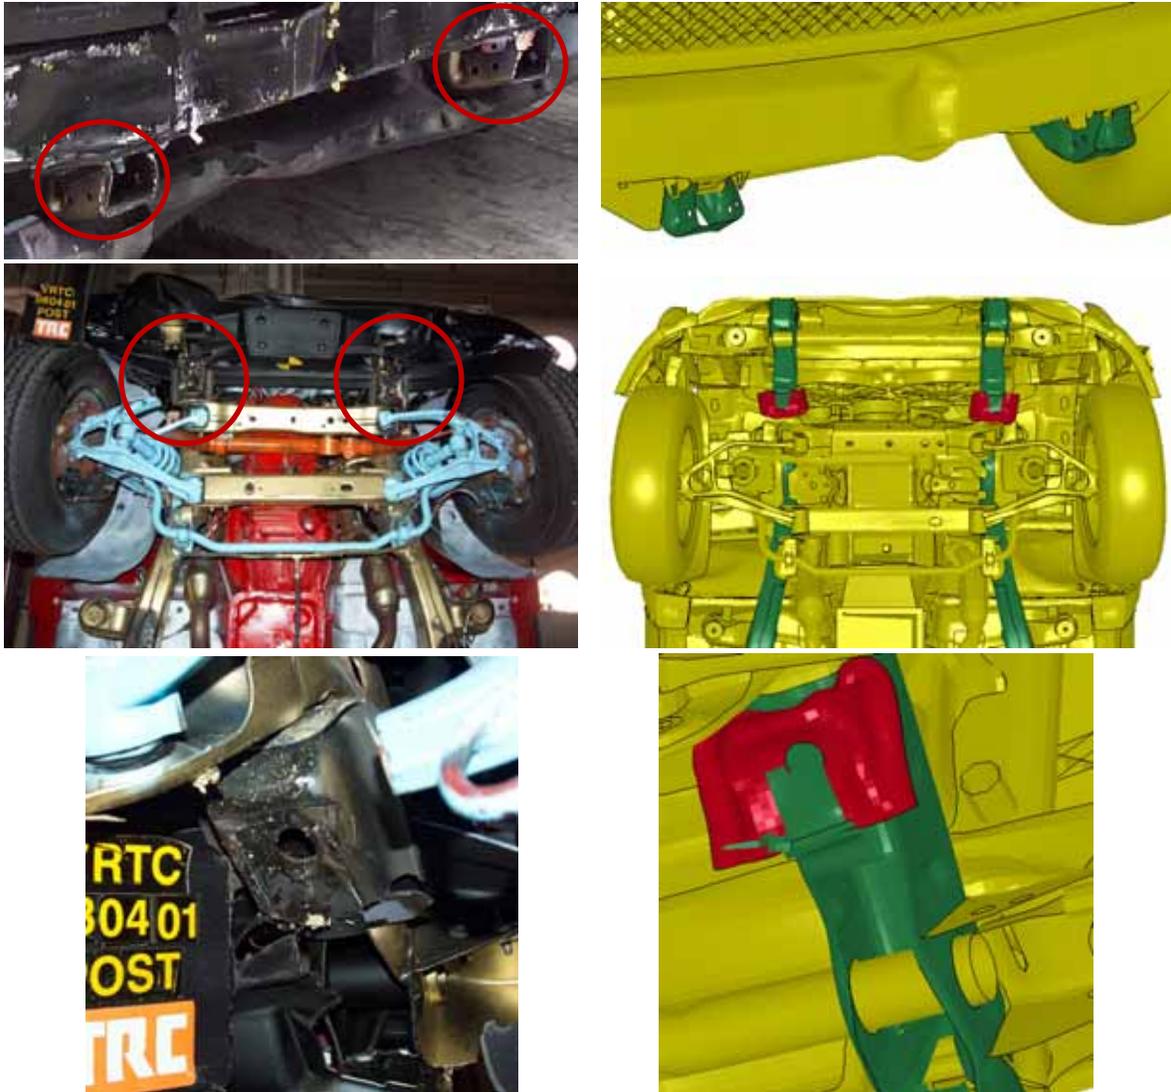

Figure 4-6: Comparison of the SEAS Deformation of Silverado

4.3 Parametric Study

The two LTV FE models were used in a parametric study to identify a suitable test condition, barrier design and assessment metrics to evaluate the strength of SEAS to improve structural interaction in frontal collisions. Two different barrier widths (750mm and 1250mm) were considered based on the physical tests conducted at VRTC. In addition, a 50% offset impact into an ORB was investigated. The impact velocity, width and height of the ORB and assessment metrics are recommended based on this parametric study.

Impact velocity

The ORB simulations were performed at five different impact velocities starting from 15 mph and in increments of 5 mph thereafter till 35 mph. Both the 750 mm and 1250 mm wide ORB barrier were used. These simulations were performed with the F250. The top of the ORB

was aligned at 510 mm as in the tests conducted at VRTC. Figure 4-7 shows the force-displacement (F-D) response for each of the ORB at different impact velocities. These F-D curves were generated from the total force on the ORB and the displacement of the vehicle as measured by the accelerometer mounted at the rear deck⁴. Impact velocities over 25 mph resulted in a secondary impact on the ORB by the power train and suspension components (Figure 4-8 and Figure 4-9). This secondary impact will have confounding effects on the assessment metrics to effectively evaluate the strength of SEAS. The impact velocities of 15, 20 and 25 mph resulted in very similar F-D response. The only noticeable difference was the increased crush at higher velocities in order to manage the increase in kinetic energy. Hence, an upper limit of 25 mph was recommended for the ORB test based on the SEAS design for the F250.

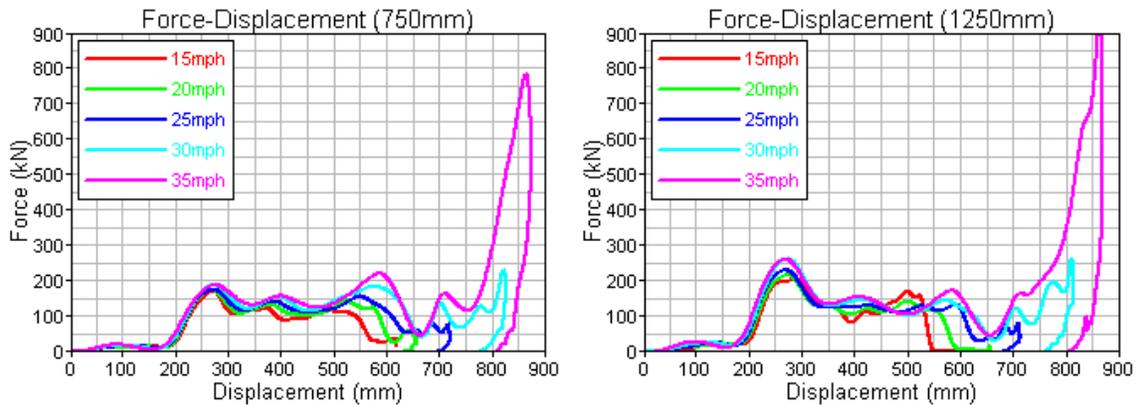

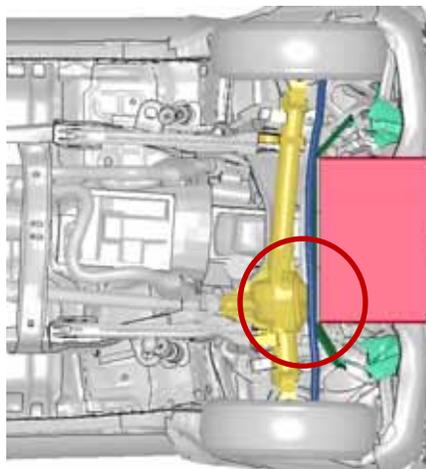

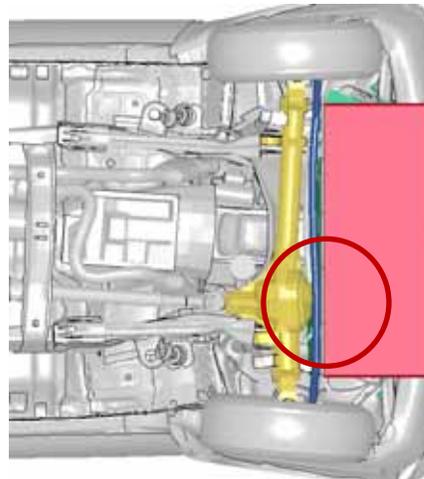

Figure 4-7: F-D Curves at varying Impact Velocities (F250)

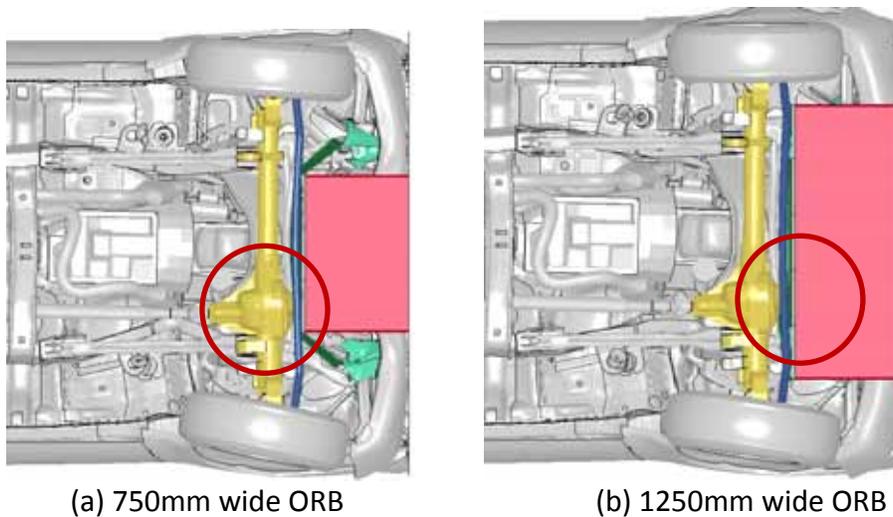

(a) 750mm wide ORB

(b) 1250mm wide ORB

Figure 4-8: Interaction of Underbody Component at 35mph Impact (F250)

⁴ The accelerometer response from the rear deck was chosen rather than from the CG to eliminate the second order effects experienced by the accelerometer at the CG due to the compliance in the body mounts. The accelerometer response at the rear deck is a first order effect which captures the SEAS loading without any interference from the body mount compliance.

(a) 750mm wide ORB (b) 1250mm wide ORB
 Figure 4-9: Interaction of Underbody Components at 30mph Impact (F250)

Width of ORB

The width of the ORB should be selected such that the ORB can effectively evaluate the strength of SEAS for the different SEAS designs (F250 and Silverado). For example, the 750 mm wide ORB does not completely overlap the SEAS structure of the Silverado (Figure 4-10). Hence, the SEAS evaluated using the 750 mm ORB may result in a loading pattern much different from that in the real world vehicle-to-vehicle impacts. The deformation mode of the SEAS in the ORB test was compared to SEAS deformation in a full frontal simulation between F250-Neon. The SEAS loading in the F250-to-ORB simulation for the 750 mm ORB is quite different from what was observed in a full frontal vehicle-to-vehicle simulation (Figure 4-11). The 750 mm wide barrier misses the two mounting brackets of the F250 SEAS and forces the entire load onto the cross-member which is different from what is observed in a full frontal vehicle-to-vehicle simulation. On the other hand, the 1250 mm wide ORB generates very similar deformation mode as in the full frontal vehicle-to-vehicle test (Figure 4-11). Both the F250 and Silverado SEAS overlaps the full face of the 1250 mm wide barrier (Figure 4-12).

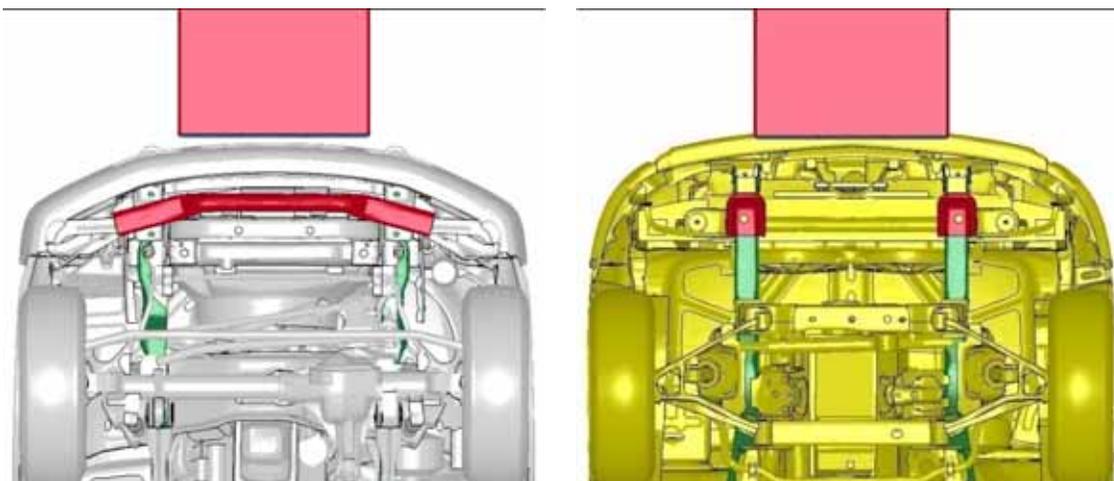

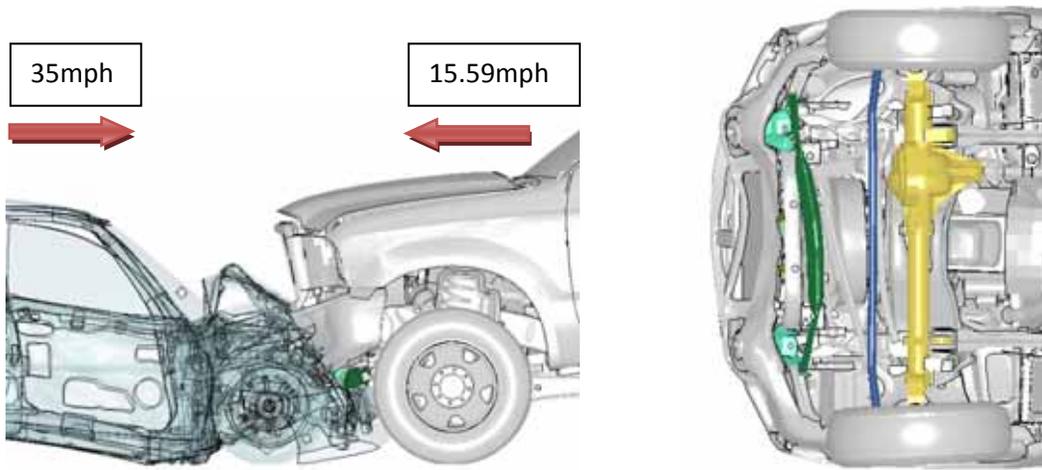

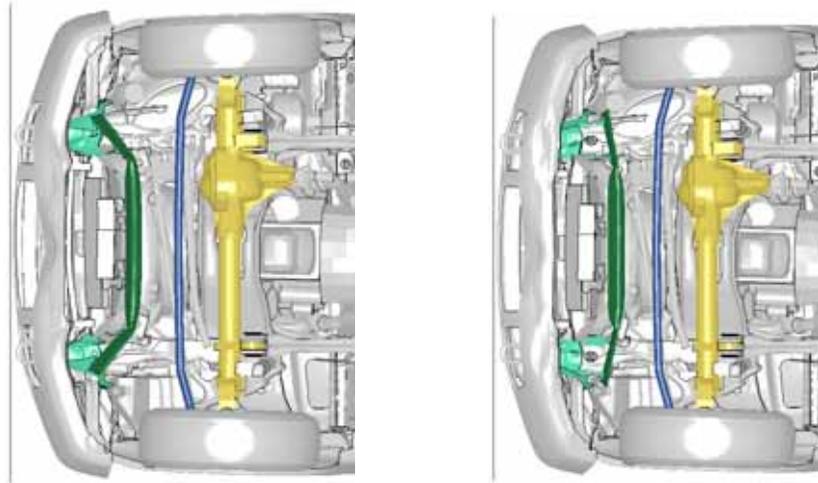

Figure 4-10: SEAS overlap for 750 mm wide ORB (F250 & Silverado)

(a) Deformation Shape of SEAS in Vehicle to Vehicle Impact Simulation (Neon – F250)

(b) Deformation Shape of SEAS (Left: 750mm wide ORB, Right: 1250mm wide ORB)

Figure 4-11: Comparison of Deformation Shape of SEAS in V-t-V Impact and ORB Test

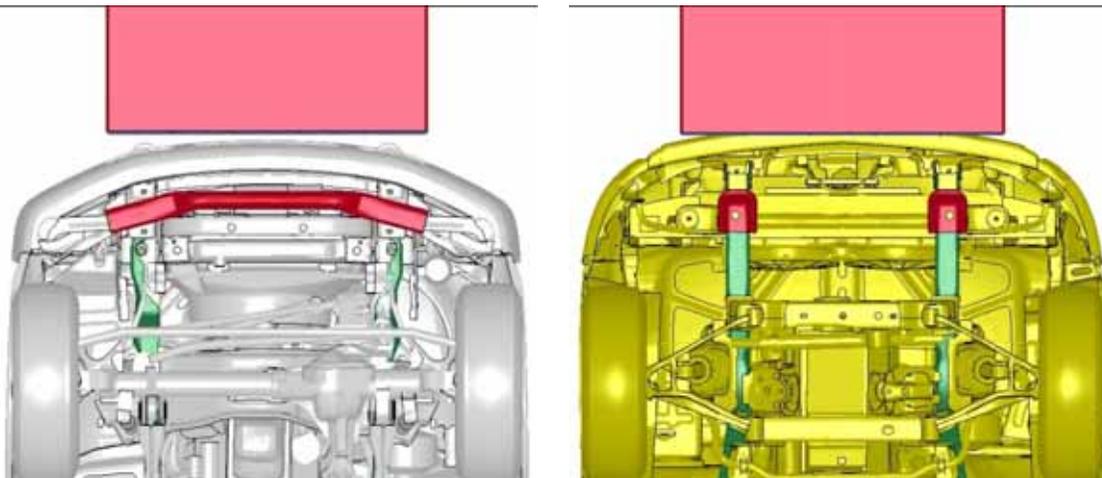

Figure 4-12: SEAS overlap for 1250 mm wide ORB (F250 & Silverado)

Height of ORB

According to the AAM voluntary commitment, for option 2 LTVs, the SEAS shall be no higher than the bottom of the Part 581 zone (16 to 20 inches above ground level). Having the SEAS structure overlap the Part 581 zone might improve structural interaction in frontal collisions between passenger cars and option 2 LTVs preventing underride of the frontal structures. Hence, designing the top height of the ORB to the top of the Part 581 zone (20 inches or 508 mm) would ensure good SEAS overlap with the passenger car primary structures. Figure 4-13 shows the F250 and Silverado alignment with the ORB (top height of 510 mm) before and after impact. The strength of the F250 SEAS can be effectively evaluated with this ORB since no part of the PEAS interacts with the barrier. This would closely resemble the SEAS interaction with a passenger car. The Silverado SEAS design is a different design approach compared to the F250. The PEAS of the Silverado overlaps more than 50% of the Part 581 zone, hence the strength of the SEAS cannot be evaluated with the ORB with a top height of 510 mm.

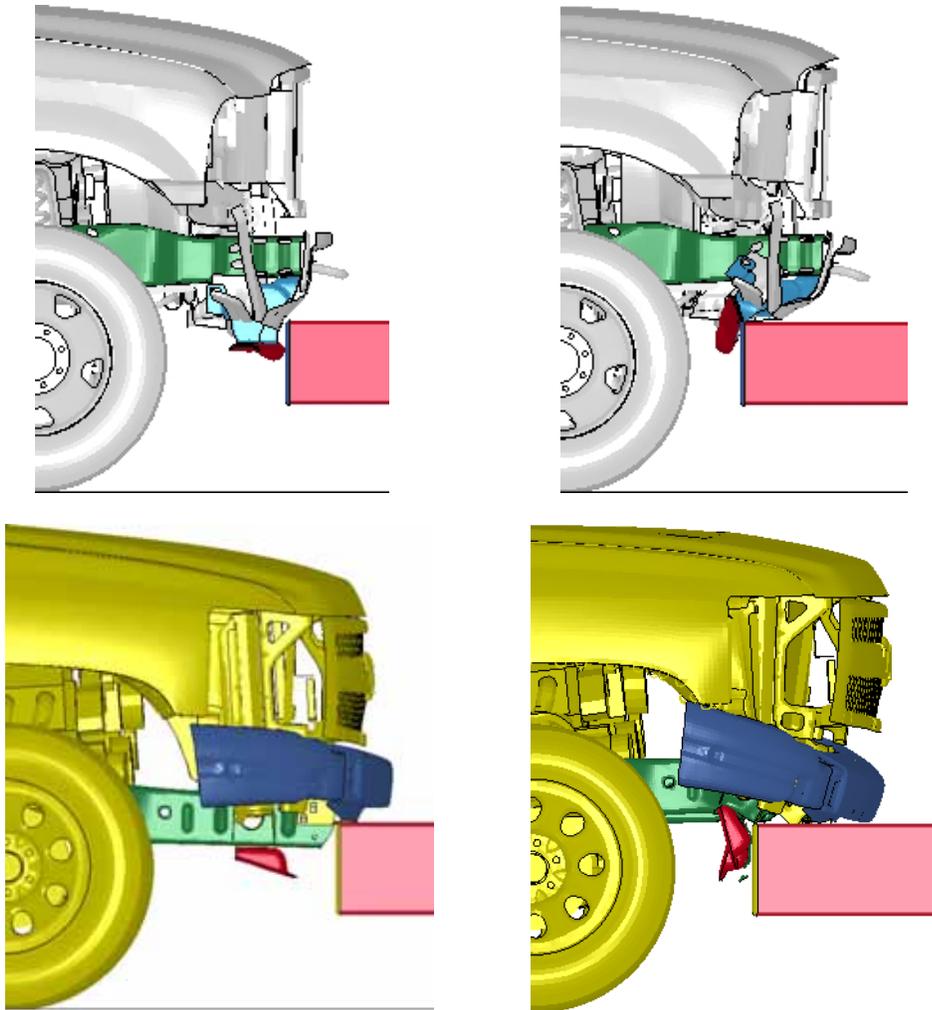

Figure 4-13: Top height of ORB at 510 mm (F250 & Silverado)

The SEAS designs of the F250 and the Silverado present unique challenges to design and develop a laboratory test procedure for SEAS strength evaluation. The F250 design relies on the blocker beam type SEAS to prevent passenger cars from under-riding in frontal collisions. On the other hand, the Silverado design relies more on the vertical height of the PEAS to improve structural interaction in frontal collisions. The presence of SEAS in the Silverado confirms to the AAM voluntary agreement. New and emerging SEAS designs should be monitored to study its influence in structural interaction in frontal collisions. More research is required to better understand the requirements of an ORB test for SEAS evaluation.

Assessment metrics

The ORB is instrumented with load cells to measure the impact force. The F-D characteristic was evaluated using the total force on the ORB and the displacement of the vehicle as measured by the accelerometer mounted at the rear deck of the LTV. Figure 4-14 shows the F-D response for the F250 as measured at the ORB and at the rigid wall. The force measured by the ORB starts increasing when the SEAS impact the ORB at about 200 mm of vehicle displacement. The SEAS continues to load the ORB till the front of the vehicle engages the rigid wall. The rigid wall is offset 500 mm behind the front surface of the ORB. Up until this point, the F-D response on the ORB is purely the result of SEAS loading the ORB.

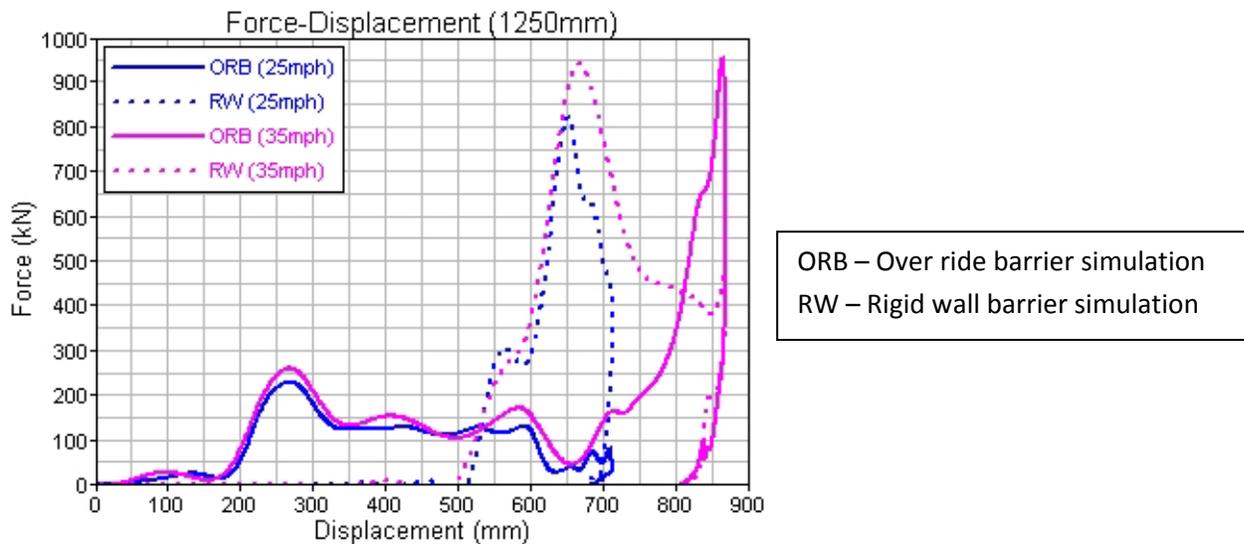

Figure 4-14: F-D response as measured at the ORB and the rigid wall barrier test (F250)

Measurement of energy absorption of the SEAS is an appropriate method to evaluate the efficiency of the SEAS but, practically, the energy cannot be measured in physical tests. Therefore, a measure of stiffness derived from F-D relationship would be an appropriate metric to evaluate the strength of SEAS. Therefore, the stiffness of the SEAS can be evaluated using the Kw400 method [3]. The Kw400 evaluation would encourage SEAS structures to be positioned as forward as possible to the front surface of the vehicle. This would help engage the frontal structures of the passenger cars and prevent potential underriding. Table 4-1 shows the Kw400 values from the F-D response measured on the ORB for the 750 mm and 1250 mm

wide ORB at different impact velocities. These Kw400 values were much lower than the Kw400 values of the compact and mid-size passenger cars (Figure 4-15). In a full frontal impact between the F250 and a compact car, the SEAS of the F250 would deform more than the frontal structure of the passenger car due to the Kw400 mismatch. This may reduce the effectiveness of structural interaction between the SEAS and the front of the passenger car. Additional work is required to define the limits of the Kw400 for the ORB test to evaluate the SEAS strength.

Table 4-1: Kw400 (N/mm) of F250 in ORB Simulations

Impact Speed	Width of Over Ride Barrier	
	750 mm	1250 mm
15mph	313.89	379.28
20mph	333.47	397.06
25mph	352.08	426.39
30mph	378.38	478.61
35mph	393.63	493.89

Kw400 versus Weight for MY 00-05

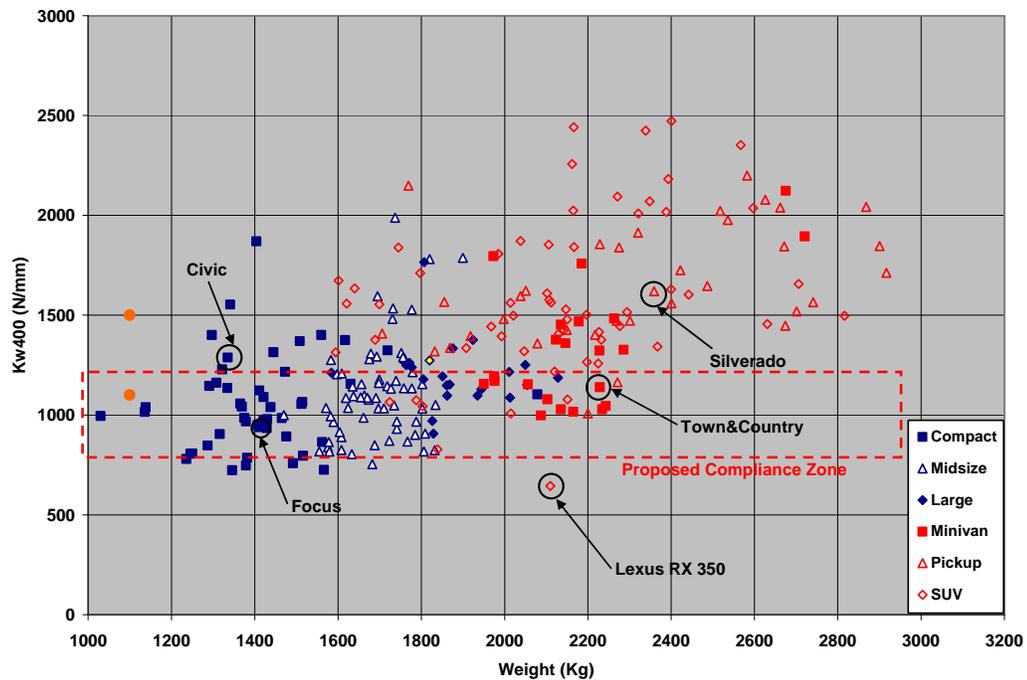

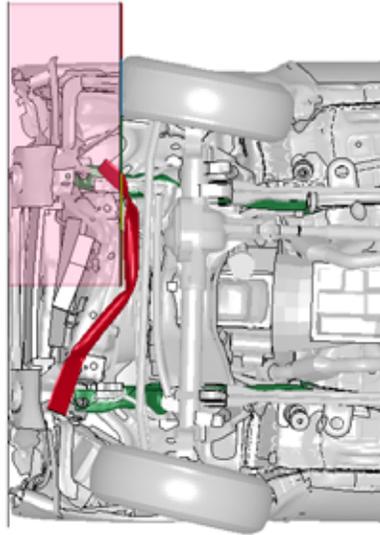

Figure 4-15: Kw400 for MY 2000-05 vehicles from NCAP tests

50% frontal offset test

In the real world, there is significant number of frontal crashes between passenger cars and LTVs with partial overlap. Considering this, it might be beneficial to evaluate the SEAS structure in an offset ORB test. 50% offset ORB (1250 mm wide barrier) simulations were conducted with the F250 at different impact velocities. Figure 4-16 shows the deformation mode of SEAS in a 50% frontal offset ORB simulation. The Kw400 values decreased around 35% for the offset ORB

simulations compared to the full frontal ORB simulations (Table 4-2). The range of Kw400 values and the need for an offset ORB test needs further investigation.

(a) F250 at 25mph

Figure 4-16: 50% Offset Simulation

Table 4-2: Kw400 (N/mm) of F250 in full frontal and 50% offset frontal ORB simulations

Impact Speed	Type of Over Ride Barrier		Kw400 difference (%)
	Full overlap	50% Offset	
15mph	379.28	253.20	33%
20mph	397.06	256.45	35%
25mph	426.39	284.67	33%
30mph	478.61	300.14	37%
35mph	493.89	309.13	37%

4.4 Summary

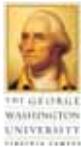

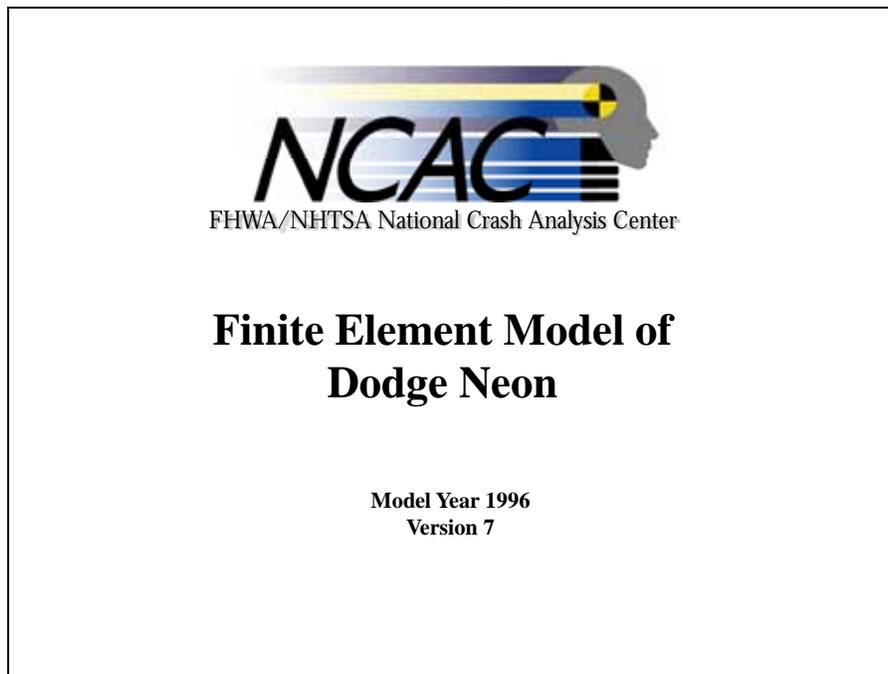

A feasibility study of an ORB test condition, barrier design and assessment metric were investigated using FE models of option 2 LTVs. The two LTV FE models were validated in both NCAP tests and ORB tests performed at VRTC. A parametric study was conducted to identify impact velocity, width and height of the ORB and the relevant assessment metrics to evaluate the strength of the SEAS. Based on this study, an impact velocity of 25 mph was identified as a potential impact speed for the ORB test. A 1250 mm wide barrier with a top height aligned with the top of the Part 581 zone (508 mm) may be considered as a potential barrier. It may also be beneficial to consider an offset ORB test rather than the full overlap test and place a requirement for minimum force in each load cell. Kw400 could be potentially used as an assessment metric for determining the strength of the SEAS structure. This is a limited study; additional work is required to determine the range of Kw400 values appropriate to promote good SEAS structures. In addition, this study was limited to the two SEAS designs that were available in the virtual vehicles. Other SEAS designs and their performance should be considered before an appropriate ORB test procedure is identified.

FE Model, Energy Balance

11/6/2008

Summary

- The crush mode of the rails and the structural members shows good correlation between test and simulation which is also reflected in the total wall force
- The initial 150 mm crush in the simulation shows stiffer response compared to the crash test
- Body mount failure plays a critical role in the validation process as the accelerometer is mounted in the cab
 - Further work is required to improve the failure model for the body mounts
- FE model is stable in full frontal flat rigid wall simulations (Model has been run at 25, 30, 35 and 40 mph to ensure stability)

Energy Balance

11/6/2008

Summary

- Model verified against frontal NCAP test (NHTSA Test No. 5877).
- The crush mode of the rails and the structural members shows good correlation between test and simulation.
- Engine and Body mount failure were observed in the NCAP test. Current model does not include failure of these components to ensure robustness.
- Suspension system is modeled in greater detail.
- Vehicle is set to equilibrium position under gravity loading.
- Future updates will include verification against low speed bump and terrain tests conducted at FOIL.
- FE model is stable in full frontal flat rigid wall simulations (Model has been run at 25, 30 and 35 mph to ensure stability).
