Final Regulatory Impact Analysis

The Safer Affordable Fuel-Efficient (SAFE) Vehicles Rule for Model Year 2021 – 2026 Passenger Cars and Light Trucks

March, 2020 - (updated July 1, 2020 with one Table VII-471 clarification)

July 1, 2020
The following minor clarification was made to the March, 2020 Final Regulatory Impact Analysis:

- *In Table VII-471, on page 1769, the description of "Nonzero Valuation of CH_4 and N_2O" is corrected to state "Applies values for CH_4 and N_2O developed by EPA (see page 1064)"*

I. Executive Summary

This Final Regulatory Impact Analysis (FRIA) has been prepared to assess the potential and anticipated consequences of proposed and alternative Corporate Average Fuel Economy (CAFE) standards and carbon dioxide (CO_2) standards for passenger cars and light trucks for model years (MY) 2021 through 2026. Regulatory analysis is a tool used to anticipate and evaluate likely consequences of rules. It provides a formal way of organizing the evidence on the key effects, positive and negative, of the various alternatives that are considered in developing regulations. The goal of this FRIA is to consolidate that evidence to help inform decision-makers of those potential consequences of choosing among the considered regulatory paths.

Both NHTSA and EPA are required by law to take regulatory action and do not have discretion not to set standards. NHTSA is required to set CAFE standards by the Energy Policy and Conservation Act of 1975 (EPCA), as amended by the Energy Independence and Security Act of 2007 (EISA). CAFE standards must be set at least 18 months prior to the beginning of the model year; must be set separately for each model year and for passenger cars and light trucks; must be "attribute-based and defined by a mathematical function," and must be set at the maximum feasible level that NHTSA determines manufacturers can reach for that fleet in that model year, among other requirements.[1] EPA, having found that CO_2 endangers public health and welfare,[2] must set CO_2 emissions standards for passenger cars and light trucks under section 202 (a) of the Clean Air Act (CAA) ((42 U.S.C. 7521 (a)), and under its authority to measure passenger car and passenger car fleet fuel economy pursuant to EPCA.[3]

This assessment examines the costs and benefits of proposed and alternative CAFE and CO_2 standards levels for passenger cars and light trucks for MYs 2021 through 2026. In this rulemaking, NHTSA is revising the existing CAFE standards for MY 2021 and finalizing new standards for MYs 2022-2026. EPA is revising the existing CO_2 standards for MYs 2021-2025, and finalizing new standards for MY 2026. This assessment examines the costs and benefits of setting fuel economy and CO_2 standards for passenger cars and light trucks that change at a variety of different rates during those model years.[4] It includes a discussion of the technologies that can improve fuel economy/reduce CO_2 emissions, as well as analysis of the potential impacts on vehicle retail prices, safety, lifetime fuel savings and their value to consumers, and other societal benefits such as improved energy security and impacts on emissions.[5] Estimating impacts also involves consideration of the response of consumers—e.g., whether consumers will purchase the vehicles and in what quantities.

---

[1] *See* 49 U.S.C. Section 32902 and Section V of the preamble that this FRIA accompanies for more information.
[2] 74 FR 66496, 66518 (December 15, 2009).
[3] 49 U.S.C. Section 32904 (c).
[4] Throughout this FRIA, cost and benefit analyses are presented for individual model years as well as the cumulative total for all model years through MY 2029.
[5] This analysis does not contain NHTSA's assessment of the potential environmental impacts of the proposed rule for purposes of the National Environmental Policy Act (NEPA), 42 U.S.C. 4321-4347, which is contained in the agency's Final Environmental Impact Statement (FEIS) accompanying the proposed rule.

As explained above, EISA requires NHTSA to set attribute-based CAFE standards that are based on a mathematical function. The mathematical function or "curve" representing the footprint-based standards is a constrained linear function that provides a separate fuel economy target for each vehicle footprint. EPA also sets CO_2 standards following this approach in the interest of regulatory harmonization. The CAFE and CO_2 standards and alternative standards for MYs 2021-2026 passenger cars and light trucks are based on vehicle footprint, as were the CAFE standards for MYs 2011-2021[6] and the CO_2 standards for MYs 2012-2025. These standards will become more stringent for each model year from 2021 to 2026, relative to the MY 2020 standards. Generally, the larger the vehicle footprint, the less numerically stringent the corresponding vehicle CO_2 and mpg targets. With footprint-based standards, the burden of compliance is distributed across all vehicle footprints and across all manufacturers. Each manufacturer is subject to individualized standards for passenger cars and light trucks, in each model year, based on the vehicles it produces. When standards are carefully crafted, both in terms of the footprint curves and the rate of increase in stringency of those curves, manufacturers are not compelled to build vehicles of any particular size or type.

To evaluate the costs and benefits of the rule, an analysis fleet representing the light-duty fleet in detail was constructed. This fleet provides the starting point for the simulation of manufacturers' year-by-year response through model year 2032[7] to standards defining each regulatory alternative. The analysis fleet is comprised of the best information available as of mid-2019 regarding the model year 2017 fleet, and, for each of 2,952 specific model/configurations,[8] contains information such as production volumes, fuel economy ratings, dimensions (footprint), curb weight and GVWR, engine characteristics, transmission characteristics, and other key engineering information. For each regulatory alternative, the CAFE Model was used to simulate manufacturers' year-by-year application of technology that improves fuel economy/reduces CO_2 emissions, assuming that manufacturers would respond both to the year-by-year series of standards defining the regulatory alternative and also to buyers' willingness to pay for a portion of the fuel savings expected to occur over vehicles' useful lives. In the analyses, it was assumed that, beyond any regulatory requirements, manufacturers would voluntarily supply technologies that have a consumer payback (defined by fuel savings exceeding retail price increases) in 30 months or less. This estimate equates to a willingness to pay for approximately a quarter of available fuel savings.

The agencies' proposed standards for MYs 2021-2026 are coordinated, with a goal of enabling all manufacturers to build a single fleet of vehicles that would comply with both the CAFE and CO_2 standards, helping to reduce costs and regulatory complexity. The coordinated

---

[6] Vehicle Footprint is defined as the wheelbase (the distance from the center of the front axle to the center of the rear axle) times the average track width (the distance between the centerline of the tires) of the vehicle (in square feet).
[7] As in NHTSA's analysis presented in the 2016 Draft TAR, today's analysis exercises the CAFE Model using inputs that extend the explicit compliance simulation through MY 2032—six years beyond the last year for which we propose to issue new standards. This has been done because some products are on design cycles well beyond six years, and especially with credits being able to be carried forward for up to five years, some manufacturers may not achieve full MY 2026 compliance until well beyond MY 2026.
[8] For example, a given pickup truck model might be offered in RWD and 4WD versions with a variety of cab and bed configurations, engines, transmissions, resulting in potentially many distinct configurations of this model.

program would achieve important reductions in regulatory costs and vehicle prices and achieve significant societal and consumer net benefits. It is important to note throughout this analysis that there is significant overlap in costs and benefits for NHTSA's CAFE program and EPA's CO_2 program, and therefore combined program costs and benefits are not a sum of the two individual programs.

For this rulemaking, the baseline for cost and benefit reporting for NHTSA's CAFE program is the augural standards for MYs 2022-2025 and the existing standard for MY 2021. For EPA's CO_2 program, the baseline is the currently final MYs 2021-2025 standards and EPA program provisions.

EPCA, as amended by EISA, contains a number of provisions governing how NHTSA must set CAFE standards. EPCA requires that the Department of Transportation establish separate passenger car and light truck standards[9] at "the maximum feasible average fuel economy level that the Secretary decides the manufacturers can achieve in that model year,"[10] based on the agency's consideration of four statutory factors: technological feasibility, economic practicability, the effect of other standards of the Government on fuel economy, and the need of the United States to conserve energy.[11] EPCA does not define these terms or specify what weight to give each concern in balancing them—such considerations are left within the discretion of the Secretary of Transportation (delegated to NHTSA) based upon current information. Accordingly, NHTSA interprets these factors and determines the appropriate weighting that leads to the maximum feasible standards given the circumstances present at the time of promulgating each CAFE standard rulemaking. While EISA, for MYs 2011-2020, additionally required that standards increase "ratably" and be set at levels to ensure that the CAFE of the industry-wide combined fleet of new passenger cars and light trucks reach at least 35 mpg by MY 2020,[12] EISA requires that standards for MYs 2021-2030 simply be set at the maximum feasible level as determined by the Secretary (and by delegation, NHTSA).[13]

As stated above, NHTSA and EPA are finalizing rules for passenger cars and light trucks that the agencies believe represent appropriate levels of CO_2 emissions standards and maximum feasible CAFE standards for MYs 2021-2026, pursuant to their respective statutory authorities. EPA is establishing standards that are projected to require, on an average industry fleet-wide basis, 201 grams/mile (g/mi) of CO_2 in model year 2030. NHTSA is establishing standards that are projected to require, on an average industry fleet-wide basis, 40.5 miles per gallon (mpg) in model year 2030. The agencies note that real-world CO_2 is typically 25 percent higher and real-world fuel economy is typically 20 percent lower than the CO_2 and CAFE compliance values discussed here, and also note that a portion of EPA's expected "CO_2" improvements will in fact be made through improvements in minimizing air conditioning leakage and through use of

[11] 49 U.S.C. 32902(f).
[12] 49 U.S.C. 32902(b)(2)(A) and (C).
[13] 49 U.S.C. 32902(b)(2)(B).

alternative refrigerants, which will not contribute to fuel economy but will contribute toward reductions of climate-related emissions.

The agencies project that under these final standards, required technology costs would be reduced by $86 to $126 billion over the lifetimes of vehicles through MY 2029. Equally important, per-vehicle paid by U.S. consumers for new vehicles would be from $977 to $1,083 lower, on average, than they would have been if the agencies had retained the standards set forth in the 2012 final rule and originally upheld by EPA in January 2017. While these final standards are estimated to result in 1.9 to 2.0 additional billion barrels of fuel consumed and from 867 to 923 additional million metric tons of CO_2 as compared to the current estimates of what the standards set forth in 2012 would require, elsewhere in this document and in the preamble the agencies explain at length why we believe the overall benefits of the final standards outweigh these additional costs.[14] For the CAFE program, overall (fleetwide) net benefits vary from $16.1 billion at a 7 percent discount rate to -$13.1 billion at a 3 percent discount rate. For the CO_2 program, overall (fleetwide) societal net benefits vary from $6.4 billion at a 7 percent discount rate to -$22.0 billion at a 3 percent discount rate. The net benefits straddle zero, and are small relative to the scale of technology costs, which range from -$86.3 billion to -$126.0 billion for the CAFE and CO_2 programs across 7 percent and 3 percent discount rates. Likewise, net benefits are small relative to the scale of retail fuel savings, which range from -$108.6 billion to -$185.1 billion for the CAFE and CO_2 programs across 7 percent and 3 percent discount rates. Similarly, all of the alternatives have small net benefits, ranging from $18.4 billion to -$31.1 billion for the CAFE and CO_2 programs across 7 percent and 3 percent discount rates.

The results of this analysis are summarized in the following tables. Note that for this analysis, negative signs are used for changes in costs or benefits that decrease from those that would have resulted from the augural standards for MY 2022-2025 or the existing standard for MY 2021. Any changes that would increase either costs or benefits are shown as positive changes. Thus, an alternative that decreases both costs and benefits, will show declines (i.e., a negative sign) in both categories.

Table I-1 and Table I-2 present the total costs (technology and social), benefits, and net benefits for NHTSA's 2021-2026 preferred alternative CAFE and CO_2 levels, relative to the MY 2022-2025 augural standards and current MY 2021 standard. The values in Table I-1 and Table I-2 display (in total and annualized forms) costs for all MY 1977-2029 vehicles, and the benefits and net benefits represent the impacts of the standards over the full lifetimes of the vehicles sold or projected to be sold during model years 1977-2029.

Table I-3, Table I-4, and Table I-5 show a summary of various impacts of the preferred alternative for CAFE and CO_2 standards. Impacts are presented in monetized and non-monetized values, as well as from the perspective of society and the consumer. Table I-6 and Table I-7 list costs, benefits, and net benefits for all seven alternatives that were examined.

Detailed results by model year and alternative are provided in Table I-8 through Table I-73. Table I-8 through Table I-13 list the average required MPG by model year and alternative

[14] 1.9 to 2.0 barrels of fuel is approximately 78 to 84 gallons of fuel.

for passenger cars, light trucks, and the combined light vehicle fleet. Table I-14 through Table I-19 list the average achieved MPG for these same categories. Table I-20 through Table I-25 list the average incremental technology costs and civil penalties per vehicle by model year and alternative for each light vehicle category.

Table I-26 through Table I-31 list the incremental total costs (at 3 percent discount rate) of each alternative by model year from a societal perspective, which excludes civil penalties because they are transfer payments from one societal component to another. Table I-32 through Table I-37 list the present value (at 3 percent discount rate) of the lifetime societal benefits by model year and alternative. Table I-38 through Table I-43 list the present value of net total benefits (at 3 percent discount rate). Table I-44 through Table I-49 list the incremental total costs (at 7 percent discount rate) from the societal perspective (excluding fines). Table I-50 through Table I-55 list the present value (at 7 percent discount rate) of the lifetime societal benefits by model year and alternative. Table I-56 through Table I-61 list the present value of net total benefits (at 7 percent discount rate). Table I-62 through Table I-67 list the billions of gallons of liquid fuel saved by each alternative by model year. Table I-68 through Table I-73 list the change in electricity consumption (GW-h) for each alternative by model year. A variety of other more detailed impacts of the preferred alternative are shown in Table I-74 to Table I-79.

II. Overview of Final Rule

A. Summary of Proposal

In the NPRM, the National Highway Traffic Safety Administration (NHTSA) and the Environmental Protection Agency (EPA) (collectively, "the agencies") proposed the "Safer Affordable Fuel-Efficient (SAFE) Vehicles Rule for Model Years 2021-2026 Passenger Cars and Light Trucks" (SAFE Vehicles Rule). The proposed SAFE Vehicles Rule would set Corporate Average Fuel Economy (CAFE) and carbon dioxide (CO_2) emissions standards, respectively, for passenger cars and light trucks manufactured for sale in the United States in model years (MYs) 2021 through 2026.[15]

The agencies explained that they must act to propose and finalize these standards and do not have discretion to decline to regulate. Congress requires NHTSA to set CAFE standards for each model year.[16] Congress also requires EPA to set emissions standards for light-duty vehicles if EPA has made an "endangerment finding" that the pollutant in question—in this case, CO_2—"cause[s] or contribute[s] to air pollution which may reasonably be anticipated to endanger public health or welfare."[17] NHTSA and EPA proposed the standards concurrently because tailpipe CO_2 emissions standards are directly and inherently related to fuel economy standards,[18] and, if finalized, the rules would apply concurrently to the same fleet of vehicles. By working together to develop the proposals, the agencies aimed to reduce regulatory burden on industry and improve administrative efficiency.

The agencies discussed some of the history leading to the proposal, including the 2012 final rule, the expectations regarding a mid-term evaluation as required by EPA regulation, and the rapid process over 2016 and early 2017 by which EPA issued its first Final Determination that the CO_2 standards set in 2012 for MYs 2022-2025 remained appropriate based on the information then before the EPA Administrator.[19] The agencies also discussed President Trump's direction in March 2017 to restore the original mid-term evaluation timeline, and EPA's subsequent information-gathering process and announcement that it would reconsider the

---

[15] NHTSA sets CAFE standards under the Energy Policy and Conservation Act of 1975 (EPCA), as amended by the Energy Independence and Security Act of 2007 (EISA). EPA sets CO_2 standards under the Clean Air Act (CAA).

[18] *See, e.g.*, 75 FR 25324, at 25327 (May 7, 2010) ("The National Program is both needed and possible because the relationship between improving fuel economy and reducing tailpipe CO_2 emissions is a very direct and close one. The amount of those CO_2 emissions is essentially constant per gallon combusted of a given type of fuel. Thus, the more fuel efficient a vehicle is, the less fuel it burns to travel a given distance. The less fuel it burns, the less CO_2 it emits in traveling that distance. [citation omitted] While there are emission control technologies that reduce the pollutants (e.g., carbon monoxide) produced by imperfect combustion of fuel by capturing or converting them to other compounds, there is no such technology for CO_2. Further, while some of those pollutants can also be reduced by achieving a more complete combustion of fuel, doing so only increases the tailpipe emissions of CO_2. Thus, there is a single pool of technologies for addressing these twin problems, *i.e.*, those that reduce fuel consumption and thereby reduce CO_2 emissions as well.").
[19] *See* 83 FR at 42987 (Aug.24, 2018).

January 2017 Determination.[20] EPA ultimately concluded that the standards set in 2012 for MYs 2022-2025 were no longer appropriate.[21] For NHTSA, in turn, the "augural" CAFE standards for MYs 2022-2025 were never final, and as explained in the 2012 final rule, NHTSA was obligated from the beginning to undertake a new rulemaking to set CAFE standards for MYs 2022-2025.

The NPRM thus began the rulemaking process for both agencies to establish new standards for MYs 2022-2025 passenger cars and light trucks. Standards were concurrently proposed for MY 2026 in order to provide regulatory stability for as many years as is legally permissible for both agencies together. The NPRM also included revised standards for MY 2021 passenger cars and light trucks, because the agencies tentatively concluded, based on the information and analysis then before them, that the CAFE standards previously set for MY 2021 were no longer maximum feasible, and the CO_2 standards previously set for MY 2021 were no longer appropriate. Agencies always have authority under the Administrative Procedure Act to revisit previous decisions in light of new facts, as long as they provide notice and an opportunity for comment, and the agencies stated that it is plainly the best practice to do so when changed circumstances so warrant.[22]

The NPRM proposed to maintain the CAFE and CO_2 standards applicable in MY 2020 for MYs 2021-2026, and took comment on a wide range of alternatives, including different stringencies and retaining existing CO_2 standards and the augural CAFE standards.[23] Table II-1, Table II-2, and Table II-3 show the estimates, under the NPRM analysis, of what the MY 2020 CAFE and CO_2 curves would translate to, in terms of miles per gallon (mpg) and grams per mile (g/mi), in MYs 2021-2026, as well as the regulatory alternatives considered in the NPRM. In addition to retaining the MY 2020 CO_2 standards through MY 2026, EPA proposed and sought comment on excluding air conditioning refrigerants and leakage, and nitrous oxide and methane emissions for compliance with CO_2 standards after model year 2020, in order to improve harmonization with the CAFE program. EPA also sought comment on whether to change existing methane and nitrous oxide standards that were finalized in the 2012 rule. The proposal was accompanied by a 1,600 page Preliminary Regulatory Impact Analysis (PRIA) and, for NHTSA, a 500 page Draft Environmental Impact Statement (DEIS), with more than 800 pages of appendices and the entire CAFE model, including the software source code and

[22] *See* FCC v. Fox Television, 556 U.S. 502 (2009).
[23] The agencies noted that this did not mean that the miles per gallon and grams per mile levels that were estimated for the MY 2020 fleet in 2012 would be the "standards" going forward into MYs 2021-2026. Both NHTSA and EPA set CAFE and CO_2 standards, respectively, as mathematical functions based on vehicle footprint. These mathematical functions that are the actual standards are defined as "curves" that are separate for passenger cars and light trucks, under which each vehicle manufacturer's compliance obligation varies depending on the footprints of the cars and trucks that it ultimately produces for sale in a given model year. It was the MY 2020 CAFE and CO_2 curves that the agencies proposed would continue to apply to the passenger car and light truck fleets for MYs 2021-2026. The mpg and g/mi values which those curves would eventually require of the fleets in those model years would be known for certain only at the ends of each of those model years. While it is convenient to discuss CAFE and CO_2 standards as a set "mpg," "g/mi," or "mpg-e" number, attempting to define those values based on the information then before the agency would necessarily end up being inaccurate.

documentation, all of which were also subject to comment in their entirety and all of which received significant comments.

Table II-1 – Average of OEMs' CAFE and CO_2 Estimated Proposed Requirements for Passenger Cars

Model Year	**Avg. of OEMs' Est. Requirements**

2025	33.6	245
2026	34.1	240

Table II-3 – Average of OEMs' CAFE and CO_2 Estimated Proposed Requirements (Passenger Cars and Light Trucks)

Model Year	**Avg. of OEMs' Est. Requirements**	
	CAFE (mpg)	CO_2 (g/mi)
2017	33.8	261
2018	34.8	248
2019	35.7	236
2020	36.8	224
2021	37.3	214
2022	37.9	211
2023	38.5	207
2024	39.1	204
2025	39.8	202
2026	40.4	199

Table II-4 – Regulatory Alternatives Considered in NPRM

Alternative	**Change in stringency**	**A/C efficiency and off-cycle provisions**	**CO_2 Equivalent AC Refrigerant Leakage, Nitrous Oxide and Methane Emissions Included for Compliance?**
Baseline/ No-Action	MY 2021 standards remain in place; MYs 2022-2025 augural CAFE standards are finalized and CO_2 standards remain unchanged; MY 2026 standards are set at MY 2025 levels	No change	Yes, for all MYs [24]
1 (Proposed)	Existing standards through MY 2020, then 0%/year increases for both passenger cars and light trucks, for MYs 2021-2026	No change	No, beginning in MY 2021[25]
2	Existing standards through MY 2020, then 0.5%/year increases for both passenger cars and light trucks, for MYs 2021-2026	No change	No, beginning in MY 2021

[24] The carbon dioxide equivalents of air conditioning refrigerant leakage, nitrous oxide emissions, and methane emissions were included for compliance with the EPA standards for all MYs under the baseline/no action alternative in the NPRM. Carbon dioxide equivalent is calculated using the Global Warming Potential (GWP) of each of the emissions.

[25] Beginning in MY 2021, the proposal provided that the GWP equivalents of air conditioning refrigerant leakage, nitrous oxide emissions, and methane emissions would no longer be able to be included with the tailpipe CO_2 for compliance with tailpipe CO_2 standards.

Alternative	Change in stringency	A/C efficiency and off-cycle provisions	CO_2 Equivalent AC Refrigerant Leakage, Nitrous Oxide and Methane Emissions Included for Compliance?
3	Existing standards through MY 2020, then 0.5%/year increases for both passenger cars and light trucks, for MYs 2021-2026	Phase out these adjustments over MYs 2022-2026	No, beginning in MY 2021
4	Existing standards through MY 2020, then 1%/year increases for passenger cars and 2%/year increases for light trucks, for MYs 2021-2026	No change	No, beginning in MY 2021
5	Existing standards through MY 2021, then 1%/year increases for passenger cars and 2%/year increases for light trucks, for MYs 2022-2026	No change	No, beginning in MY 2022
6	Existing standards through MY 2020, then 2%/year increases for passenger cars and 3%/year increases for light trucks, for MYs 2021-2026	No change	No, beginning in MY 2021
7	Existing standards through MY 2020, then 2%/year increases for passenger cars and 3%/year increases for light trucks, for MYs 2021-2026	Phase out these adjustments over MYs 2022-2026	No, beginning in MY 2021
8	Existing standards through MY 2021, then 2%/year increases for passenger cars and 3%/year increases for light trucks, for MYs 2022-2026	No change	No, beginning in MY 2022

The agencies explained in the NPRM that new information had been gathered and new analysis performed since publication of the 2012 final rule establishing CAFE and CO_2 standards for MYs 2017 and beyond and since issuance of the 2016 Draft TAR and EPA's 2016 and early 2017 "mid-term evaluation" process. This new information and analysis helped lead the agencies to the tentative conclusion that holding standards constant at MY 2020 levels through MY 2026 was maximum feasible, for CAFE purposes, and appropriate, for CO_2 purposes.

The agencies further explained that technologies had played out differently in the fleet from what the agencies previously assumed: that while there remain a wide variety of technologies available to improve fuel economy and reduce CO_2 emissions, it had become clear that there were reasons to temper previous optimism about the costs, effectiveness, and consumer acceptance of a number of technologies. In addition, over the years between the previous analyses and the NPRM, automakers had added considerable amounts of technologies to their new vehicle fleets, meaning that the agencies were no longer free to make certain assumptions about how some of those technologies *could* be used going forward. For example, some technologies that could be used to improve fuel economy and reduce emissions had not been used entirely for that purpose, and some of the benefit of these technologies had gone instead toward improving other vehicle attributes. Other technologies had been tried, and had been met with significant customer acceptance issues. The agencies underscored the importance of reflecting the fleet as it stands today, with the technology it has and as that technology has been used, and considering what technology remains on the table at this point, whether and when it can realistically be available for widespread use in production, and how much it would cost to implement.

The agencies also acknowledged the math of diminishing returns: as CAFE and CO_2 emissions standards increase in stringency, the benefit of continuing to increase in stringency decreases. In mpg terms, a vehicle owner who drives a light vehicle 15,000 miles per year (a typical assumption for analytical purposes)[26] and trades in a vehicle with fuel economy of 15 mpg for one with fuel economy of 20 mpg, will reduce their annual fuel consumption from 1,000 gallons to 750 gallons—saving 250 gallons annually. If, however, that owner were to trade in a vehicle with fuel economy of 30 mpg for one with fuel economy of 40 mpg, the owner's annual gasoline consumption would drop from 500 gallons/year to 375 gallons/year—only 125 gallons even though the mpg improvement is twice as large. Going from 40 to 50 mpg would save only 75 gallons/year. Yet each additional fuel economy improvement becomes much more expensive as the easiest to achieve low-cost technological improvement options are chosen. In CO_2 terms, if a vehicle emits 300 g/mi CO_2, a 20 percent improvement is 60 g/mi, so the vehicle would emit 240 g/mi; but if the vehicle emits 180 g/mi, a 20 percent improvement is only 36 g/mi, so the vehicle would get 144 g/mi. In order to continue achieving similarly large (on an absolute basis) emissions reductions, the percentage reduction must also continue to increase.

Related, average real-world fuel economy is lower than average fuel economy required under CAFE and CO_2 standards. The 2012 *Federal Register* notice announcing augural CAFE and CO_2 standards extending through MY 2025 indicated that, if met entirely through the application of fuel-saving technology, the MY 2025 CO_2 standards would result in an average requirement equivalent to 54.5 mpg. However, because the CO_2 standards provide credit for reducing leakage of AC refrigerants and/or switching to lower-GWP refrigerants, and these actions do not affect fuel economy, the notice explained that the corresponding fuel economy requirement (under the CAFE program) would be 49.7 mpg. These estimates were based on a market forecast grounded in the MY 2008 fleet. The notice also presented analysis using a market forecast grounded in the MY 2010 fleet, showing a 48.7 mpg average CAFE requirement.

In the real world, fuel economy is, on average, about 20% lower than as measured under regulatory test procedures. In the real world, then, these new standards were estimated to require 39.0-39.8 mpg.

Today's analysis indicates that the requirements under the baseline/augural CAFE standards would average 46.6 mpg in MY 2029. The lower value results from changes in the fleet forecast which reflects consumer preference for larger vehicles than was forecast for the 2012 rulemaking. In the real world, the requirements average about 37.1 mpg. Under the final standards issued today, the regulatory test procedure requirements average 40.5 mpg, corresponding to 33.2 mpg in the real world. Buyers of new vehicles experience real-world fuel

[26] A different vehicle-miles-traveled (VMT) assumption would change the absolute numbers in the example, but would not change the mathematical principles.

economy, with levels varying among drivers (due to a wide range of factors). Vehicle fuel economy labels provide average real-world fuel economy to buyers.

Table II-5 – Estimated Average Required CAFE and CO_2 Levels

	2012 Final Rule		**Current Analysis**	
	Augural, MY 2025 (2008-Based Fleet)	Augural, MY 2025 (2010-Based Fleet)	Augural, MY 2029	Final, MY 2029
CO_2 Standards				
grams/mile CO_2	163	166	175	202
equivalent mpg (if met solely with FE technology)	54.5	53.5	50.8	44.1
CAFE Standards				
mpg with AC efficiency and other off-cycle adjustments	49.7	48.7	46.6	40.5
mpg without adjustments	47.8	46.8	42.5	37.5
estimated real-world mpg	38.2	37.4	34.0	30.0

Vehicle owners also face fuel prices at the pump. The agencies noted in the NPRM that when fuel prices are high, the value of fuel saved may be enough to offset the cost of further fuel economy/emissions reduction improvements, but the agencies recognized that then-current projections of fuel prices by the Energy Information Administration did not indicate particularly high fuel prices in the foreseeable future. The agencies explained that fundamental structural shifts had occurred in global oil markets since the 2012 final rule, largely due to the rise of U.S. production and export of shale oil. The consequence over time of diminishing returns from more stringent fuel economy/emissions reduction standards, especially when combined with relatively low fuel prices, is greater difficulty for automakers to find a market of consumers willing to buy vehicles that meet the increasingly stringent standards. American consumers have long demonstrated that in times of relatively low fuel prices, fuel economy is not a top priority for the majority of them, even when highly fuel efficient vehicle models are available.

The NPRM analysis sought to improve how the agencies captured the effects of higher new vehicle prices on fleet composition as a whole by including an improved model for vehicle scrappage rates. As new vehicle prices increase, consumers tend to continue using older vehicles for longer, slowing fleet turnover and thus slowing improvements in fleet-wide fuel economy, reductions in CO_2 emissions, reductions in criteria pollutant emissions, and advances in safety. That aspect of the analysis was also driven by the agencies' updated estimates of average per-vehicle cost increases due to higher standards, which were several hundred dollars higher than previously estimated. The agencies cited growing concerns about affordability and negative equity for many consumers under these circumstances, as loan amounts grow and loan terms extend.

For all of the above reasons, the agencies proposed to maintain the MY 2020 fuel economy and CO_2 emissions standards for MYs 2021-2026. The agencies explained that they estimated, relative to the standards for MYs 2021-2026 put forth in 2012, that an additional 0.5 million barrels of oil would be consumed per day (about 2 to 3 percent of projected U.S. consumption) if that proposal were finalized, but that they also expected the additional fuel costs to be outweighed by the cost savings from new vehicle purchases; that more than 12,700 on-road fatalities and significantly more injuries would be prevented over the lifetimes of vehicles through MY 2029 as compared to the standards set forth in the 2012 final rule over the lifetimes of vehicles as more new and safer vehicles are purchased than the current (and augural) standards; and that environmental impacts, on net, would be relatively minor, with criteria and toxic air pollutants not changing noticeably, and with estimated atmospheric CO_2 concentrations increasing by 0.65 ppm (a 0.08 percent increase), which the agencies estimated would translate to 0.003 degrees Celsius of additional temperature increase relative to the standards finalized in 2012.

Under the NPRM analysis, the agencies tentatively concluded that maintaining the MY 2020 curves for MYs 2021-2026 would save American auto consumers, the auto industry, and the public a considerable amount of money as compared to EPA retaining the previously-set CO_2 standards and NHTSA finalizing the augural standards. The agencies explained that this had been identified as the preferred alternative, in part, because it appeared to maximize net benefits compared to the other alternatives analyzed, and recognizing the statutory considerations for both agencies. Relative to the standards issued in 2012, under CAFE standards, the NPRM analysis estimated that costs would decrease by $502 billion overall at a three-percent discount rate ($335 billion at a seven-percent discount rate) and benefits were estimated to decrease by $326 billion at a three-percent discount rate ($204 billion at a seven-percent discount rate). Thus, net benefits were estimated to increase by $176 billion at a three-percent discount rate and $132 billion at a seven-percent discount rate. The estimated impacts under CO_2 standards were estimated to be similar, with net benefits estimated to increase by $201 billion at a three-percent discount rate and $141 billion at a seven-percent discount rate.

The NPRM also sought comment on a variety of potential changes to NHTSA's and EPA's compliance programs for CAFE and CO_2 as well as related programs, including questions about automaker requests for additional flexibilities and agency interest in reducing market-distorting incentives and improving transparency; and on a proposal to withdraw California's CAA preemption waiver for its "Advanced Clean Car" regulations, with an accompanying discussion of preemption of State standards under EPCA.[27] The agencies sought comment broadly on all aspects of the proposal.

---

[27] Agency actions relating to California's CAA waiver and EPCA preemption have since been finalized, *see* 84 FR 51310 (Sept. 27, 2019), and will not be discussed in great detail as part of this final rule.

B. Public Participation Opportunities and Summary of Comments

The NPRM was published on NHTSA's and EPA's websites on August 2, 2018, and published in the *Federal Register* on August 24, 2018, beginning a 60-day comment period. The agencies subsequently extended the official comment period for an additional three days, and left the dockets open for more than a year after the start of the comment period, considering late comments to the extent practicable. A separate *Federal Register* notice also published on August 24, 2018, which announced the locations, dates, and times of three public hearings to be held on the proposal: one in Fresno, California, on September 24, 2018; one in Dearborn, Michigan, on September 25, 2018; and one in Pittsburgh, Pennsylvania, on September 26, 2018. Each hearing started at 10 am local time; the Fresno hearing ended at 5:10 pm and resulted in a 235 page transcript; the Dearborn hearing ran until 5:26 pm and resulted in a 330 page transcript; and the Pittsburgh hearing ran until 5:06 pm and also resulted in a 330 page transcript. Each hearing also collected several hundred pages of comments from participants, in addition to the hearing transcripts.

Besides the comments submitted as part of the public hearings, NHTSA's docket received a total of 173,359 public comments in response to the proposal as of September 18, 2019, and EPA's docket a total of 618,647 public comments, for an overall total of 792,006. NHTSA also received several hundred comments on its DEIS to the separate DEIS docket. While the majority of individual comments were form letters, the agencies received over 6,000 pages of substantive comments on the proposal.

Many commenters generally supported the proposal and many commenters opposed it. Commenters supporting the proposal tended to cite concerns about the cost of new vehicles, while commenters opposing the proposal tended to cite concerns about additional fuel expenditures and the impact on climate change. Many comments addressed the modeling used for the analysis, and specifically the inclusion, operation, and results of the sales and scrappage modules that were part of the NPRM's analysis, while many addressed the NPRM's safety findings and the role that those findings played in the proposal's justification. Many other comments addressed California's standards and role in Federal decision-making; as discussed above, those comments are further summarized and responded to in the separate *Federal Register* notice published in September 2019. Nearly every aspect of the NPRM's analysis and discussion received some level of comment by at least one commenter. The comments received, as a whole, were both broad and deep, and the agencies appreciate the level of engagement of commenters in the public comment process and the information and opinions provided.

C. Changes in Light of Public Comments and New Information

The agencies made a number of changes to the analysis between the NPRM and the final rule in response to public comments and new information that was received in those comments or otherwise became available to the agencies. While these changes, their rationales, and their effects are discussed in detail in the sections below, the following represents a high-level list of some of the most significant changes:

- Some regulatory alternatives were dropped from consideration, and one was added;

- updated analysis fleet, and changes to technologies on "baseline" vehicles within the fleet to reflect better their current properties and improve modeling precision;
- no civil penalties assumed to be paid after MY 2020 under CAFE program;
- updates and expansions in accounting for certain over-compliance credits, including early credits earned in EPA's program;
- updates and expansions to CAFE Model's technology paths;
- updates to inputs defining the range of manufacturer-, technology-, and product-specific constraints;
- updates to allow the model to adopt a more advanced technology if it is more cost-effective than an earlier technology on the path;
- precision improvements to the modeling of A/C efficiency and off-cycle credits;
- updates to model's "effective cost" metric;
- extended explicit simulation of technology application through MY 2050;
- expanded presentation of the results to include "calendar year" analysis;
- quantifying different types of health impacts from changes in air pollution, rather than only accounting for such impacts in aggregate estimates of the social costs of air pollution;
- updated costs to 2018 dollars;
- updated fuel costs based on the AEO 2019 version of NEMS;
- a variety of technology updates in response to comments and new information;
- updated accounting of rebound VMT between regulatory alternatives;
- updated estimates of the macroeconomic cost of petroleum dependence;
- updated response of total new vehicle sales to increases in fuel efficiency and price; and
- updated response of vehicle retirement rates to changes in new vehicle fuel efficiency and transaction price.

Sections IV and VI below discuss these updates in significant detail.

D. Final Standards—Stringency

As explained above, the agencies have chosen to set CAFE and CO_2 standards that increase in stringency by 1.5 percent year over year for MYs 2021-2026. Separately, EPA has decided to retain the A/C refrigerant and leakage and CH_4 and N_2O standards set forth in 2012 for MYs 2021 and beyond, and the stringency of the CO_2 standards in this final rule reflect the "offset" also established in 2012 based on assumptions made at that time about anticipated HFC emissions reductions.

When the agencies state that stringency will increase at 1.5 percent per year, that means that the footprint curves which actually define the standards for CAFE and CO_2 emissions will become more stringent at 1.5 percent per year. Consistent with Congress's direction in EISA to set CAFE standards based on a mathematical formula, which EPA harmonized with for the CO_2 emissions standards, the standard curves are equations, which are slightly different for CAFE and CO_2, and within each program, slightly different for passenger cars and light trucks. Each program has a basic equation for a fleet standard, and then values that change to cause the stringency changes are the coefficients within the equations. For passenger cars, consistent with prior rulemakings, NHTSA is defining fuel economy targets as follows:

$$TARGET_{FE} = \frac{1}{MIN\left[MAX\left(c \times FOOTPRINT + d, \frac{1}{a}\right), \frac{1}{b}\right]}$$

where

$TARGET_{FE}$ is the fuel economy target (in mpg) applicable to a specific vehicle model type with a unique footprint combination,

a is a minimum fuel economy target (in mpg),

b is a maximum fuel economy target (in mpg),

c is the slope (in gallons per mile per square foot, or gpm, per square foot) of a line relating fuel consumption (the inverse of fuel economy) to footprint, and

d is an intercept (in gpm) of the same line.

Here, *MIN* and *MAX* are functions that take the minimum and maximum values, respectively, of the set of included values. For example, *MIN*[40,35] = 35 and *MAX*(40, 25) = 40, such that *MIN*[*MAX*(40, 25), 35] = 35.

For light trucks, also consistent with prior rulemakings, NHTSA is defining fuel economy targets as follows:

$$TARGET_{FE} = MAX\left(\frac{1}{MIN\left[MAX\left(c \times FOOTPRINT + d, \frac{1}{a}\right), \frac{1}{b}\right]}, \frac{1}{MIN\left[MAX\left(g \times FOOTPRINT + h, \frac{1}{e}\right), \frac{1}{f}\right]}\right)$$

where

$TARGET_{FE}$ is the fuel economy target (in mpg) applicable to a specific vehicle model type with a unique footprint combination,

a, *b*, *c*, and *d* are as for passenger cars, but taking values specific to light trucks,

e is a second minimum fuel economy target (in mpg),

f is a second maximum fuel economy target (in mpg),

g is the slope (in gpm per square foot) of a second line relating fuel consumption (the inverse of fuel economy) to footprint, and

h is an intercept (in gpm) of the same second line.

The final CAFE standards (described in terms of their footprint-based curves) are as follows, with the values for the coefficients changing over time:

Table II-6 – Final Standards – Passenger Cars

	2021	**2022**	**2023**	**2024**	**2025**	**2026**
Fuel Economy Targets						
a (mpg)	49.48	50.24	51.00	51.78	52.57	53.37
b (mpg)	37.02	37.59	38.16	38.74	39.33	39.93
c (gpm per s.f.)	0.000453	0.000447	0.000440	0.000433	0.000427	0.000420
d (gpm)	0.00162	0.00159	0.00157	0.00155	0.00152	0.00150

Table II-7 – Final Standards – Light Trucks

	2021	**2022**	**2023**	**2024**	**2025**	**2026**
Fuel Economy Targets						
a (mpg)	39.71	40.31	40.93	41.55	42.18	42.82
b (mpg)	25.63	26.02	26.42	26.82	27.23	27.64
c (gpm per s.f.)	0.000506	0.000499	0.000491	0.000484	0.000477	0.000469
d (gpm)	0.00443	0.00436	0.00429	0.00423	0.00417	0.00410

These equations are presented graphically below, where the x-axis represents vehicle footprint and the y-axis represents fuel economy, showing that in the CAFE context, targets are higher (fuel economy) for smaller footprint vehicles and lower for larger footprint vehicles:

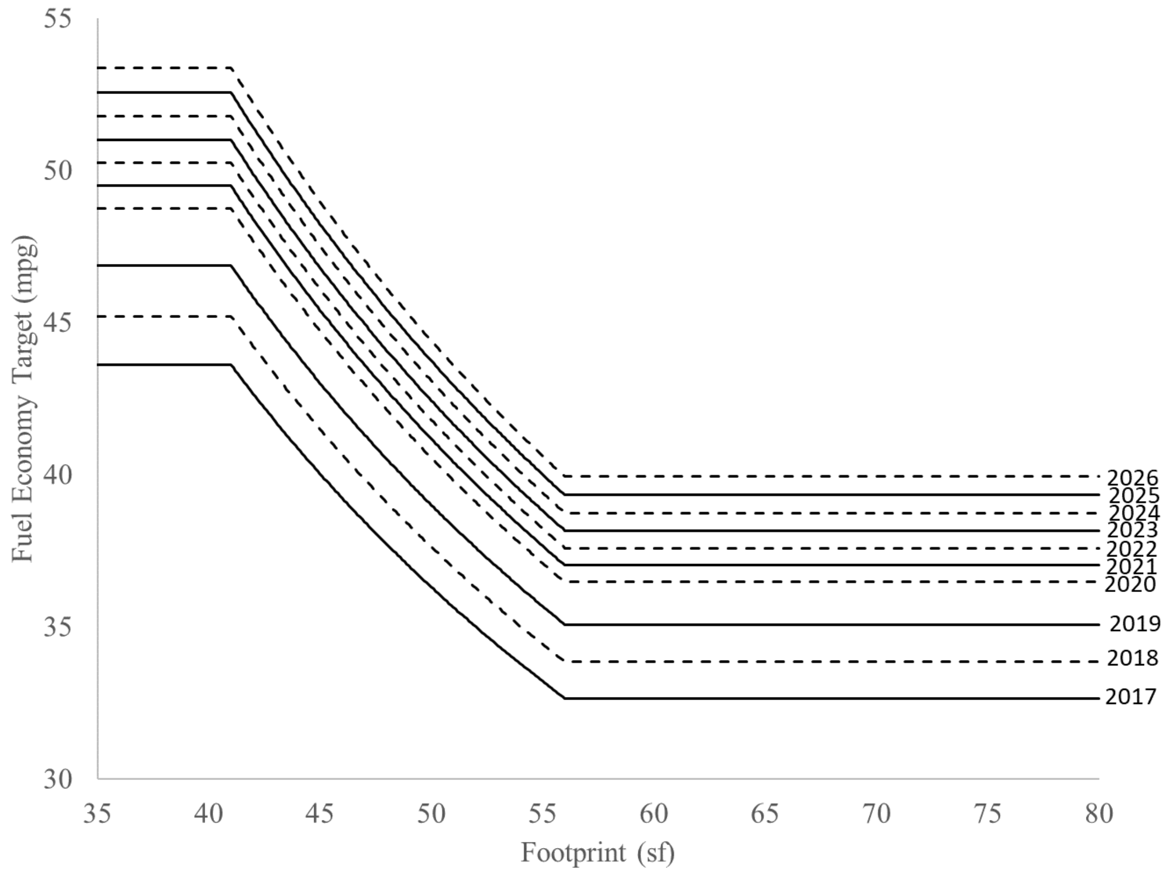

Figure II-1 – Passenger Car Fuel Economy Targets

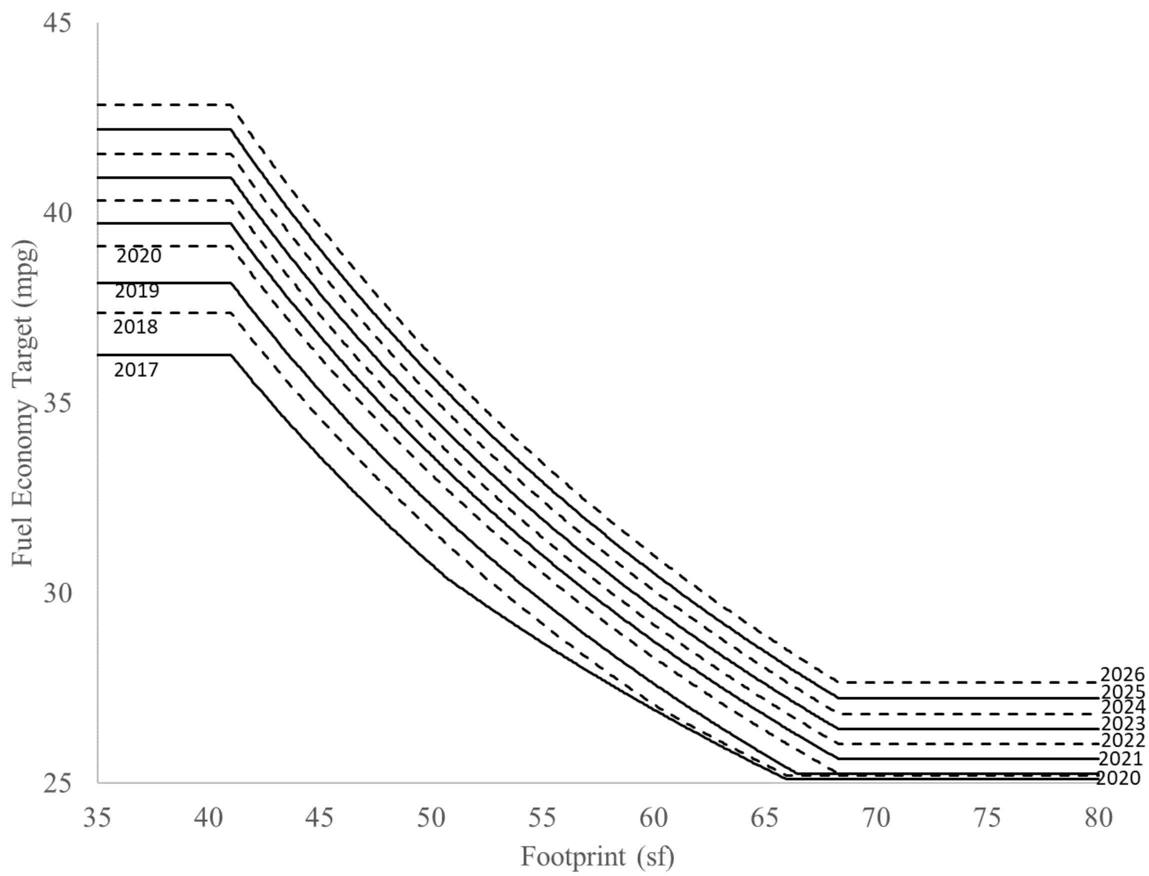

Figure II-2 – Light Truck Fuel Economy Targets

EPCA, as amended by EISA, requires that any manufacturer's domestically-manufactured passenger car fleet must meet the greater of either 27.5 mpg on average, or 92 percent of the average fuel economy projected by the Secretary for the combined domestic and non-domestic passenger automobile fleets manufactured for sale in the U.S. by all manufacturers in the model year, which projection shall be published in the Federal Register when the standard for that model year is promulgated in accordance with 49 U.S.C. 32902(b).[28] Any time NHTSA establishes or changes a passenger car standard for a model year, the MDPCS for that model year must also be evaluated or re-evaluated and established accordingly. Thus, this final rule establishes the applicable MDPCS for MYs 2021-2026. Table II-8 lists the minimum domestic passenger car standards.

[28] 49 U.S.C. 32902(b)(4).

Table II-8 – Minimum Standards for Domestic Passenger Car Fleets (mpg)

2021	2022	2023	2024	2025	2026
39.9	40.6	41.1	41.8	42.4	43.1

EPA CO_2 standards are as follows. Rather than expressing these standards as linear functions with accompanying minima and maxima, similar to the approach NHTSA has followed since 2005 in specifying attribute-based standards, the following tables specify flat standards that apply below and above specified footprints, and a linear function that applies between those footprints. The two approaches are mathematically identical. For passenger cars with a footprint of less than or equal to 41 square feet, the gram/mile CO_2 target value is selected for the appropriate model year from Table II-9:

Table II-9 – Final CO_2 Targets for Passenger Cars Smaller than 41 ft^2

Model year	CO_2 target value (grams/mile)
2012	244.0
2013	237.0
2014	228.0
2015	217.0
2016	206.0
2017	195.0
2018	185.0
2019	175.0
2020	166.0
2021	161.8
2022	159.0
2023	156.4
2024	153.7
2025	151.2
2026 and later	148.6

For passenger cars with a footprint of greater than 56 square feet, the gram/mile CO_2 target value is selected for the appropriate model year from Table II-10:

Table II-10 – Final CO_2 Targets for Passenger Cars Larger than 58 ft^2

Model year	CO_2 target value (grams/mile)
2012	315.0
2013	307.0
2014	299.0
2015	288.0

Model year	CO_2 target value (grams/mile)
2016	277.0
2017	263.0
2018	250.0
2019	238.0
2020	226.0
2021	220.9
2022	217.3
2023	213.7
2024	210.2
2025	206.8
2026 and later	203.4

For passenger cars with a footprint that is greater than 41 square feet and less than or equal to 56 square feet, the gram/mile CO_2 target value is calculated using the following equation and rounded to the nearest 0.1 grams/mile.

Target CO_2 = $[a \times f] + b$

Where *f* is the vehicle footprint and *a and b* are selected from Table II-11 for the appropriate model year:

Table II-11 – Final CO_2 Targets for Passenger Cars Between 41 and 58 ft^2

Model year	**a**	***b***
2012	4.72	50.5
2013	4.72	43.3
2014	4.72	34.8
2015	4.72	23.4
2016	4.72	12.7
2017	4.53	8.9
2018	4.35	6.5
2019	4.17	4.2
2020	4.01	1.9
2021	3.94	0.2
2022	3.88	-0.1
2023	3.82	-0.4
2024	3.77	-0.6
2025	3.71	-0.9
2026 and later	3.65	-1.2

For light trucks with a footprint of less than or equal to 41 square feet, the gram/mile CO_2 target value is selected for the appropriate model year from Table II-12:

Table II-12 – Final CO_2 Targets for Light Trucks Smaller than 41 ft^2

Model year	CO_2 target value (grams/mile)
2012	294.0
2013	284.0
2014	275.0
2015	261.0
2016	247.0
2017	238.0
2018	227.0
2019	220.0
2020	212.0
2021	206.6
2022	203.1
2023	199.7
2024	196.3
2025	193.0
2026 and later	189.8

For light trucks with a footprint greater than the minimum value specified in the table below for each model year, the gram/mile CO_2 target value is selected for the appropriate model year from Table II-13:

Table II-13 – Final CO_2 Targets for Passenger Cars Larger than 66-74 ft^2

Model year	Minimum footprint	CO_2 target value (grams/mile)
2012	66.0	395.0
2013	66.0	385.0
2014	66.0	376.0
2015	66.0	362.0
2016	66.0	348.0
2017	66.0	347.0
2018	66.0	342.0
2019	66.4	339.0
2020	68.3	337.0
2021	73.5	329.7
2022	74.0	324.4
2023	74.0	319.2
2024	74.0	314.0
2025	74.0	308.9
2026 and later	74.0	303.9

For light trucks with a footprint that is greater than 41 square feet and less than or equal to the maximum footprint value specified in Table II-14 below for each model year, the gram/mile CO_2 target value is calculated using the following equation and rounded to the nearest 0.1 grams/mile.

Target $CO_2 = (a \times f) + b$

Where f is the footprint and *a and b* are selected from Table II-14 below for the appropriate model year:

Table II-14 – Final CO_2 Targets for Passenger Cars Between 41 and 66-74 ft^2

Model year	**Maximum footprint**	**a**	**b**
2012	66.0	4.04	128.6
2013	66.0	4.04	118.7
2014	66.0	4.04	109.4
2015	66.0	4.04	95.1
2016	66.0	4.04	81.1
2017	50.7	4.87	38.3
2018	60.2	4.76	31.6
2019	66.4	4.68	27.7
2020	68.3	4.57	24.6
2021	73.5	4.51	21.7
2022	74.0	4.44	21.0
2023	74.0	4.38	20.3
2024	74.0	4.31	19.6
2025	74.0	4.25	19.0
2026 and later	74.0	4.18	18.3

These equations are presented graphically below, where the x-axis represents vehicle footprint and the y-axis represents the CO_2 target. The targets are lower for smaller footprint vehicles and higher for larger footprint vehicles:

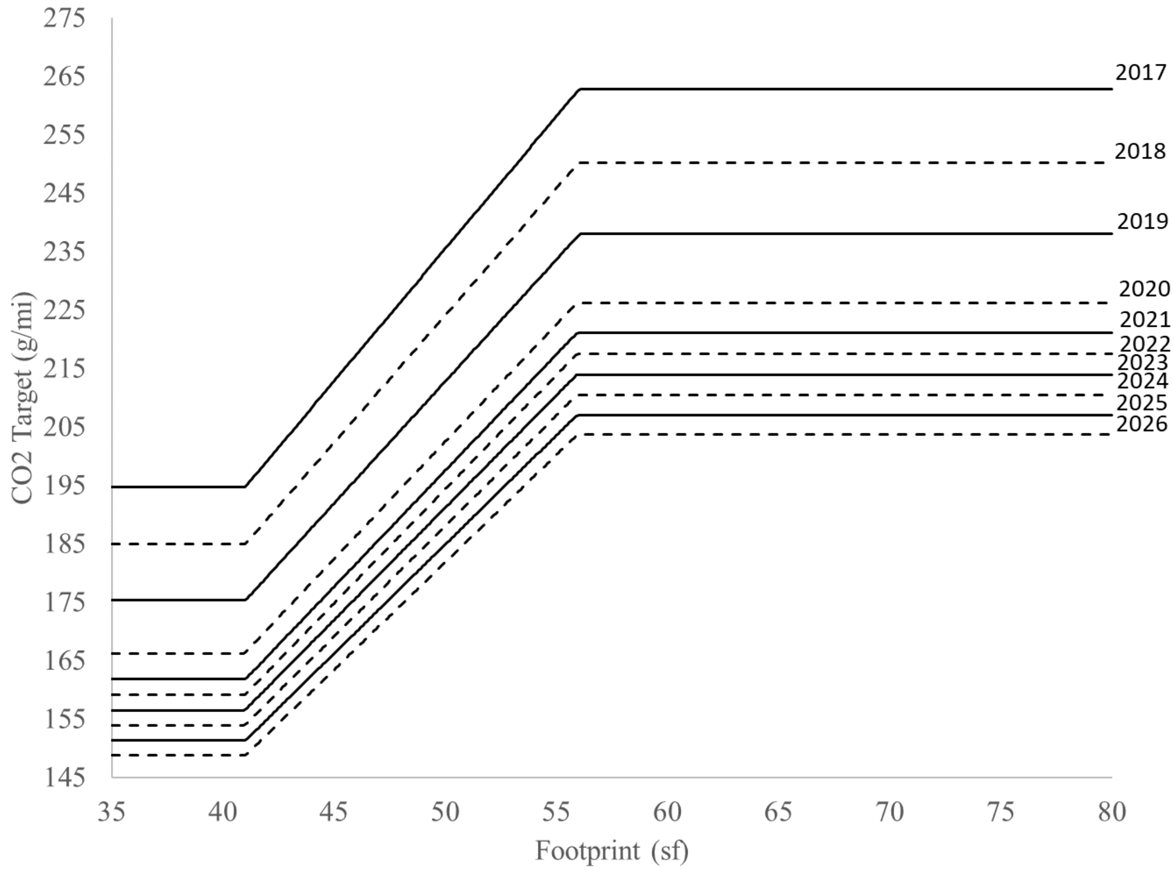

Figure II-3 – Passenger Car CO_2 Targets

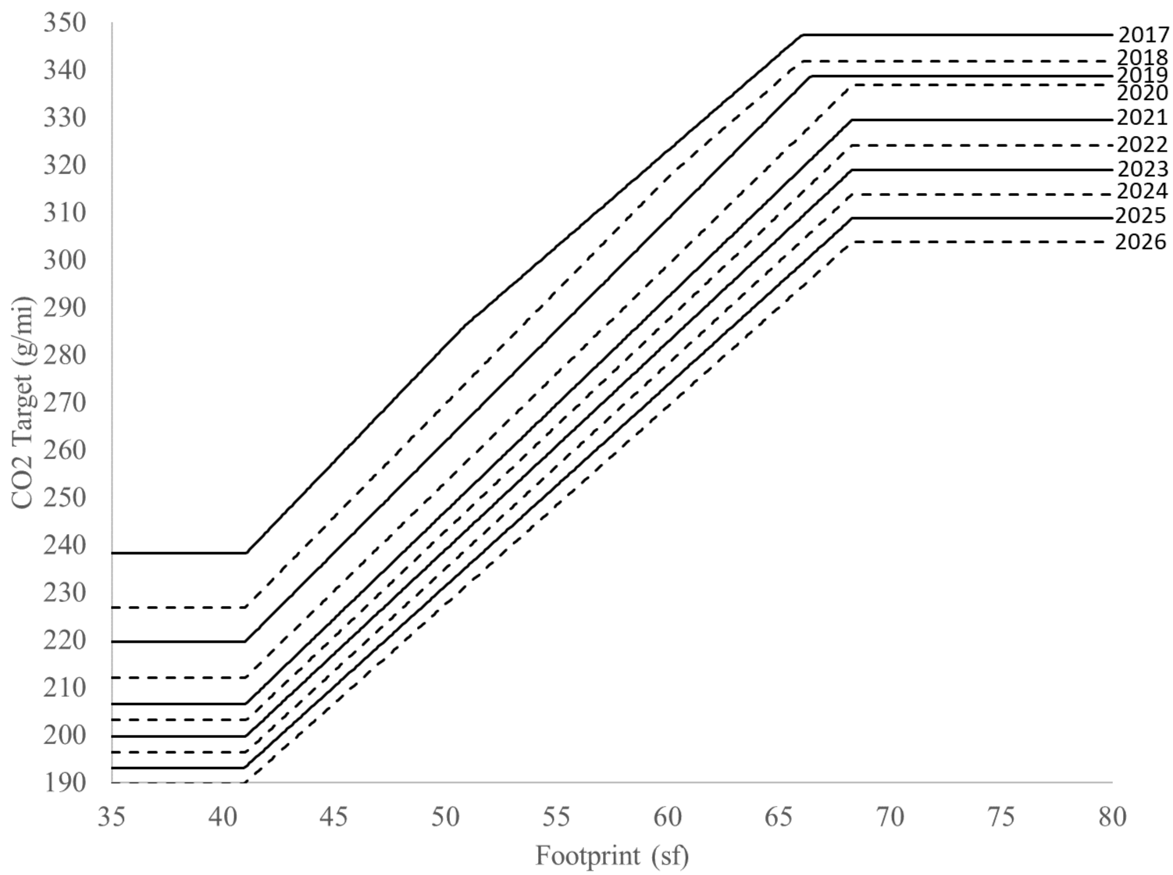

Figure II-4 – Light Truck CO_2 Targets

Except that EPA elected to apply a slightly different slope when defining passenger car targets, CO_2 targets may be expressed as direct conversion of fuel economy targets, as follows:

$$TARGET_{CO2} = \frac{8887\ g/gal}{TARGET_{FE}} + OFFSET$$

where 8887 g/gal relates grams of CO_2 emitted to gallons of fuel consumed, and *OFFSET* reflects the fact that that HFC emissions from lower-GWP A/C refrigerants and less leak-prone A/C systems are counted toward average CO_2 emissions, but EPCA provides no basis to count reduced HFC emissions toward CAFE levels.

For the reader's benefit, Table II-15, Table II-16, and Table II-17 show the estimates, under the final rule analysis, of what the MYs 2021-2026 CAFE and CO_2 curves would translate to, in terms of miles per gallon (mpg) and grams per mile (g/mi).

Table II-15 – Average of OEMs' CAFE and CO_2 Estimated Final Requirements for Passenger Cars

Model Year	**Avg. of OEMs' Est. Requirements**	
	CAFE (mpg)	CO_2 (g/mi)
2017	39.0	220
2018	40.4	209
2019	41.9	197
2020	43.6	187
2021	44.2	178
2022	44.9	175
2023	45.6	171
2024	46.3	168
2025	47.0	167
2026	47.7	165

Table II-16 – Average of OEMs' CAFE and CO_2 Estimated Final Requirements for Light Trucks

Model Year	**Avg. of OEMs' Est. Requirements**	
	CAFE (mpg)	CO_2 (g/mi)
2017	29.4	306
2018	30.0	293
2019	30.5	281
2020	31.1	268
2021	31.6	257
2022	32.1	253
2023	32.6	250
2024	33.1	248
2025	33.6	245
2026	34.1	240

Table II-17 – Average of OEMs' CAFE and CO_2 Estimated Final Requirements (Passenger Cars and Light Trucks)

Model Year	**Avg. of OEMs' Est. Requirements**	
	CAFE (mpg)	CO_2 (g/mi)
2017	33.8	261
2018	34.8	248
2019	35.7	236
2020	36.8	224
2021	37.3	214
2022	37.9	211
2023	38.5	207
2024	39.1	204
2025	39.8	202
2026	40.4	199

As the following tables demonstrate, averages of manufacturers' estimated requirements are more stringent (i.e., for CAFE, higher, and for CO_2, lower) under the final standards than under the proposed standards:

Table II-18 – Average of OEMs' CAFE Estimated Final Requirements (Passenger Cars and Light Trucks) under Proposed and Final Standards

Model Year	**Avg. of OEMs' Est. Requirements**	
	Proposed Standards	Final Standards
2017	33.8	33.8
2018	34.8	34.8
2019	35.7	35.7
2020	36.8	36.8
2021	36.8	37.3
2022	36.8	37.9
2023	36.8	38.5
2024	36.9	39.1
2025	36.9	39.8
2026	36.9	40.4

Table II-19 – Average of OEMs' CO_2 Estimated Final Requirements (Passenger Cars and Light Trucks) under Proposed and Final Standards

2017	261	261
2018	248	248
2019	236	236
2020	225	224
2021	216	214
2022	214	211
2023	211	207
2024	209	204
2025	208	202
2026	206	199

E. Final Standards—Impacts

This section summarizes the estimated costs and benefits of the MYs 2021-2026 CAFE and CO_2 emissions standards for passenger cars and light trucks, as compared to the regulatory alternatives considered. These estimates helped inform the agencies' choices among the regulatory alternatives considered and provide further confirmation that the final standards are maximum feasible, for NHTSA, and appropriate, for EPA. The costs and benefits estimated to result from the CAFE standards are presented first, followed by those estimated to result from the CO_2 standards. For several reasons, the estimates for costs and benefits presented for the different programs, while consistent, are not identical. NHTSA's and EPA's standards are projected to result in slightly different fuel efficiency improvements. EPA's CO_2 standard is nominally more stringent in part due to its assumptions about manufacturers' use of air conditioning leakage/refrigerant replacement credits, which are expected to result in reduced emissions of HFCs. NHTSA's final standards are based solely on assumptions about fuel economy improvements, and do not account for emissions reductions that do not relate to fuel economy. In addition, the CAFE and CO_2 programs offer somewhat different program flexibilities and provisions, primarily because NHTSA is statutorily prohibited from considering some flexibilities when establishing CAFE standards, while EPA is not.[29] The analysis underlying this final rule reflects many of those additional EPA flexibilities, which contributes to differences in how the agencies estimate manufacturers could comply with the respective sets of standards, which in turn contributes to differences in estimated impacts of the standards. These differences in compliance flexibilities are discussed in more detail in Section IX below.

Table II-20 to Table II-23 present all subcategories of costs and benefits of this final rule for all seven alternatives proposed. Costs include application of fuel economy technology to new

[29] *See* 49 U.S.C. 32902(h); CAA Sec. 202(a).

vehicles, consumer surplus, crash costs due to changes in VMT, as well as, noise and congestion. Benefits include fuel savings, consumer surplus, refueling time, and clean air.

Table II-20 – Benefits and Costs of Final CAFE Standards and Alternatives Over the Lifetimes of Vehicles Produced Through MY 2029 at a 3 Percent Discount Rate (Billions of 2018 Dollars)

F. Other Programmatic Elements

1. Compliance and Flexibilities

Automakers seeking to comply with the CAFE and CO_2 standards are generally expected to add fuel economy-improving technologies to their new vehicles to boost their overall fleet fuel economy levels. Readers will remember that improving fuel economy directly reduces CO_2 emissions, because CO_2 is a natural and inevitable byproduct of fossil fuel combustion to power vehicles. The CAFE and CO_2 programs contain a variety of compliance provisions and flexibilities to accommodate better automakers' production cycles, to reward real-world fuel economy improvements that cannot be reflected in the 1975-developed test procedures, and to incentivize the production of certain types of vehicles. The agencies sought comment on a broad variety of changes and potential expansions of the programs' compliance flexibilities in the NPRM, and decided, after considering the comments, to make a few changes to the flexibilities proposed in the NPRM in this final rule. The most noteworthy change is the retention, in the CO_2 program, of the flexibilities that allow automakers to continue to use HFC reductions toward their CO_2 compliance, and that extend the "0 grams/mile" assumption for electric vehicles through MY 2026 (i.e., recognizing only the tailpipe emissions of full battery-electric vehicles and not recognizing the upstream emissions caused by the electricity usage of those vehicles). In the NPRM, EPA had proposed to remove and sought comment on removing those flexibilities from the CO_2 program, but determined not to remove them in this final rule. EPA and NHTSA are also removing from the programs, starting in MY 2022, the credit/FCIV for full-size pickup trucks that are either hybrids or over-performing by a certain amount relative to their targets, and allowing technology suppliers to begin the petition process for off-cycle credits/adjustments.

Table II-24, Table II-25, Table II-26, and Table II-27 provide a summary of the various compliance provisions in the two programs; their authorities; and any changes included as part of this final rule:

Table II-24 – Statutory Flexibilities for Over-Compliance with Standards

Regulatory item	**NHTSA**			**EPA**		
	Authority	Current Program	Final Rule	Authority	Current Program	Final Rule
Credit Earning	49 U.S.C. 32903(a)	Yes, denominated in tenths of a mpg	No change	CAA 202(a)	Yes, denominated in g/mi	No change
Credit "Carry-forward"	49 U.S.C. 32903(a)(2)	5 MYs into the future	No change	CAA 202(a)	5 MYs into the future (except MYs 2010-2015 = credits may be carried forward through MY 2021)	No change
Credit "Carryback" (AKA "deficit carry-forward")	49 U.S.C. 32903(a)(1)	3 MYs into the past	No change	CAA 202(a)	3 MYs into the past	No change
Credit Transfer	49 U.S.C. 32903(g)	Up to 2 mpg per fleet; transferred credits may not be used to meet min DPC standard	No change; Alliance/Global request to reconsider prior interpretation is denied	CAA 202(a)	Unlimited	No change
Credit Trade	49 U.S.C. 32903(f)	Unlimited quantity; traded credits may not be used to meet min DPC standard	No change	CAA 202(a)	Unlimited	No change

Table II-25 – Flexibilities that Address Gaps in Compliance Test Procedures

Regulatory item	**NHTSA**			**EPA**		
	Authority	Current Program	Final Rule	Authority	Current Program	Final Rule
A/C efficiency	49 U.S.C. 32904	Allows mfrs to earn "fuel consumption improvement values" (FCIVs) equivalent to EPA credits starting in MY 2017	No change, except to add advanced A/C compressor technology to the pre-approved menu; (Alliance/ Global request to allow retroactive starting in MY 2012 is denied)	CAA 202(a)	"Credits" for A/C efficiency improvements up to caps of 5.0 g/mi for cars and 7.2 g/mi for trucks	No change, except to add advanced A/C compressor technology to the pre-approved menu.
Off-cycle	49 U.S.C. 32904	Allows mfrs to earn "fuel consumption improvement values" (FCIVs) equivalent to EPA credits starting in MY 2017	Add high efficiency alternators to the pre-approved menu; (Alliance/ Global request to allow retroactive starting in MY 2012 is denied) allow suppliers to begin petition proess	CAA 202(a)	"Menu" of pre-approved credits (~10), up to cap of 10 g/mi for MY 2014 and beyond; other pathways require EPA approval through either 5-cycle testing or through public notice and comment	Add high efficiency alternators to the pre-approved menu; allow suppliers to begin petition process

Table II-26 – Incentives that Encourage Application of Technologies

Regulatory item	**NHTSA**			**EPA**		
	Authority	Current Program	Final Rule	Authority	Current Program	Final Rule
Full-size pickup trucks with HEV or overperforming target	49 U.S.C. 32904	Allows mfrs to earn FCIVs equivalent to EPA credits starting in MY 2017 and ending in MY 2025	Delete beginning with MY 2022	CAA 202(a)	10 g/mi for full-size pickups with mild hybrids OR overperforming target by 15% (MYs 2017-2021); 20 g/mi for full-size pickups with strong hybrids OR overperforming target by 20% (MYs 2017-2025)	Delete beginning with MY 2022

Table II-27 – Incentives that Encourage Alternative Fuel Vehicles

Regulatory item	NHTSA			EPA		
	Authority	Current Program	Final Rule	Authority	Current Program	Final Rule
Dedicated alternative fuel vehicle	49 U.S.C. 32905(a) and (c)	Fuel economy calculated assuming gallon of liquid or gallon equivalent gaseous alt fuel = 0.15 gallons of gasoline; for EVs petroleum equivalency factor[30]	No change	CAA 202(a)	Multiplier incentives for EVs and FCVs (each vehicle counts as 2.0/1.75/1.5 vehicles in 2017-2021), NGVs (1.6/1.45/1.3 vehicles); each EV = 0 g/mi upstream emissions through MY 2021 (then phases out based on per-mfr production cap of 200k vehicles)	Multiplier of 2.0 added for MY 2022-2026 NGVs. No change to EV and FCV multipliers that phase out after MY 2021. Electricity usage = 0 g/mi extended through MY 2026.
Dual-fueled vehicles	49 U.S.C. 32905(b), (d), and (e); 32906(a)	FE calc using 50% operation on alt fuel and 50% on gasoline through MY 2019. Starting with MY 2020, NHTSA will begin using the SAE defined "Utility Factor" methodology to account for actual potential use, and "F-factor" for FFV. NHTSA will continue to incorporate the 0.15 incentive factor.	No change	CAA 202(a)	Multiplier incentives for PHEVs and NGVs (each vehicle counts as 1.6/1.45/1.3 vehicles in 2017-2021); electric operation = 0 g/mi through MY 2021 (then phases out based on per-mfr production cap of 200k vehicles); "Utility Factor" method for use, and "F-factor" for FFV.	Multiplier of 2.0 added for MY 2022-2026 NGVs. No change to EV and FCV multipliers that phase out after MY 2021. Electricity usage = 0 g/mi extended through MY 2026.

[30] The CAFE program uses an energy efficiency metric and standards that are expressed in miles per gallon. For PHEVs and BEVs, to determine gasoline the equivalent fuel economy for operation on electricity, a Petroleum Equivalency Factor (PEF) is applied to the measured electrical consumption. The PEF for electricity was established by the Department of Energy, as required by statute, and includes an accounting for upstream energy associated with the production and distribution for electricity relative to gasoline. Therefore, the CAFE program includes upstream accounting based on the metric that is consistent with the fuel economy metric. The PEF for electricity also includes an incentive that effectively counts only 15 percent of the electrical energy consumed.

Regulatory item	NHTSA			EPA		
	Authority	Current Program	Final Rule	Authority	Current Program	Final Rule
Connected/ Automated Vehicles	n/a	n/a	n/a	CAA 202(a)	Mfrs can petition for off-cycle credits	No change
High-octane fuel blends	n/a	n/a	n/a	CAA 202(a)	No incentives or requirements	No change

Providing a technology neutral basis by which manufacturers meet fuel economy and CO_2 emissions standards encourages an efficient and level playing field. The agencies continue to have a desire to minimize incentives that disproportionately favor one technology over another. Some of this may involve regulations established by other Federal agencies. In the near future, NHTSA and EPA intend to work with other relevant Federal agencies to pursue regulatory means by which we can further ensure technology neutrality in this field.

2. Preemption/Waiver

As discussed above, the issues of Clean Air Act waivers of preemption under Section 209 and EPCA/EISA preemption under 49 U.S.C. 32919 are not addressed in today's final rule, as they were the subject of a separate final rulemaking action by the agencies in September 2019. While many comments were received in response to the NPRM discussion of those issues, those comments have been addressed and responded to as part of that separate rulemaking action.

III. Purpose of the Rule

The Administrative Procedure Act (APA) requires agencies to incorporate in their final rules a "concise general statement of their basis and purpose."[31] While the entire preamble document represents the agencies' overall explanation of the basis and purpose for this regulatory action, this section within the preamble is intended as a direct response to that APA (and related CAA) requirements. Executive Order 12866 further states that "Federal agencies should promulgate only such regulations as are required by law, are necessary to interpret the law, or are made necessary by compelling public need, such as material failures of private markets to protect or improve the health and safety of the public, the environment, or the well-being of the American people."[32] Section III.C of this FRIA discusses at greater length the question of whether a market failure exists that these final rules may address.

NHTSA and EPA are legally obligated to set CAFE and GHG standards, respectively, and do not have the authority to decline to regulate.[33] The agencies are issuing these final rules to fulfill their respective statutory obligations to provide maximum feasible fuel economy standards and limit emissions of pollutants from new motor vehicles which have been found to endanger public health and welfare (in this case, specifically carbon dioxide (CO_2); EPA has

[31] 5 U.S.C. 553(c); *see also* Clean Air Act section 307(d)(6)(A), 42 U.S.C. 7607(d)(6)(A).
[32] EO 12866, Section 1(a).
[33] For CAFE, *see* 49 U.S.C. 32902; for CO_2, *see* 42 U.S.C. 7521(a).

already set standards for methane (CH_4), nitrous oxide (N_2O), and hydrofluorocarbons (HFCs) and is not revising them in this rule). Continued progress in meeting these statutory obligations is both legally necessary and good for America—greater energy security and reduced emissions protect the American public. The final standards continue that progress, albeit at a slower rate than the standards finalized in 2012.

National annual gasoline consumption and CO_2 emissions currently total about 140 billion gallons and 5,300 million metric tons, respectively. The majority of this gasoline (about 130 billion gallons) is used to fuel passenger cars and light trucks, such as will be covered by the CAFE and CO_2 standards issued today. Accounting for both tailpipe emissions and emissions from "upstream" processes (e.g., domestic refining) involved in producing and delivering fuel, passenger cars and light trucks account for about 1,500 million metric tons (mmt) of current annual CO_2 emissions. The agencies estimate that under the standards issued in 2012, passenger car and light truck annual gasoline consumption would steadily decline, reaching about 80 billion gallons by 2050. The agencies further estimate that, because of this decrease in gasoline consumption under the standards issued in 2012, passenger car and light truck annual CO_2 emissions would also steadily decline, reaching about 1,000 mmt by 2050. Under the standards issued today, the agencies estimate that, instead of declining from about 140 billion gallons annually today to about 80 billion gallons annually in 2050, passenger car and light truck gasoline consumption would decline to about 95 billion gallons. The agencies correspondingly estimate that instead of declining from about 1,500 mmt annually today to about 1,000 mmt annually in 2050, passenger car and light truck CO_2 emissions would decline to about 1,100 mmt. In short, the agencies estimate that under the standards issued today, annual passenger car and light truck gasoline consumption and CO_2 emissions will continue to steadily decline over the next three decades, even if not quite as rapidly as under the previously-issued standards.

The agencies also estimate that these impacts on passenger car and light truck gasoline consumption and CO_2 emissions will be accompanied by a range of other energy- and climate-related impacts, such as reduced electricity consumption (because today's standards reduce the estimated rate at which the market might shift toward electric vehicles) and increased CH_4 and N_2O emissions. These estimated impacts, discussed below and in the FEIS accompanying today's notice, are dwarfed by estimated impacts on gasoline consumption and CO_2 emissions.

As explained above, these final rules set or amend fuel economy and carbon dioxide standards for model years 2021-2026. Many commenters argued that it was not appropriate to amend previously-established CO_2 and CAFE standards, generally because those commenters believed that the administrative record established for the 2012 final rule and EPA's January 2017 Final Determination was superior to the record that informed the NPRM, and that that prior record led necessarily to the policy conclusion that the previously-established standards should remain in place.[34] Some commenters similarly argued that EPA's Revised Final Determination—which, for EPA, preceded this regulatory action—was invalid because, they

[34] Comments arguing that the prior record was superior to the current record, and thus a better basis for decision-making, will be addressed throughout the balance of this FRIA.

allege, it did not follow the procedures established for the mid-term evaluation that EPA codified into regulation,[35] and also because the Revised Final Determination was not based on the prior record.[36]

The agencies considered a range of alternatives in the proposal, including the baseline/no action alternative of retaining the existing EPA carbon dioxide standards. As the agencies explained in the proposal, the proposal was entirely *de novo*, based on an entirely new analysis reflecting the best and most up-to-date information available to the agencies.[37] This rulemaking action is separate and distinct from EPA's Revised Final Determination, which itself was neither a proposed nor a final decision that the standards "must" be revised. EPA retained full discretion in this rulemaking to revise the standards or not revise them. In any event, the case law is clear that agencies are free to reconsider their prior decisions.[38] With that legal principle in mind, the agencies agree with commenters that the amended (and new) CO_2 and CAFE standards must be consistent with the CAA and EPCA/EISA, respectively, and the preamble and this FRIA explain in detail why the agencies believe they are consistent. The section below discusses briefly the authority given to the agencies by their respective governing statutes, and the factors that Congress directed the agencies to consider as they exercise that authority in pursuit of fulfilling their statutory obligations.

A. EPA's Statutory Requirements

EPA is setting national CO_2 standards for passenger cars and light trucks under Section 202(a) of the Clean Air Act (CAA).[39] Section 202(a) of the CAA requires EPA to establish standards for emissions of pollutants from new motor vehicles which cause or contribute to air pollution which may reasonably be anticipated to endanger public health or welfare.[40] In establishing such standards, EPA considers issues of technical feasibility, cost, available lead

Cir. 2012) (" 'If EPA makes a finding of endangerment, the Clean Air Act requires the [a]gency to regulate emissions of the deleterious pollutant from new motor vehicles. …Given the non-discretionary duty in Section 202(a)(1) and the limited flexibility available under Section 202(a)(2), which this court has held related only to the motor vehicle industry, …EPA had no statutory basis on which it could ground [any] reasons for further inaction' ") (quoting Massachusetts v. EPA, 549 U.S. 497, 533-35 (2007).

time, and other factors. Standards under section 202(a) thus take effect only "after providing such period as the Administrator finds necessary to permit the development and application of the requisite technology, giving appropriate consideration to the cost of compliance within such period."[41] EPA's statutory requirements are further discussed in Section VIII.A.

B. NHTSA's Statutory Requirements

NHTSA is setting national Corporate Average Fuel Economy (CAFE) standards for passenger cars and light trucks for each model year as required under EPCA, as amended by EISA.[42] EPCA mandates a motor vehicle fuel economy regulatory program that balances statutory factors in setting minimum fuel economy standards to facilitate energy conservation. EPCA allocates the responsibility for implementing the program between NHTSA and EPA as follows: NHTSA sets CAFE standards for passenger cars and light trucks; EPA establishes the procedures for testing, tests vehicles, collects and analyzes manufacturers' data, and calculates the individual and average fuel economy of each manufacturer's passenger cars and light trucks; and NHTSA enforces the standards based on EPA's calculations.

The following sections enumerate specific statutory requirements for NHTSA in setting CAFE standards and NHTSA's interpretations of them, where applicable. Many comments were received on these requirements and interpretations. Because this is intended as an overview section, those comments will be addressed below in Section VIII rather than here, and the agencies refer readers to that part of the document for more information.

For each future model year, EPCA (as amended by EISA) requires that DOT (by delegation, NHTSA) establish separate passenger car and light truck standards at "the maximum feasible average fuel economy level that the Secretary decides the manufacturers can achieve in that model year,"[43] based on the agency's consideration of four statutory factors: "technological feasibility, economic practicability, the effect of other motor vehicle standards of the Government on fuel economy, and the need of the United States to conserve energy."[44] The law also allows NHTSA to amend standards that are already in place, as long as doing so meets these requirements.[45] EPCA does not define these terms or specify what weight to give each concern in balancing them; thus, NHTSA defines them and determines the appropriate weighting that leads to the maximum feasible standards given the circumstances in each CAFE standard rulemaking.[46]

---

[41] 42 U.S.C. 7521(a)(2).
[42] EPCA and EISA direct the Secretary of Transportation to develop, implement, and enforce fuel economy standards (*see* 49 U.S.C. 32901 *et. seq*.), which authority the Secretary has delegated to NHTSA at 49 CFR 1.94(c).
[43] 49 U.S.C. 32902(a) and (b).
[44] 49 U.S.C. 32902(f).
[45] 49 U.S.C. 32902(g).
[46] *See* Center for Biological Diversity v. NHTSA, 538 F.3d 1172, 1195 (9th Cir. 2008) (hereafter "CBD v. NHTSA") ("The EPCA clearly requires the agency to consider these four factors, but it gives NHTSA discretion to decide how to balance the statutory factors – as long as NHTSA's balancing does not undermine the fundamental purpose of the EPCA: energy conservation.")

EISA added several other requirements to the setting of separate passenger car and light truck standards. Standards must be "based on 1 or more vehicle attributes related to fuel economy and express[ed] ... in the form of a mathematical function."[47] New standards must also be set at least 18 months before the model year in question, as would amendments to increase standards previously set.[48] NHTSA must regulations prescribing average fuel economy standards for at least 1, but not more than 5, model years at a time.[49] A number of comments addressed these requirements; for the reader's reference, those comments will be summarized and responded to in Section VIII. EISA also added the requirement that NHTSA set a minimum standard for domestically-manufactured passenger cars,[50] which will also be discussed further in Section VIII below.

For MYs 2011-2020, EISA further required that the separate standards for passenger cars and for light trucks be set at levels high enough to ensure that the achieved average fuel economy for the entire industry-wide combined fleet of new passenger cars and light trucks reach at least 35 mpg not later than MY 2020, and standards for those years were also required to "increase ratably."[51] For model years after 2020, standards must be set at the maximum feasible level.[52]

1. Factors that Must be Considered in Deciding What Levels of CAFE Standards are "maximum feasible"

a) Technological Feasibility

"Technological feasibility" refers to whether a particular method of improving fuel economy can be available for commercial application in the model year for which a standard is being established. Thus, in determining the level of new standards, the agency is not limited to technology that is already being commercially applied at the time of the rulemaking. For this rulemaking, NHTSA has evaluated and considered all types of technologies that improve real-world fuel economy, although not every possible technology was expressly included in the analysis, as discussed in Section VI and also in Section VIII.

b) Economic Practicability

"Economic practicability" refers to whether a standard is one "within the financial capability of the industry, but not so stringent as to" lead to "adverse economic consequences,

---

[47] 49 U.S.C. 32902(b)(3)(A).
[48] 49 U.S.C. 32902(a), (g)(2).
[49] 49 U.S.C. 39202(b)(3)(B).
[50] 49 U.S.C. 32902(b)(4).
[51] 49 U.S.C. 32902(b)(2)(A) and (C). NHTSA has CAFE standards in place that are projected to result in industry-achieved fuel economy levels over 35 mpg in MY 2020. EPA typically provides verified final CAFE data from manufacturers to NHTSA several months or longer after the close of the MY in question, so the actual MY 2020 fuel economy will not be known until well after MY 2020 has ended. The standards for all MYs up to and including 2020 are known and not at issue in this regulatory action, so these provisions are noted for completeness rather than immediate relevance to this final rule. Because neither of these requirements apply after MY 2020, they are not relevant to this rulemaking and will not be discussed further.
[52] 49 U.S.C. 32902(b)(2)(B).

such as a significant loss of jobs or the unreasonable elimination of consumer choice."[53] The agency has explained in the past that this factor can be especially important during rulemakings in which the automobile industry is facing significantly adverse economic conditions (with corresponding risks to jobs). Economic practicability is a broad factor that includes considerations of the uncertainty surrounding future market conditions and consumer demand for fuel economy in addition to other vehicle attributes.[54] In an attempt to evaluate the economic practicability of different future levels of CAFE standards (i.e., the regulatory alternatives considered in this rulemaking), NHTSA considers a variety of factors, including the annual rate at which manufacturers can increase the percentage of their fleet(s) that employ a particular type of fuel-saving technology, the specific fleet mixes of different manufacturers, assumptions about the cost of the standards to consumers, and consumers' valuation of fuel economy, among other things, including, in part, safety.

It is important to note, however, that the law does not preclude a CAFE standard that poses considerable challenges to any individual manufacturer. The Conference Report for EPCA, as enacted in 1975, makes clear, and the case law affirms, "a determination of maximum feasible average fuel economy should not be keyed to the single manufacturer which might have the most difficulty achieving a given level of average fuel economy."[55] Instead, NHTSA is compelled "to weigh the benefits to the nation of a higher fuel economy standard against the difficulties of individual automobile manufacturers."[56] Accordingly, while the law permits NHTSA to set CAFE standards that exceed the projected capability of a particular manufacturer as long as the standard is economically practicable for the industry as a whole, the agency cannot simply disregard that impact on individual manufacturers.[57] That said, in setting fuel economy standards, NHTSA does not seek to maintain competitive positions among the industry players, and notes that while a particular CAFE standard may pose difficulties for one manufacturer as being too high or too low, it may also present opportunities for another. NHTSA has long held that the CAFE program is not necessarily intended to maintain the competitive positioning of each particular company. Rather, it is intended to enhance the fuel economy of the vehicle fleet on American roads, while protecting motor vehicle safety and paying close attention to the economic risks.

c) The Effect of Other Motor Vehicle Standards of the Government on Fuel Economy

"The effect of other motor vehicle standards of the Government on fuel economy" involves an analysis of the effects of compliance with emission, safety, noise, or damageability

[57] *Id*. ("…the Secretary must weigh the benefits to the nation of a higher average fuel economy standard against the difficulties of individual automobile manufacturers.")

standards on fuel economy capability and thus on average fuel economy. In many past CAFE rulemakings, NHTSA has said that it considers the adverse effects of other motor vehicle standards on fuel economy. It said so because, from the CAFE program's earliest years,[58] the effects of such compliance on fuel economy capability over the history of the program have been negative ones. For example, safety standards that have the effect of increasing vehicle weight lower vehicle fuel economy capability and thus decrease the level of average fuel economy that the agency can determine to be feasible. NHTSA has considered the additional weight that it estimates would be added in response to new safety standards during the rulemaking timeframe. NHTSA has also accounted for EPA's "Tier 3" standards for criteria pollutants in its estimates of technology effectiveness.[59]

The NPRM also discussed how EPA's CO_2 standards for light-duty vehicles and California's Advanced Clean Cars program fit into NHTSA's consideration of "the effect of other motor vehicle standards of the Government on fuel economy." The agencies note that on September 19, 2019, to ensure One National Program for automobile fuel economy and carbon dioxide emissions standards, the agencies finalized regulatory text related to preemption of State tailpipe CO_2 standards and Zero Emission Vehicle (ZEV) mandates under EPCA and partial withdrawal of a waiver previously provided to California under the Clean Air Act.[60] This final rule's impact on State programs—including California's—will therefore be somewhat different from the NPRM's consideration. In the interest of brevity, this FRIA will hold further discussion of that point, along with responses to comments received, until Section VIII.

d) The Need of the United States to Conserve Energy

"The need of the United States to conserve energy" means "the consumer cost, national balance of payments, environmental, and foreign policy implications of our need for large quantities of petroleum, especially imported petroleum."[61] Environmental implications principally include changes in emissions of carbon dioxide and criteria pollutants and air toxics. Prime examples of foreign policy implications are energy independence and security concerns.

(1) Consumer Costs and Fuel Prices

Fuel for vehicles costs money for vehicle owners and operators. All else equal (and this is an important qualification), consumers benefit from vehicles that need less fuel to perform the same amount of work. Future fuel prices are a critical input into the economic analysis of potential CAFE standards because they determine the value of fuel savings both to new vehicle buyers and to society, the amount of fuel economy that the new vehicle market is likely to demand in the absence of new standards, and they inform NHTSA about the consumer cost of the nation's need for large quantities of petroleum. In this final rule, NHTSA's analysis relies on fuel price projections estimated using the version of NEMS used for the U.S. Energy Information

Administration's (EIA) Annual Energy Outlook for 2019.[62] Federal government agencies generally use EIA's price projections in their assessment of future energy-related policies.

(2) National Balance of Payments

Historically, the need of the United States to conserve energy has included consideration of the "national balance of payments" because of concerns that importing large amounts of oil created a significant wealth transfer to oil-exporting countries and left the U.S. economically vulnerable.[63] As recently as 2009, nearly half of the U.S. trade deficit was driven by petroleum,[64] yet this concern has largely lain fallow in more recent CAFE actions, in part because other factors besides petroleum consumption have since played a bigger role in the U.S. trade deficit.[65] Given significant recent increases in U.S. oil production and corresponding decreases in oil imports, this concern seems likely to remain fallow for the foreseeable future.[66] Increasingly, changes in the price of fuel have come to represent transfers between domestic consumers of fuel and domestic producers of petroleum rather than gains or losses to foreign entities.

As flagged in the NPRM, some commenters raised concerns about potential economic consequences for automaker and supplier operations in the U.S. due to disparities between CAFE standards at home and their counterpart fuel economy/efficiency and CO_2 standards abroad. NHTSA finds these concerns more relevant to technological feasibility and economic

---

[62] The analysis for the proposal relied on fuel price projections from AEO 2017; the difference in the projections is discussed in Section VI.

[63] *See, e.g.*, 42 FR 63184, 63192 (Dec. 15, 1977) ("A major reason for this need [to reduce petroleum consumption] is that the importation of large quantities of petroleum creates serious balance of payments and foreign policy problems. The United States currently spends approximately $45 billion annually for imported petroleum. But for this large expenditure, the current large U.S. trade deficit would be a surplus.")

[65] *See, e.g.*, Nida Çakir Melek and Jun Nie, "What Could Resurging U.S. Energy Production Mean for the U.S. Trade Deficit," Mar. 7, 2018, Federal Reserve Bank of Kansas City. Available at https://www.kansascityfed.org/publications/research/mb/articles/2018/what-could-resurging-energy-production-mean. The authors state that "The decline in U.S. net energy imports has prevented the total U.S. trade deficit from widening further. …In 2006, petroleum accounted for about 16 percent of U.S. goods imports and about 3 percent of U.S. goods exports. By the end of 2017, the share of petroleum in total goods imports declined to 8 percent, while the share in total goods exports almost tripled, shrinking the U.S. petroleum trade deficit. Had the petroleum trade deficit not improved, all else unchanged, the total U.S. trade deficit would likely have been more than 35 percent wider by the end of 2017."

[66] For an illustration of recent increases in U.S. production, *see, e.g.*, 'U.S. crude oil and liquid fuels production," Short-Term Energy Outlook, U.S. Energy Information Administration (Aug. 2019), available at http://www.eia.gov/outlooks/steo/images/Fig16.png. EIA noted in April 2019 that "Annual U.S. crude oil production reached a record level of 10.96 million barrels per day (b/d) in 2018, 1.6 million b/d (17%) higher than 2017 levels. In December 2018, monthly U.S. crude oil production reached 11.96 million b/d, the highest monthly level of crude oil production in U.S. history. U.S crude oil production has increased significantly over the past 10 years, driven mainly by production from tight rock formations using horizontal drilling and hydraulic fracturing. EIA projects that U.S. crude oil production will continue to grow in 2019 and 2020, averaging 12.3 million b/d and 13.0 million b/d, respectively." "Today in Energy: U.S. crude oil production grew 17% in 2018, surpassing the previous record in 1970," EIA, Apr. 9, 2019. Available at http://www.eia.gov/todayinenergy/detail.php?id=38992.

practicability considerations than to the national balance of payments. The discussion in Section VIII below addresses this topic in more detail.

(3) Environmental Implications

Higher fleet fuel economy can reduce U.S. emissions of various pollutants by reducing the amount of oil that is produced and refined for the U.S. vehicle fleet, but can also increase emissions by reducing the cost of driving, which can result in more vehicle miles traveled (*i.e.*, the rebound effect). Thus, the net effect of more stringent CAFE standards on emissions of each pollutant depends on the relative magnitude of both its reduced emissions in fuel refining and distribution and increases in its emissions from vehicle use. Fuel savings from CAFE standards also necessarily results in lower emissions of CO_2, the main greenhouse gas emitted as a result of refining, distributing, and using transportation fuels. Reducing fuel consumption directly reduces CO_2 emissions because the primary source of transportation-related CO_2 emissions is fuel combustion in internal combustion engines.

NHTSA has considered environmental issues, both within the context of EPCA and the context of the National Environmental Policy Act (NEPA), in making decisions about the setting of standards since the earliest days of the CAFE program. As courts of appeal have noted in three decisions stretching over the last 20 years,[67] NHTSA defined "the need of the United States to conserve energy" in the late 1970s as including, among other things, environmental implications. In 1988, NHTSA included climate change concepts in its CAFE notices and prepared its first environmental assessment addressing that subject.[68] It cited concerns about climate change as one of its reasons for limiting the extent of its reduction of the CAFE standard for MY 1989 passenger cars.[69] Since then, NHTSA has considered the effects of reducing tailpipe emissions of CO_2 in its fuel economy rulemakings pursuant to the need of the United States to conserve energy by reducing petroleum consumption.

(4) Foreign Policy Implications

U.S. consumption and imports of petroleum products can impose additional costs (*i.e.*, externalities) on the domestic economy that are not reflected in the market price for crude petroleum or in the prices paid by consumers for petroleum products such as gasoline. NHTSA has said previously that these costs can include (1) higher prices for petroleum products resulting from the effect of U.S. oil demand on world oil prices, (2) the risk of disruptions to the U.S. economy caused by sudden increases in the global price of oil and its resulting impact on fuel prices faced by U.S. consumers, and (3) expenses for maintaining the strategic petroleum reserve (SPR) to provide a response option should a disruption in commercial oil supplies threaten the U.S. economy, to allow the U.S. to meet part of its International Energy Agency obligation to

[68] 53 FR 33080, 33096 (Aug. 29, 1988).
[69] 53 FR 39275, 39302 (Oct. 6, 1988).

maintain emergency oil stocks, and to provide a national defense fuel reserve.[70] Higher U.S. consumption of crude oil or refined petroleum products increases the magnitude of these external economic costs, thus increasing the true economic cost of supplying transportation fuels above the resource costs of producing them. Conversely, reducing U.S. consumption of crude oil or refined petroleum products (by reducing motor fuel use) can reduce these external costs.

While these costs are considerations, the United States has significantly increased oil production capabilities in recent years, to the extent that the U.S. is currently producing enough oil to satisfy nearly all of its energy needs and is projected to continue to do so (or even become a net energy exporter in the near future).[71] This has added stable new supply to the global oil market, which ameliorates the U.S.' need to conserve energy from a security perspective even given that oil is a global commodity. The agencies discuss this issue in more detail in Section VIII below.

2. Factors that NHTSA is Prohibited From Considering

EPCA states that in determining the level at which it should set CAFE standards for a particular model year, NHTSA may not consider the ability of manufacturers to take advantage of several EPCA provisions that facilitate compliance with CAFE standards and thereby can reduce their costs of compliance.[72] As discussed further below, NHTSA cannot consider compliance credits that manufacturers earn by exceeding the CAFE standards and then use to achieve compliance in years in which their measured average fuel economy falls below the standards. NHTSA also cannot consider the use of alternative fuels by dual-fueled vehicles (such as plug-in hybrid electric vehicles) nor the availability of dedicated alternative fuel vehicles (such as battery electric or hydrogen fuel cell vehicles) in any model year. EPCA encourages the production of alternative fuel vehicles by specifying that their fuel economy is to be determined using a special calculation procedure that results in those vehicles being assigned a higher fuel economy level than they actually achieve. For non-statutory incentives that NHTSA developed by regulation, NHTSA does not consider these incentives subject to the EPCA prohibition on considering flexibilities. These topics will be addressed further in Section VIII below.

3. Other Considerations in Determining Maximum Feasible CAFE Standards

NHTSA historically has interpreted EPCA's statutory factors as including consideration for potential adverse safety consequences in setting CAFE standards. Courts have consistently

---

[70] While the U.S. maintains a military presence in certain parts of the world to help secure global access to petroleum supplies, that is neither the primary nor the sole mission of U.S. forces overseas. Additionally, the scale of oil consumption reductions associated with CAFE standards would be insufficient to alter any existing military missions focused on ensuring the safe and expedient production and transportation of oil around the globe. See the FRIA's discussion on energy security for more information on this topic.

[71] *See* AEO 2019, at 14 ("In the Reference case, the United States becomes a net exporter of petroleum liquids after 2020 as U.S. crude oil production increases and domestic consumption of petroleum products decreases."). *Available at* https://www.eia.gov/outlooks/aeo/pdf/aeo2019.pdf.

[72] 49 U.S.C. 32902(h).

recognized that this interpretation is reasonable. As courts have recognized, "NHTSA has always examined the safety consequences of the CAFE standards in its overall consideration of relevant factors since its earliest rulemaking under the CAFE program."[73] The courts have consistently upheld NHTSA's implementation of EPCA in this manner.[74] Thus, in evaluating what levels of stringency would result in maximum feasible standards, NHTSA assesses the potential safety impacts and considers them in balancing the statutory considerations and to determine the maximum feasible level of the standards.[75] Many commenters addressed the NPRM's analysis of safety impacts; those comments will be summarized and responded to in Section VI.D.2 and also in each agency's discussion in Section VIII.

The above sections explain what Congress thought was important enough to codify when it directed each agency to regulate, and begin to explain how the agencies have interpreted those directions over time and in this final rule. The next section looks more closely at the interplay between Congress's direction to the agencies and the aspects of the market that these regulations affect, as follows.

C. Is there a market failure that justifies increasing standards?

As noted above, Executive Order 12,866 advises that "Federal agencies should promulgate only such regulations as are required by law, or are made necessary by compelling need, such as material failures of private markets to protect or improve the health and safety of the public, the environment, or the wellbeing of the American people…." As the preceding sections explained, both NHTSA and EPA are required by law to regulate fuel economy and CO_2 emissions, respectively. However, Section 1(b) of Executive Order 12,866 also asks agencies to "…identify the problem[s] that [they] intend to address (including, where applicable, the failures of private markets or public institutions that warrant new agency action) as well as assess the significance of that problem."[76]

---

[73] *Competitive Enterprise Institute v. NHTSA*, 901 F.2d 107, 120 n. 11 (D.C. Cir. 1990) ("*CEI-I*") (citing 42 Fed. Reg. 33534, 33551 (Jun. 30, 1977).

[74] *See, e.g., Competitive Enterprise Institute v. NHTSA*, 956 F.2d 321, 322 (D.C. Cir. 1992) ("*CEI-II*") (in determining the maximum feasible fuel economy standard, "NHTSA has always taken passenger safety into account," citing *CEI-I*, 901 F.2d at 120 n. 11); *Competitive Enterprise Institute v. NHTSA*, 49 F.3d 481, 483-83 (D.C. Cir. 1995) (same); *Center for Biological Diversity v. NHTSA*, 538 F.3d 1172, 1203-04 (9th Cir. 2008) (upholding NHTSA's analysis of vehicle safety issues with weight in connection with the MYs 2008-2011 light truck CAFE rulemaking).

[75] NHTSA stated in the NPRM that "While we discuss safety as a separate consideration, NHTSA also considers safety as closely related to, and in some circumstances a subcomponent of, economic practicability. On a broad level, manufacturers have finite resources to invest in research and development. Investment into the development and implementation of fuel saving technology necessarily comes at the expense of investing in other areas such as safety technology. On a more direct level, when making decisions on how to equip vehicles, manufacturers must balance cost considerations to avoid pricing further consumers out of the market. As manufacturers add technology to increase fuel efficiency, they may decide against installing new safety equipment to reduce cost increases. And as the price of vehicles increase beyond the reach of more consumers, such consumers continue to drive or purchase older, less safe vehicles. In assessing practicability, NHTSA also considers the harm to the nation's economy caused by highway fatalities and injuries." 83 FR at 43209 (Aug. 24, 2018). Many comments were received on this issue, which will be discussed further in Section VIII below.

[76] Circular A-4, at 4.

The first question posed by EO 12,866—whether a market failure exists that these standards can correct—is a difficult one, which Congress arguably asked and answered when it originally required DOT to regulate fuel economy. Congress established the CAFE program—in the wake of the oil embargo of 1973-1974—to address the risk of gasoline shortages and price shocks by reducing the nation's use of petroleum and its dependence on imported sources of supply. While Congress did not cite a specific market failure in enacting the EPCA, the underlying quandary the act attempted to redress was that car buyers' choices among competing models—and the levels of fuel economy they offered—increased the risks and attendant costs of gasoline shortages or price shocks in ways that buyers did not adequately internalize.

For EPA's purposes, regulations on motor vehicles' CO_2 emissions are intended to address the risk of climate change. In economics, an "externality" market failure occurs when the production or consumption of some good or service imposes uncompensated costs on a third party. Consumers' potential failure to purchase vehicles with CO_2 emissions sufficiently low to protect the planet adequately from the risks of climate change is an obvious example of an economic externality. More formally, the potential market failure would be that vehicle buyers in the U.S. may not fully consider the costs of additional climate-related damages that CO_2 emissions from the models they choose can impose on other households and businesses. Section 202(a) of the CAA requires EPA to regulate emissions once EPA makes an "endangerment finding," determining that emissions from motor vehicles may reasonably be anticipated to endanger public health or welfare. This provision suggests that Congress was indeed more concerned about the external consequences of vehicles' emissions of air pollutants than buyers themselves appeared to be, and thus elected to require vehicle manufacturers to reduce those emissions (through EPA regulation under the CAA) from the models they offered for sale. As explained above, EPA found in 2009 that CO_2 emissions—and their contribution to the threat of climate change—endanger human health and welfare, thus classifying them as an air pollutant and triggering EPA's obligation to regulate their permissible levels.

In response to EO 12,866's challenge to agencies to identify market failures their regulations address and to indicate exactly how those regulations would address those market failures, NHTSA and EPA initially pointed to external costs that petroleum consumption imposes on the U.S. economy. These included potential costs for businesses and households to adjust to sudden increases in prices for petroleum products, as well as losses in economic output in the event petroleum imports were curtailed or interrupted. New car buyers inflicted potential economic harm on the rest of the U.S. economy, the agencies originally argued, because they did not recognize how their choices among competing vehicle models – and the fuel economy levels they featured – could increase the risk that petroleum supplies might be interrupted or foreign producers would suddenly raise prices.

More recently, the agencies have justified stricter CAFE and CO_2 emissions standards by asserting that buyers do not take advantage of opportunities to improve their *own* well-being, by purchasing models whose higher fuel economy would more than repay their higher initial purchase prices via future savings in fuel costs. This newer rationale is fundamentally different from asserting that some externality—whereby buyers' choices cause economic harm to *others*—exists to justify regulating fuel economy or CO_2 emissions, or adopting more demanding regulations. EPA and NHTSA have previously labeled this behavior an example of the "energy paradox," whereby consumers voluntarily forego investments that conserve energy even when those initial outlays appear likely to repay themselves—in the form of savings in energy costs—over the relatively near term.[77]

However, recent research cast doubt on whether such an energy paradox exists in the case of fuel economy—that is, on whether buyers of new vehicles inadequately consider the value of future savings in fuel costs they would experience from purchasing models that feature higher fuel economy—and about how extensive it might be. Several recent studies have estimated the fraction of appropriately discounted lifetime fuel savings offered by models featuring higher fuel economy that car shoppers appear to value or willing to pay for. These estimates are typically drawn from one of three sources—(1) buyers' choices among competing models with different purchase prices, fuel economy levels, and other features; (2) statistically "decomposing" vehicle prices into the values buyers attach to their individual features, one of which is fuel economy; or (3) analyzing how selling prices for vehicles with different fuel economy levels respond to variation in fuel prices and the changes it causes in their lifetime fuel costs.

The estimates these studies report may partly reflect variation among buyers' preferences for different vehicle features (such as fuel economy, but also size or utility), the financial constraints they face, how much they drive, or their expectations about future fuel prices, so they should be interpreted cautiously. However, the most careful recent studies suggest that on average buyers appear to undervalue the savings from higher fuel economy at most modestly, and perhaps not at all, after accounting for the influence of vehicles' other attributes on prices and purchasing decisions.[78] This research suggests that the energy paradox, sometimes described as buyers' "myopia" in assessing the value of future fuel savings, is a much weaker rationale for regulating fuel economy than the agencies had previously asserted.

IPI commented that the agencies' obligation to consider market failures in setting standards derives not just from Executive Order 12,866 but also from the agencies' respective statutes, and argued that the agencies had defined market failures too narrowly in their proposal.[79] Specifically, IPI stated that NHTSA's task under EPCA is "not so restricted to only protecting consumers from gas price spikes," and argued that NHTSA must also consider "externalities relating to energy security, national security, positional goods, global climate change, and air and water pollution associated with fuel production and consumption; asymmetric information, attention costs, and other information failures; internalities, including myopia; and various supply-side market failures, including first-mover disadvantage."[80]

For EPA's task under the CAA, IPI stated that, although while EPA must "protect the planet from unchecked climate change, [it] must not ignore other related market failures that cause harm to public health and welfare, including the issues and market failures [as described

[80] *Id.*

for NHTSA above].”[81] IPI argued that the proposal was arbitrary and capricious for not “consider[ing] important aspects of the problem set before the agencies by Congress,” and also for not considering the market failures discussed in the 2012 final rule.[82] CBD, *et al.*, asserted similarly that the agencies’ respective statutes require their actions to be more technology-forcing than what markets would otherwise achieve, in effect asserting that innovations in technology confer external benefits that vehicle manufacturers or buyers do not fully consider.[83]

With regard to the specific market failures CAFE and CO_2 standards could potentially address, Global Automakers suggested that climate effects are indeed an externality that more stringent standards can address,[84] while CFA stated that regulating fuel economy and CO_2 emissions can address an extensive catalog of market failures, including externalities, marketing, availability of fuel-efficient models, transaction cost friction, information asymmetry, behavioral issues, and access to capital, among others.[85] CFA asserted that advances in economic theory had heavily criticized the neoclassical model, and that “a great deal of empirical evidence supports [that the] standards are seen as an important and, in many ways, preferred policy approach.”[86] On this basis, CFA stated that attribute-based standards that “are set at a moderately aggressive level” and are “consistent with the rate of improvement that the auto industry achieved in the first decade of the fuel economy standard setting program,” among other things, would address the market failure.[87]

IPI argued that regulation of fuel economy (presumably also CO_2 emissions) is necessary because “many vehicle attributes, like horsepower and size, are positional goods—that is, they confer status on buyers of cars and light truck models that feature them prominently, so regulation of fuel economy can help correct the positional externality.”[88] IPI also noted the externality of health effects associated with refueling. IPI cited Alcott and Sunstein (2015) to argue, like CFA, that fuel economy standards can correct market failures like informational failure, myopia, supply-side failures, positional externalities, etc., and by doing so, can provide net private welfare gains—that is, improve the utility of vehicle buyers *themselves*, not just that of *other* households or businesses.[89]

[85] CFA, Comments, NHTSA-2018-0067-12005, at 61-64.
[86] *Id.* at 63.
[87] *Id.* at 64.
[88] IPI, Appendix, NHTSA-2018-0067-12213, at 33.
[89] *Id.* at 34. Note, however, that the reference cited does *not* address the question of whether fuel economy standards can be effective in correcting those market failures. Instead, it explores the circumstances under which fuel economy standards can improve welfare when vehicle buyers undervalue savings in fuel costs from purchasing more fuel-efficient models. *See generally,* Allcott, Hunt, and Cass R. Sunstein, “Regulating Internalities,” Working Paper 20087, National Bureau of Economic Research, May 2015, available at https://www.nber.org/papers/w21187.pdf.

EDF and CARB both asserted that an energy paradox exists in the case of fuel economy, with EDF arguing (like CFA) that information asymmetry—that is, unequal access of vehicle manufacturers and potential buyers to information about the cost savings likely to result from owning higher-mpg models—coupled with limited availability of fuel-efficient models, leads consumers to purchase vehicles with lower fuel economy than they otherwise would.[90] CARB simply stated that the NPRM analysis did not account for the energy paradox.[91]

The agencies agree with these commenters that the market failures CAFE and CO_2 standards can help address are likely to exist, but note that little of the behavior in the broad catalog identified by commenters actually represents market failures, and instead simply reflects consumers' preferences for features other than fuel economy. Even in the few cases of potential market failures that commenters identify related to the hypothetical energy paradox, the agencies question whether more stringent CAFE and CO_2 standards are necessary to address the phenomena, or are even likely to be effective in doing so. In the agencies' view, neither the logical arguments nor the limited empirical evidence that commenters presented convincingly demonstrate the capacity of more stringent CAFE and CO_2 standards to resolve, or even mitigate, most of the various phenomena they describe as market failures.

For example, the idea that regulating fuel economy and CO_2 emissions can mitigate the consequences of inadequate access to information by placing decisions that depend on access to complete information in the hands of regulators rather than buyers has superficial appeal. Yet commenters do not establish that such a drastic step is necessary to overcome any inadequacy of information, or that requiring manufacturers to supply higher fuel economy will be more effective than less intrusive approaches such as expanding the range of information available to buyers. As OMB Circular A-4 notes, "Because information, like other goods, is costly to produce and disseminate, your evaluation will need to do more than demonstrate the possible existence of incomplete or asymmetric information."[92]

In the few cases where commenters cited empirical evidence to support their arguments that stricter fuel economy and CO_2 regulations are an appropriate response to market failures, that evidence is limited and unpersuasive. As one illustration, the frequent assertion that buyers' widespread aversion to the prospect of financial losses makes them hesitant to purchase higher-mpg models appears to be traceable to findings from classroom experiments on small numbers of university students, rather than to large-scale empirical evidence drawn from buyers' observed behavior.[93] Commenters' repeated emphasis on loss aversion as a critical source of buyers'

---

[91] CARB, Detailed Comments, NHTSA-2018-0067-11873, at 188-89.
[92] Circular A-4, at 5.
[93] CFA, Comments, NHTSA-2018-0067-12005, at 16 *et seq*; Consumers Union, Attachment 4, NHTSA-2018-0067-12068, at 12; Attachment 3, NHTSA-2018-0067-11741, at 5-6, CARB at 214, and States at 87 each assert that loss aversion is an important source of car buyers' hesitance to purchase higher-mpg models, variously citing Greene, David L., John German, and Mark A. Delucchi, "Fuel Economy: The Case for Market Failure," Reducing Climate Impacts in the Transportation Sector, Springerin James S. Cannon and Daniel Sperling, eds., Springer, 2009, at pp. 181-205; (2009);; Greene, David L. (2010). How consumers value fuel economy: A literature review (No. EPA-420-R-10-008); Greene, David L., "Uncertainty, Loss Aversion and Markets for Energy Efficiency", Energy

unwillingness to choose levels of fuel economy that appear to be in their own financial interest also ignores recent research questioning whether loss aversion is a plausible motivation for such systematic or universal behavior by consumers.[94]

Another example is commenters' repeated citation of the study of households' difficulties in analyzing the financial value of purchasing vehicles with higher fuel economy conducted by Turrentine and Kurani, which relies on interviews with a limited number of subjects (57 California households) to conclude that consumers are systematically unable to perform the calculations necessary to estimate the value of fuel savings.[95] These same commenters

---

Economics, vol. 33, at pp. 608-616, (2011) and Greene, David L., "Consumers' Willingness to Pay for Fuel Economy: Implications for Sales of New Vehicles and Scrappage of Used Vehicles," attachment to comments by CARB, Oct. 10, 2018. However, none of these sources presents empirical evidence on how the frequency of actual common loss aversion actually is among real world vehicle buyers, instead simply asserting (or implicitly assuming) that loss aversion it is likely to be widespread. Further, their (identical) estimates of the *degree* of loss aversion are difficult to trace, and appear to be drawn from classroom exercises administered to limited numbers of university students, not from empirical research involving real world vehicle buyers. One source cited for their repeated assertion that losses of a given dollar amount are valued twice as highly as gains of the same amount is Gal, David, "A psychological law of inertia and the illusion of loss aversion," Judgment and Decision Making, Vol. 1, No. 1, at pp. 23-32 (July 2006,), pp. 23–32, but this reference does not report such a value. Another source repeatedly cited by Greene and co-authors, Benartzi, Shlomo, and Richard H. Thaler, "Myopic Loss Aversion and the Equity Premium Puzzle," Quarterly Journal of Economics, Vol. 110, No. 1, at pp. 73-92 (February 1995), pp. 73-92, does report this value (at p. 74), although only in passing, and cites other references as its original source. The original sources of the claim that losses are values twice as highly as equivalent gains appear to be Kahneman, Daniel, Jack L. Knetsch, and Richard H. Thaler, "Experimental Tests of the Endowment Effect and the Coase Theorem," Journal of Political Economy, Vol. 98, No. 6, pp. 1325-48. (Dec., 1990) (pp. 1325-1348, specifically Section II), pp. 1329-1336; and Tversky, Amos, and Daniel Kahneman, "Loss Aversion in Riskless Choice: A Reference-Dependent Model," Quarterly Journal of Economics, Vol. 106, No. 4, at pp. 1039-61 (Nov., 1991) (pp. 1039-1061, specifically pp. 1053-1054). Neither of these references, however, makes any claim about the generality of the estimate or its applicability to non-experimental settings for consumer behavior.

[94] *See* Gal, David, "A psychological law of inertia and the illusion of loss aversion," Judgment and Decision Making, Vol. 1, No. 1, pp. 23-32 (July 2006,) pp. 23–32,; Erev, I., E. Ert, and E. Yechiam, "Loss aversion, diminishing sensitivity, and the effect of experience on repeated decisions,.", Journal of Behavioral Decision Making, Vol. 21 (2008), pp. 575–597; (2008); Ert, E., and I. Erev, "On the descriptive value of loss aversion in decisions under risk: Six clarifications," Judgment and Decision Making, Vol. 8 (2013), at pp. 214–235; (2013); Gal, David and Rucker, Derek, "The Loss of Loss Aversion: Will It Loom Larger Than Its Gain?" Journal of Consumer Psychology, Vol. 28 No. 3, (July 2018), at pp. 497-516 (July 2018) available at (https://onlinelibrary.wiley.com/doi/abs/10.1002/jcpy.1047); and Gal, David, "Why the Most Important Idea in Behavioral Decision-Making Is a Fallacy," Scientific American, Observations, (July 31, 2018), available at (https://blogs.scientificamerican.com/observations/why-the-most-important-idea-in-behavioral-decision-making-is-a-fallacy/).

[95] ICCT at p. 4 and Consumers Union at p. 12 (among others), citing Turrentine, T. S., & Kurani, K. S., "Car buyers and fuel economy?", Energy policy, Vol. 35 No. 2 (2007), at 1213-1223, available at https://www.sciencedirect.com/science/article/pii/S0301421506001200, as evidence that most or all new-car shoppers are incapable of calculating the savings they would realize from purchasing a higher-mpg model, and further misinterpret the study as evidence that buyers invariably underestimate the value of increased fuel economy. Yet this widely relied-upon analysis included only 57 households, all located in California. As an illustration, citing Turrentine and Kurani, ICCT asserts "There is substantial circumstantial evidence that *most consumers in the U.S.* place a low value on fuel economy." *See* ICCT at 4 (emphasis added). Similarly, Consumers Union simply asserts that "Households do not track gasoline prices over time and cannot accurately estimate future gas prices or cost savings." See Consumers Union at 12, again citing Turrentine and Kurani as authority).

consistently ignore the wealth of detailed, publicly-available information on the fuel economy of new vehicle models, and shoppers' ready access to user-friendly tools to estimate the savings they are likely to realize from purchasing higher-mpg models. These tools include the label that prominently displays how much a vehicles' fuel economy will save, or conversely, cost a purchaser in fuel costs over 5 years of use in color and large type (*see* Figure III-1), which is legally required to be prominently displayed on all new cars vehicles offered for sale.[96] Separately, new car dealers are also required to prominently display the Federal Fuel Economy Guide for each model year of new vehicles offered for sale, which provides fuel economy information for all vehicles from that model year.[97]

Similarly, no commenters offered empirical evidence to support their repeated assertions that buyers or the public actually view features such as styling, size, or performance as "positional goods" to which other potential buyers might aspire, or considered the possibility that high fuel economy or advanced technology (such as hybrid or electric propulsion) might *themselves* represent such positional attributes.[98] Nor do commenters provide any empirical evidence that the various aspects of behavior they allege lead buyers to underinvest in fuel economy—ranging from unwillingness to spend time or effort estimating likely fuel savings, to inattentiveness to the economic and social importance of improved fuel economy, inability to obtain information about the savings it offers them, and incorrect "framing" of the choice among

[96] *See* 15 U.S.C. 1531, *et seq*., and 49 CFR 575.401.
[97] 40 CFR 600.405-08 and 600.407-08.
[98] For evidence that prestige appears to be a motivation for purchasing advanced-technology vehicles, see Hidrue, Michael K., et al., "Willingness to pay for electric vehicles and their attributes," Resource and Energy Economics, Vol. 33, Issue 3 (September 2011), at pp. 686-705; Chua, Wan Ying, Lee, Alvin and Sadeque, Saalem 2010, "Why do people buy hybrid cars?," Proceedings of Social Marketing Forum, University of Western Australia, Perth, Western Australia, Edith Cowan University, Churchlands, W.A., at pp. 1-13; Liu, Yizao, "Household demand and willingness to pay for hybrid vehicles," Energy Economics, Volume 44, 2014, at pp. 191-197; Hur, Won-Moo, Jeong Woo, and Yeonshim Kim, "The Role of Consumer Values and Socio-Demographics in Green Product Satisfaction: The Case of Hybrid Cars," Psychological Reports, Volume 117, issue 2, October 2015, at pp. 406-427. A useful summary of many studies appears in Table 1 (p. 196) of Makoto Tanaka, Takanori Ida, Kayo Murakami, Lee Friedman, "Consumers' willingness to pay for alternative fuel vehicles: A comparative discrete choice analysis between the US and Japan," Transportation Research Part A: Policy and Practice, Volume 70, 2014, at pp. 194-209 (Table 1 at p. 196). Some of these studies find that buyers are apparently willing to pay significant price premiums for the prestige or status value of hybrids or battery-electric vehicles—which their authors speculate may derive from their "greenness"—because their purchases cannot be explained on the basis of economic or financial considerations. Others find that average or typical shoppers' willingness to pay advanced-technology vehicles is below the price premiums they command, suggesting that their purchasers must derive some status or prestige value from owning and driving them.

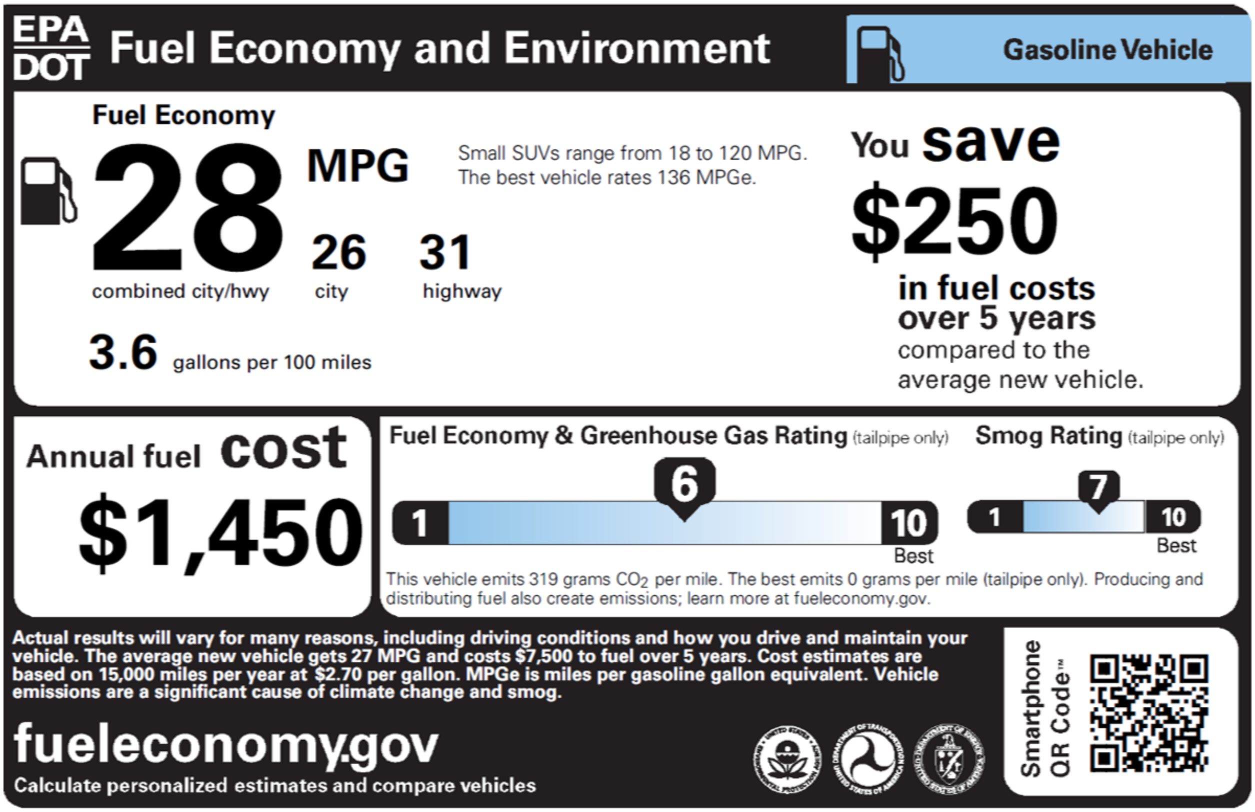

Figure III-1 – Fuel Economy and Environment Label Example

models with different levels of fuel economy—are widespread, empirically significant, or systematically likely to lead buyers to under- rather than over-invest in fuel economy.

The most frequent argument that an energy paradox or energy efficiency “gap” exists in the case of fuel economy is the observation that many U.S. vehicle buyers seem unwilling to pay higher prices for models whose increased fuel economy would appear to repay their additional investment within a relatively brief ownership period. However, this argument is unpersuasive for at least three reasons: most obviously, it does not acknowledge the possibility that engineering studies systematically underestimate costs to produce vehicles with higher fuel economy, and thus the prices that buyers would be asked to pay for models with improved fuel economy. Nor does it account for potential sacrifices in *other* vehicle attributes that manufacturers may make in order to achieve higher fuel economy without increasing vehicles’ purchase prices beyond consumers’ willingness to pay. Finally, claims that consumers are acting irrationally by refusing to purchase higher-mpg models usually reach this conclusion by comparing rates at which they implicitly discount future fuel costs—and thus evaluate savings from purchasing more fuel-efficient models—to interest rates in financial markets that incorporate time horizons or risk profiles that may be very different from those of consumers.

Even putting these concerns aside, comparing future fuel savings to the costs of purchasing more expensive models that offer higher fuel economy demonstrates only that buyers are not behaving as analysts *expect them to* and *believe they should* behave. These comparisons do not demonstrate that consumers are necessarily acting irrationally, and cannot diagnose the nature of information shortcomings buyers face, reasons that they might interpret such information incorrectly, or identify behavioral inconsistencies they may exhibit. In short, conjectures about why buyers *might* undervalue potential savings from investing in higher-efficiency vehicle models do not represent evidence that they actually *do so*, and as discussed above, recent research seems to show that such behavior is not widespread, if it exists at all.

Past joint rulemaking efforts by NHTSA and EPA have repeatedly sought to identify a plausible explanation for car buyers' perceived undervaluation of improved fuel economy. The agencies have occasionally relied on explanations such as consumers' insufficient appreciation of the importance of fuel economy, the difficulty of obtaining adequate information about the fuel economy of competing models or of converting competing models' fuel economy ratings to future fuel costs and savings, or consumers' misunderstanding or mistrust of such information when it is provided to them. At other times, the agencies have pointed to consumers' "myopia" about the future—asserting that for some reason, they appear to underestimate future fuel costs and savings—or argued that shoppers are insufficiently attentive to fuel costs when comparing competing models, that the value of improved fuel economy is obscured ("shrouded") by vehicles' other, more visible attributes, or that uncertainty about the savings in fuel costs owners will actually realize causes them to undervalue those savings when comparing the upfront costs of models with different fuel economy.

Despite the frequency with which the agencies have cited these hypotheses, clear support for any of them remains elusive. Consumers have long had ready access to detailed information about individual models' fuel economy, which appears prominently on the labels displayed by new cars,[99] and is published online and in printed outlets that shoppers use routinely rely widely on to compare models.[100] In addition, the fuel economy actually experienced by previous buyers of individual models is increasingly reported in readily accessible on-line databases.[101]

Similarly, consumers appear to be well aware of the prices they pay for gasoline and how those vary among retail outlets, and are reminded clearly and frequently of the financial consequences of their fuel economy choices each time they purchase fuel. Increasingly, consumers also have ready online access to comparisons of fuel prices at competing locations near their homes or along routes they travel.[102] There is also considerable evidence that drivers' forecasts of future fuel prices are more accurate than those issued by government agencies or

[99] Fuel economy labels have been displayed on the window sticker of all new light duty cars and trucks since the mid-1970s, as required by the Energy Policy and Conservation Act. *See* https://www.epa.gov/fueleconomy/history-fuel-economy-labeling. Among the information *currently* required to be posted on the fuel economy label is both an estimated annual fuel cost for the vehicle, as well as an estimate of how that cost compares to the fuel cost over five years for an average new vehicle, so it is unclear what information consumers lack that prevents them from making an informed decision in this regard.
[100] *See, e.g.*, http://www.fueleconomy.gov, where consumers can find and compare the fuel economy (and greenhouse gas CO_2 and smog emissions) of different vehicle models across model years, as well as upload information about their own real-world fuel economy and compare it to other drivers.
[101] *See id.*
[102] *See, e.g.*, Gas Buddy, available at www.gasbuddy.com.

private forecasting services.[103] Evidence exists that car buyers and owners anticipate extreme volatility in fuel prices, recognize that there is considerable uncertainty about future fuel prices and potential savings from driving a higher-mpg model, and respond cautiously to these uncertainties when evaluating competing vehicle models,[104] none of which suggests a market failure as much as it suggests that consumers balance multiple, often competing objectives, and make choices based on the outcome of such balancing.

In past rulemakings, the agencies have also hypothesized that consumers may "satisfice"—that is, select some minimum acceptable level of fuel economy, and then evaluate models that achieve that minimum on the basis of their other attributes. This explanation for buyers' reluctance to purchase more fuel-efficient vehicles ignores the possibility that they do account fully for the value of higher fuel economy in their decision-making, but simply value differences in vehicles' other attributes more highly than they do fuel economy, which would not reveal irrational or myopic behavior.

A related argument has been that calculating future savings attributable to fuel economy is complicated, so car shoppers resort to simplified decision rules to choose among models with

[103] Anderson *et al.* report evidence that consumers believe fuel prices are likely to remain constant in inflation-adjusted terms.; s*ee* Anderson, Soren T., Ryan Kellogg, and James M. Sallee, "What do consumers believe about future gasoline prices?" Journal of Environmental Economics and Management, vol. 66 no. 3 (2013), at pp. 383-403. (2013). Other evidence generally supporting this view is reported by Allcott, Hunt, "Consumers' Perceptions and Misperceptions of Energy Costs," American Economic Review: Papers & Proceedings, Vol. 101 No. 3 (2011), at pp. 98–104, (2011), although Allcott finds that some fraction of consumers consistently believes that gasoline prices will rise in the future. In related research, Anderson *et al.* demonstrate that consumers' expectations that gasoline prices will return to their current levels, even after sudden and significant variation, is generally accurate; *see* Anderson, Soren T., Ryan Kellogg, James M. Sallee, and Richard T. Curtin, "Forecasting Gasoline Prices Using Consumer Surveys." American Economic Review: Papers & Proceedings, Vol. 101 No. 3 (2011), at pp. 110-14. (2011). In contrast to many consumers' expectation that fuel prices may vary over the future but will generally return to current levels, the U.S. Energy Information Administration predicted that gasoline prices would rise significantly over the future at the time the two previous rules establishing CAFÉE standards for model years 2012-16 and 2017-21 were adopted, in 2010 and 2012; see Energy Information Administration (EIA), Annual Energy Outlook 2010), Table A12, p. 131, available at https://www.eia.gov/outlooks/archive/aeo10/pdf/0383(2010).pdf, Table A12, p. 131; and Annual Energy Outlook 2012, Appendix A, Table A12, at p. 155, available at https://www.eia.gov/outlooks/archive/aeo12/pdf/appa.pdf, Table A12, p. 155. As of those same dates, forecasts of future petroleum prices issued by other government agencies and most private forecasting services (with the notable exception of HIS-Global Insight, which projected little or no increase in future prices) agreed closely with EIA's forecasts that prices would increase significantly over both the near- and longer-term futures; see EIA, Annual Energy Outlook 2010, Table 10, at p. 86; and Annual Energy Outlook 2012, Table 23, available athttps://www.eia.gov/outlooks/archive/aeo12/table_23.php. Expressed in constant-dollar terms, U.S. gasoline prices in 2019 are essentially unchanged from those in 2010, although prices have varied significantly above and below that level during the intervening period. *See* https://www.eia.gov/dnav/pet/hist/LeafHandler.ashx?n=pet&s=emm_epm0_pte_nus_dpg&f=m.

[104] For such evidence, *see* Allcott, Hunt, "Consumers' Perceptions and Misperceptions of Energy Costs," American Economic Review: Papers & Proceedings, Vol. 101 No. 3 (2011), at pp. 98–104; (2011); Greene, David L., (2010). "How consumers value fuel economy: A literature review" No. EPA-420-R-10-008 (2010) (No. EPA-420-R-10-008); Brownstone, David, David Bunch, and Kenneth Train, "Joint Mixed Logit Models of Stated and Revealed Preferences for Alternative-Fuel Vehicles," Transportation Research Part B, Vol. 34 (2000), at pp. 315-338, (2000), among many other sources.

different fuel economies, and relying on these rules-of-thumb causes them to choose models with lower fuel economy.[105] However, it is unclear why buyers' reliance on simplified procedures or approximations for estimating the value of fuel savings would necessarily lead them to systematically choose models with *lower* fuel economies rather than leading some to underinvest in fuel economy while others overinvest.

The agencies have also frequently described consumers as "loss averse," making them reluctant to pay the upfront and certain higher prices for models offering better fuel economy when the future savings they expect to realize are more distant and less certain.[106] The agencies' past assumption that loss aversion is universal (and equally strong) among new-car shoppers appears to be a simplification that is largely unsupported by empirical evidence, and in any case has been challenged both as a widespread feature of consumer behavior and more specifically as an explanation for vehicle shoppers' reluctance to purchase more costly models that offer higher fuel economy.[107] Further, the extremely wide variety of competing models among which car buyers can choose enables many of those searching for a model with better fuel economy at a comparable price to do so simply by choosing a version with fewer other features, which might partly offset the effect of their aversion to the prospect of losses from paying a higher purchase price.

OMB Circular A-4 does acknowledge that "[e]ven when adequate information is available, people can make mistakes by processing it poorly." It goes on to say that people may rely on "mental rules-of-thumb" that produce errors, or cognitive "availability" may lead to consumers overstating the likelihood of an event. However, Circular A-4 also cautions that "the mere possibility of poor information processing is not enough to justify regulation," and that potential problems with information processing "should be carefully documented." Some of the above examples of potential market failures may fall into this category, but lack evidentiary support. As with claims of asymmetric information, it is very difficult to distinguish between information processing errors and behavior consistent with consumer preferences for time and other vehicle attributes that differ from what government agency analysts *believe* they should be.

Similarly, the agencies have occasionally noted (and seemingly been critical of) some consumers' apparent preferences for vehicle attributes that convey social status, such as size or styling, and suggested that they may give inadequate attention to fuel economy because it does not provide similar status. The agencies have also suggested that consumers may be reluctant to purchase more fuel-efficient models because they associate higher fuel economy with inexpensive, less well-designed vehicles. These might be plausible explanations, were they not contradicted by concurrent arguments that potential buyers are inattentive to or uninformed about fuel economy, or have difficulty isolating it from vehicles' other attributes. Moreover, the market currently offers a wide range of highly fuel efficient (and advanced technology) vehicles at many different price points, including in the luxury and performance segments, which belies the assumption that fuel economy is inconsistent with positional attributes. In any case, consumers' hesitance to choose models offering higher fuel economy because they are reluctant

---

to sacrifice improvements in other vehicle attributes on which they place higher values cannot reasonably be characterized as a market failure.

Although past rulemakings have raised the possibility that car buyers' apparent tendency to underinvest in fuel economy could plausibly be explained by their use of discount rates exceeding those the agencies employ to assess the present value of fuel savings, the agencies have generally dismissed that possibility. In combination with factors such as their valuation of vehicles' attributes other than fuel economy, differences in driving habits that affect fuel economy and in how much they expect to drive newly- purchased cars, and variation in their expectations about future fuel prices, differing attitudes about the importance of future costs relative to more immediate ones could readily explain buyers' apparent reluctance to purchase models offering fuel economy levels that the agencies interpret as privately "optimal."

As with consumption of any good or service, the agencies believe consumers' choice in vehicles represents what economists call "constrained optimization." That is, consumers select a bundle of vehicle features—within their budget constraint—that optimizes the value to them. The agencies also believe, as is the case in every constrained consumer choice, that each of these attributes provide what economists call diminishing marginal returns (or value) to consumers. For instance, the agencies believe that consumers value vehicle size, comfort, performance, trim-level, appearance, etc. As such, fuel-saving technologies that increase the cost of the car are just one of many vehicle attributes that consumers balance against each other. And instead of using their entire budget on a single vehicle attribute, consumers tend to sacrifice some degree of many or all attributes in a degree that varies according to their preferences so that they can consume some degree of most or all attributes they value. This means that many consumers may not maximize fuel-saving technologies in their vehicle selection, but instead may choose some other bundle of attributes. The agencies' use of a 30 month pay-back period in this analysis—as opposed to fuel-savings over the life of the vehicle—is consistent with the constrained optimization consumers perform when selecting a vehicle. It is a reasonable representation of consumers' valuation of fuel-saving technologies, given the diminishing marginal returns of additional fuel economy. If the agencies had used the entire undiscounted fuel-savings over the entire life of the vehicle, the agencies would be effectively modeling a scenario where consumers maximize fuel economy to the detriment of *all other vehicle attributes* —an assumption that is evidently wrong. As such, it is not necessary that purchasers do not value lifetime fuel savings—and, in all likelihood, purchasers would prefer vehicles with better fuel efficiency *and* all of their preferred attributes—but rather consumers are forced to choose between fuel economy and other vehicle attributes while weighing how much each attribute contributes to the total cost of the vehicle.

Finally, the agencies have also previously speculated that vehicle producers may be reluctant to offer models featuring the higher levels of fuel economy that buyers are willing to pay for, and that buyers' apparent underinvestment in fuel economy reflects this lack of choice. The agencies have speculated that such behavior by manufacturers could arise from their collective underestimation of the value that buyers attach to fuel economy, or failing this, from limitations on competition among them to supply improved fuel economy, whether voluntarily or as a consequence of the industry's structure.[108] The agencies have also raised the seemingly contradictory argument that producers have more complete knowledge about fuel economy than potential buyers ("asymmetric information") causing them to provide *lower* levels than buyers demand, and speculated that deliberate decisions by manufacturers may limit the range of fuel economy they offer in particular market segments.[109]

The overarching theme of these arguments seems to be that vehicle manufacturers cannot identify—or can, but voluntarily forego—opportunities to increase sales and profits at the expense of their rivals by offering models that feature higher fuel economy. The agencies have sometimes ascribed this behavior to the risk that producers might incur large investments to produce the more fuel-efficient models that would enable them to seize these opportunities, but subsequently lose sales and profits to competitors who simply followed suit after their rivals were successful. This explanation is at odds with the customary view that innovative producers can be rewarded—substantially, even if only temporarily—with commensurate profits that justify taking such risks, when they correctly assess consumer demand for innovative features or products.

In any case, behavior on the part of individual businesses that leaves obvious opportunities to increase profits unexploited *by an entire industry* seems extremely implausible, particularly in light of the fact that auto manufacturers are profit-seeking businesses whose ownership shares are publicly traded and subject to regular market valuation. This notion also seems to ignore the range of choices already available in the current automobile market, where extraordinarily efficient models are available in nearly every vehicle class or market segment, including plug-in hybrid and fully electric versions of aa rapidly increasing number of models. Automobile manufacturers can, and in fact are, competing on the basis of fuel economy.

As mentioned above, the extent to which an increase in the stringency of Federal fuel economy standards may produce a net improvement in consumer welfare (net of any corresponding losses to those same consumers) depends upon the existence of a market failure related to incomplete or asymmetric information. The preceding discussion casts doubt on the theoretical case for such a market failure here and emphasizes the lack of evidentiary support for it. Even if the agencies were to accept for the sake of argument that an information asymmetry exists and that there were compelling evidence in support of it (and ignore the ample amount of evidence – including legally required disclosures – to the contrary), it is unlikely that the optimal policy to addressing the problem would be to increase the stringency of fuel economy standards.

Federal regulatory agencies frequently cite market failures arising from information asymmetry to justify regulation, but generally those market failures are more effectively addressed by fixing the informational problem itself, rather than by increasing the stringency of some design or performance standard that is intended to compensate for the problem. OMB Circular A-4 says "If intervention is contemplated to address a market failure that arises from inadequate or asymmetric information, informational remedies will often be preferred," such as, for example, the fuel economy label that Congress mandates in addition to the CAFE and CO_2

[108] *See* 75 FR at 25653-64 (May 7, 2010); *and* 77 FR at 63115 (Oct. 15, 2012).
[109] *See, e.g.* 75 FR 25510–13; 76 FR 57315–19; 77 FR 62914.

standards. Circular A-4 goes on to say that regulatory programs such as "standardized testing and rating systems, … mandatory disclosure requirements, and government provision of information" are potential remedies, but conspicuously fails to identify remedies for information asymmetries that involve increasing the stringency of standards.

The central analysis presented in this final regulatory impact analysis does not account for the possibility that imposing stricter standards may require manufacturers to make sacrifices in other vehicle features that compete with fuel economy, and that some buyers may value more highly. If this proved to be the case, more stringent alternatives could impose offsetting losses on buyers well beyond the increases in vehicle prices that are necessary for manufacturers to recover their outlays for adding new technology (or changing design features) to improve fuel economy. By doing so, it could significantly reduce the estimates of total and net benefits the agencies report. To further illustrate this issue, a sensitivity analysis that incorporates a conservative estimate of consumers' valuation of other vehicle attributes was conducted, as further discussed Section VI.D.1.b)(11).[110] It is also possible that buyers may have time preferences that cause them to discount the future at higher rates than the agencies are directed to consider in their regulatory evaluations.

If either case is true – that the analysis is incomplete regarding consumer valuation of other vehicle attributes or discount rates used in regulatory analysis inaccurately represent consumers' time preferences – no market failure would exist to support the hypothesis of a fuel efficiency gap. In either case, the agencies' central analysis would overstate both the net private and social benefits from adopting more stringent fuel economy and CO_2 emissions standards. For instance, in the Preamble, Table VII-97 shows that the CAFE final rule would generate $16.1 billion in total social net benefits using a 7 percent discount rate, but without the large net private loss of $26.1 billion, the net social benefits would equal the external net benefits, or $42.2 billion. Because government action cannot improve net social benefits in the absence of a market failure, if no market failure exists to motivate the $26.1 billion in private losses to consumers, the net benefits of these final standards would be $42.2 billion.

In sum, the agencies do not take a position in this rule on whether a fuel efficiency gap exists or constitutes a failure of private markets. Accordingly, the final regulatory impact analysis is not constrained in any manner that ensures the private net benefits of more stringent standards will necessarily be either positive or negative. In fact, however, the analysis supporting this final rule *does* present a situation where adopting more stringent CAFE and CO_2 emission standards aligns consumers' decisions with a simplified representation of *their own economic interests*, and by doing so improves their well-being from what they would experience under less stringent standards. In other words, the final modelling results reflect the case where

---

[110] This sensitivity analysis assumes that consumer's value of other vehicle attributes is *at least as great as a portion* of the fuel savings that consumers supposedly "leave on the table." In this analysis, the private net benefits of the final rule are a positive $15 billion using a 7 percent discount rate—which is consistent with the theory that providing consumers with greater choices will enhance their private welfare. The net external benefits are identical to the primary analysis, or $34 billion, so the sensitivity results show the final rule improves net social benefits by $49 billion.

some fuel efficiency gap persists (albeit of smaller magnitude than the agencies found in previous analyses), despite our expressed reservations about its likelihood.

Whether the market failures pertaining to the "energy paradox" suggested by commenters actually *exist* is not simply a *threshold* issue, raising the question of whether there is some rationale for the agencies to regulate fuel economy and CO_2 emissions. The market failure rationale also raises an important question of *magnitude*, which asks whether their extent or severity is sufficient to justify tightening standards beyond those that are currently in place. The critical distinction between these two aspects of the market failure rationale is that while the existence of a market failure might justify imposing regulations on fuel economy or emissions initially, it does not by itself necessarily justify *specific levels of* standards. The agencies agree with commenters that there are various externalities that CAFE and CO_2 standards can address, with energy security and climate change externalities paramount among these in their extent, magnitude, and economic importance.

The agencies also caution that adopting stricter CAFE and CO_2 standards may create or exacerbate other externalities, as for example when the resulting increase in driving due to the well-documented fuel economy rebound effect contributes to additional traffic congestion, increases crashes that cause injuries and property damage, and adds to traffic noise. Changes in still other externalities resulting from tighter standards, such as emissions of criteria pollutants and air toxics from vehicles themselves and from the processes of producing and distributing fuel, are more difficult to anticipate. Such impacts will vary in their direction and magnitude depending on the stringency of standards, and are also influenced by the magnitude of the fuel economy rebound effect. All of these effects are tracked and estimated carefully in the agencies' analysis, and are discussed extensively in Sections VI and VII of the Preamble as well as later in the FRIA. Section IIIof the Preamble explains how the agencies accounted for these effects in their decision to establish the final standards.

The FRIA shows that the external net benefits—those incremental reductions and increases in the harms associated with market failures upon which there is little disagreement or doubt—are higher for less stringent alternatives than the more stringent ones. When private benefits and costs are factored in—including those related to the much-debated and more-uncertain energy paradox—the variation in net benefits among alternatives narrows substantially. However, the agencies' stress that the FRIA is a supplement—not a replacement—to the agencies' analysis of their various statutory obligations and factors, which often balance against each other. As such, the FRIA is a tool to help organize information for decision-makers and does not by itself determine the option the that agencies ultimately select.

IV. Purpose of Analytical Approach Considered as Part of Decision-making

A. Relationship of Analytical Approach to Governing Law

Like the NPRM, today's final rule is supported by extensive analysis of potential impacts of the regulatory alternatives under consideration. Below, Section VI reviews the analytical approach, Section VII summarizes the results of the analysis, and Section VIII explains how the final standards—informed by this analysis—fulfill the agencies' statutory obligations. Accompanying today's notice, a final Regulatory Impact Analysis (FRIA) and, for NHTSA's consideration, a final Environmental Impact Analysis (FEIS), together provide a more extensive and detailed enumeration of related methods, estimates, assumptions, and results. The agencies' analysis has been constructed specifically to reflect various aspects of governing law applicable to CAFE and CO_2 standards, and has been expanded and improved in response to comments received to the NPRM and based on additional work by the agencies. The analysis aided the agencies in implementing their statutory obligations, including the weighing of competing considerations, by reasonably informing the agencies about the estimated effects of choosing different regulatory alternatives.

The agencies' analysis makes use of a range of data (i.e., observations of things that have occurred), estimates (i.e., things that may occur in the future), and models (i.e., methods for making estimates). Two examples of *data* include (1) records of actual odometer readings used to estimate annual mileage accumulation at different vehicle ages and (2) CAFE compliance data used as the foundation for the "analysis fleet" containing, among other things, production volumes and fuel economy levels of specific configurations of specific vehicle models produced for sale in the U.S. Two examples of *estimates* include (1) forecasts of future GDP growth used, with other estimates, to forecast future vehicle sales volumes and (2) the "retail price equivalent" (RPE) factor used to estimate the ultimate cost to consumers of a given fuel-saving technology, given accompanying estimates of the technology's "direct cost," as adjusted to account for estimated "cost learning effects" (i.e., the tendency that it will cost a manufacturer less to apply a technology as the manufacturer gains more experience doing so).

The agencies' analysis makes use of several models, some of which are actually integrated systems of multiple models. As discussed in the NPRM, the agencies' analysis of CAFE and CO_2 standards involves two basic elements: first, estimating ways each manufacturer could potentially respond to a given set of standards in a manner that considers potential consumer response; and second, estimating various impacts of those responses. Estimating manufacturers' potential responses involves simulating manufacturers' decision-making processes regarding the year-by-year application of fuel-saving technologies to specific vehicles. Estimating impacts involves calculating resultant changes in new vehicle costs, estimating a variety of costs (e.g., for fuel) and effects (e.g., CO_2 emissions from fuel combustion) occurring as vehicles are driven over their lifetimes before eventually being scrapped, and estimating the monetary value of these effects. Estimating impacts also involves consideration of the response of consumers—e.g., whether consumers will purchase the vehicles and in what quantities. Both of these basic analytical elements involve the application of many analytical inputs.

The agencies' analysis uses the CAFE Model to estimate manufacturers' potential responses to new CAFE and CO_2 standards and to estimate various impacts of those responses. The model may be characterized as an integrated system of models. For example, one model estimates manufacturers' responses, another estimates resultant changes in total vehicle sales, and still another estimates resultant changes in fleet turnover (i.e., scrappage). The CAFE model makes use of many inputs, values of which are developed *outside* of the model and not *by* the model. For example, the model applies fuel prices; it does not estimate fuel prices. The model does not determine the form or stringency of the standards; instead, the model applies inputs specifying the form and stringency of standards to be analyzed and produces outputs showing effects of manufacturers working to meet those standards, which become the basis for comparing between different potential stringencies.

The agencies also use EPA's MOVES model to estimate "tailpipe" (a.k.a. "vehicle" or "downstream") emission factors for criteria pollutants,[111] and use four DOE and DOE-sponsored models to develop inputs to the CAFE model, including three developed and maintained by DOE's Argonne National Laboratory. The agencies use the DOE Energy Information Administration's (EIA's) National Energy Modeling System (NEMS) to estimate fuel prices,[112] and use Argonne's Greenhouse gases, Regulated Emissions, and Energy use in Transportation (GREET) model to estimate emissions rates from fuel production and distribution processes.[113] DOT also sponsored DOE/Argonne to use Argonne's Autonomie full-vehicle modeling and simulation system to estimate the fuel economy impacts for roughly a million combinations of technologies and vehicle types.[114, 115] Section VI.B.3, below, details of the agencies' use of these models. In addition, as discussed in the final EIS accompanying today's notice, DOT relied on a range of climate and photochemical models to estimate impacts on climate, air quality, and public health. The EIS discusses and documents the use of these models.

As further explained in the NPRM,[116] to prepare for analysis supporting the proposal, DOT expanded the CAFE model to address EPA statutory and regulatory requirements through a year-by-year simulation of how manufacturers could comply with EPA's CO_2 standards, including:

- Calculation of vehicle models' CO_2 emission rates before and after application of fuel-saving (and, therefore, CO_2-reducing) technologies;
- Calculation of manufacturers' fleet average CO_2 emission rates;
- Calculation of manufacturers' fleet average CO_2 emission rates under attribute-based CO_2 standards;
- Accounting for adjustments to average CO_2 emission rates reflecting reduction of air conditioner refrigerant leakage;
- Accounting for the treatment of alternative fuel vehicles for CO_2 compliance;

[112] *See* https://www.eia.gov/outlooks/aeo/info_nems_archive.php. Today's final rule uses fuel prices estimated using the Annual Energy Outlook (AEO) 2019 version of NEMS (*see* https://www.eia.gov/outlooks/aeo/data/browser/#/?id=3-AEO2019&cases=ref2019&sourcekey=0).
[113] Information regarding GREET is available at https://greet.es.anl.gov/index.php. Today's notice uses the 2018 version of GREET.
[114] As part of the Argonne simulation effort, individual technology combinations simulated in Autonomie were paired with Argonne's BatPAC model to estimate the battery cost associated with each technology combination based on characteristics of the simulated vehicle and its level of electrification. Information regarding Argonne's BatPAC model is available at http://www.cse.anl.gov/batpac/.
[115] In addition, the impact of engine technologies on fuel consumption, torque, and other metrics was characterized using GT POWER simulation modeling in combination with other engine modeling that was conducted by IAV Automotive Engineering, Inc. (IAV). The engine characterization "maps" resulting from this analysis were used as inputs for the Autonomie full-vehicle simulation modeling. Information regarding GT Power is available at https://www.gtisoft.com/gt-suite-applications/propulsion-systems/gt-power-engine-simulation-software.
[116] 83 FR 42986, 43003 (Aug. 24, 2018).

- Accounting for production "multipliers" for PHEVs, BEVs, compressed natural gas (CNG) vehicles, and fuel cell vehicles (FCVs);
- Accounting for transfer of CO_2 credits between regulated fleets; and
- Accounting for carried-forward (a.k.a. "banked") CO_2 credits, including credits from model years earlier than modeled explicitly.

As further discussed in the NPRM, although EPA had previously developed a vehicle simulation tool ("ALPHA") and a fleet compliance model ("OMEGA"), and had applied these in prior actions, having considered the facts before the Agency in 2018, EPA determined that, "it is reasonable and appropriate to use DOE/Argonne's model for full-vehicle simulation, and to use DOT's CAFE model for analysis of regulatory alternatives."[117]

As discussed below and in Section VI.B.3, some commenters—some citing deliberative EPA staff communications during NPRM development, and one submitting comments by a former EPA staff member closely involved in the origination of the above-mentioned OMEGA model—took strong exception to EPA's decision to rely on DOE/Argonne and DOT-originated models as the basis for analysis informing EPA's decisions regarding CO_2 standards. Some commenters argued that the EPA Administrator must consider exclusively models and analysis originating with EPA staff, and that to do otherwise would be arbitrary and capricious. As explained below (and as explained in the NPRM), it is reasonable for the Administrator to consider analysis and information produced from many sources, including, in this instance, the DOE/Argonne and DOT models. The Administrator has the discretion to determine what information reasonably and appropriately informs decisions regarding emissions standards. Some commenters conflated models with decisions, suggesting that the former mechanically *determine* the latter. The CAA authorizes the EPA Administrator, not a model, to make decisions about emissions standards, just as EPCA provides similar authority to the Secretary. Models produce analysis, the results of which help to inform decisions. However, in making such decisions, the Administrator may and should consider other relevant information beyond the outputs of any models—including public comment—and, in all cases, must exercise judgment in establishing appropriate standards.

Some commenters conflated models with inputs and/or with results of the modeling. All of the models mentioned above rely on inputs, including not only data (i.e., facts), but also estimates (inputs about the future are estimates, not data). Given these inputs, the models produce estimates—ultimately, the agencies' reported estimates of the potential impacts of standards under consideration. In other words, inputs do not define models; models use inputs. Therefore, disagreements about inputs do not logically extend to disagreements about models. Similarly, while models determine resulting outputs, they do so based on inputs. Therefore, disagreements about results do not necessarily imply disagreements about models; they may merely reflect disagreements about inputs. With respect to the Administrator's decisions regarding models underlying today's analysis, comments regarding inputs, therefore, are more appropriately addressed separately, which is done so below in Section VI.

[117] 83 FR 42986, 43000 (Aug. 24, 2018).

The EPA Administrator's decision to continue relying on the DOE/Argonne Autonomie tool and DOT CAFE model rather than on the corresponding tools developed by EPA staff is informed by consideration of comments on results and on technical aspects of the models themselves. As discussed below, some commenters questioned specific aspects of the CAFE model's simulation of manufacturer's potential responses to CO_2 standards. Considering these comments, the CAFE model applied in the final rule's analysis includes some revisions and updates. For example, the "effective cost" metric used to select among available opportunities to apply fuel-saving technologies now uses a "cost per credit" metric rather than the metric used for the NPRM. Also, the model's representation of sales "multipliers" EPA has included for CNG vehicles, PHEVs, BEVs, and FCVs reflects current EPA regulations or, as an input-selectable option, an alternative approach under consideration. On the other hand, some commenters questioning the CAFE model's approach to some CO_2 program features appear to ignore the fact that prior analysis by EPA (using EPA's OMEGA) model likewise did not account for the same program features. For example, some stakeholders took issue with the CAFE model's approach to accounting for banked CO_2 credits and, in particular, credits banked prior to the model years accounted for explicitly in the analysis. In the course of updating the basis for analysis fleet from model year 2016 to model year 2017, the agencies have since updated corresponding inputs. However, even though the ability to carry forward credits impacts outcomes, EPA's OMEGA model used in previous rulemakings never attempted to account for credit banking and, indeed, lacking a year-by-year structure, *cannot* account for credit banking. Therefore, at least with respect to this important CO_2 program flexibility, the CAFE model provides a more complete and realistic basis for estimating actual impacts of new CO_2 standards.

For its part, NHTSA remains confident that the combination of the Autonomie and CAFE models remains the best available for CAFE rulemaking analysis, and notes, as discussed below, that even the environmental group coalition stated that the CAFE model is aligned with EPCA requirements.[118] In late 2001, after Congress discontinued an extended series of budget "riders" prohibiting work on CAFE standards, NHTSA and the DOT Volpe Center began development of a modeling system appropriate for CAFE rulemaking analysis, because other available models were not designed with this purpose in mind, and lacked capabilities important for CAFE rulemakings. For example, although NEMS had procedures to account for CAFE standards, those procedures did not provide the ability to account for specific manufacturers, as is especially relevant to the statutory requirement that NHTSA consider the economic practicability of any new CAFE standards. Also, as early as the first rulemaking making use of this early CAFE model, commenters stressed the importance of product redesign schedules, leading developers to introduce procedures to account for product cadence. In the 2003 notice regarding light truck standards for MYs 2005-2007, NHTSA stated that "we also changed the methodology to recognize that capital costs require employment of technologies for several years, rather than a single year…. In our view, this makes the Volpe analysis more consistent with the [manually implemented] Stage analysis and better reflects actual conditions in the automotive industry."[119] Since that time, NHTSA and the Volpe Center have significantly refined the CAFE model with

[118] Environmental group coalition, NHTSA-2018-0067-12000, Appendix A, at 24-25.
[119] 68 FR at 16885 (Apr. 7, 2003).

each of rulemaking. For example, for the 2006 rulemaking regarding standards for MYs 2008-2011 light trucks, NHTSA introduced the ability to account for attribute-based standards, account for the social cost of CO_2 emissions, estimate stringencies at which net benefits would be maximized, and perform probabilistic uncertainty analysis (i.e., Monte Carlo simulation).[120] For the 2009 rulemaking regarding standards for MY 2011 passenger cars and light trucks, we introduced the ability to account for attribute-based passenger car standards, and the ability to apply "synergy factors" to estimate how some technology pairings impact fuel consumption,[121] For the 2010 rulemaking regarding standards for MYs 2012-2016, we introduced procedures to account for FFV credits, and to account for product planning as a multiyear consideration.[122] For the 2012 rulemaking regarding standards for MYs 2017-2025, we introduced several new procedures, such as (1) accounting for electricity used to charge electric vehicles (EVs) and plug-in hybrid electric vehicles (PHEVs), (2) accounting for use of ethanol blends in flexible-fuel vehicles (FFVs), (3) accounting for costs (i.e., "stranded capital") related to early replacement of technologies, (4) accounting for previously-applied technology when determining the extent to which a manufacturer could expand use of the technology, (5) applying technology-specific estimates of changes in consumer value, (6) simulating the extent to which manufacturers might utilize EPCA's provisions regarding generation and use of CAFE credits, (7) applying estimates of fuel economy adjustments (and accompanying costs) reflecting increases in air conditioner efficiency, (8) reporting privately-valued benefits, (9) simulating the extent to which manufacturers might voluntarily apply technology beyond levels needed for compliance with CAFE standards, and (10) estimating changes in highway fatalities attributable to any applied reductions in vehicle mass.[123] Also for this 2012 rulemaking, we began making use of Autonomie to estimate fuel consumption impacts of different combinations of technologies, using these estimates to specify inputs to the CAFE model.[124] In 2016, providing analyses for both the draft TAR regarding light-duty CAFE standards and the final rule regarding fuel consumption standards for heavy-duty pickup trucks and vans, we greatly expanded the agency's use of Autonomie-based full vehicle simulations and introduced the ability to simulate compliance with attribute-based standards for heavy-duty pickups and vans.[125] And, as discussed in at length in the NPRM and below, for this rulemaking, we have, among other things, refined procedures to account for impacts on highway travel and safety, added procedures to simulate compliance with CO_2 standards, refined procedures to account for compliance credits, and added procedures to account for impacts on sales, scrappage, and employment. We have also significantly revised the model's graphical user interface (GUI) in order to make the model easier to operate and understand. Like any model, both Autonomie and the CAFE model benefit from ongoing refinement. However, NHTSA is confident that this combination of models produces a more realistic characterization of the potential impacts of new standards than would another combination of available models. Some stakeholders, while commenting on specific aspects of the inputs, models, and/or results, commended the agencies' exclusive reliance on the

DOE/Argonne Autonomie tool and DOT CAFE model. With respect to CO_2 standards, these stakeholders noted not only technical reasons to use these models rather than the EPA models, but also other reasons such as efficiency, transparency, and ease with which outside parties can exercise models and replicate the agencies' analysis. These comments are discussed below and in Section VI.

Nevertheless, some comments regarding the model's handling of CAFE and/or CO_2 standards, and some comments regarding the model's estimation of resultant impacts, led the agencies to make changes to specific aspects of the model. Comments on and changes to the inputs and model are discussed below and in Section VI; results are discussed in Section VII; and the meaning of results in the context of the applicable statutory requirements is discussed in Section VIII.

As explained, the analysis is designed to reflect a number of statutory and regulatory requirements applicable to CAFE and tailpipe CO_2 standard setting. EPCA contains a number of requirements governing the scope and nature of CAFE standard setting. Among these, some have been in place since EPCA was first signed into law in 1975, and some were added in 2007, when Congress passed EISA and amended EPCA. The CAA, as discussed elsewhere, provides EPA with very broad authority under Section 202(a), and does not contain EPCA/EISA's prescriptions. In the interest of harmonization, however, EPA has adopted some of the EPCA/EISA requirements into its tailpipe CO_2 regulations, and NHTSA, in turn, has created some additional flexibilities by regulation not expressly envisioned by EPCA/EISA in order to harmonize better with some of EPA's programmatic decisions. EPCA/EISA requirements regarding the technical characteristics of CAFE standards and the analysis thereof include, but are not limited to, the following, and the analysis reflects these requirements as summarized:

<u>Corporate Average Standards</u>: 49 U.S.C. 32902 requires standards that apply to the average fuel economy levels achieved by each corporation's fleets of vehicles produced for sale in the U.S.[126] CAA Section 202(a) does not preclude the EPA Administrator from expressing CO_2 standards as *de facto* fleet average requirements, and EPA has adopted a similar approach in the interest of harmonization. The CAFE Model, used by the agencies to conduct the bulk of today's analysis, calculates the CAFE and CO_2 levels of each manufacturer's fleets based on estimated production volumes and characteristics, including fuel economy levels, of distinct vehicle models that could be produced for sale in the U.S.

<u>Separate Standards for Passenger Cars and Light Trucks</u>: 49 U.S.C. 32902 requires the Secretary of Transportation to set CAFE standards separately for passenger cars and light trucks. CAA Section 202(a) does not preclude the EPA Administrator from specifying CO_2 standards separately for passenger cars and light trucks, and EPA has adopted a similar approach. The

[126] This differs from safety standards and traditional emissions standards, which apply separately to each vehicle. For example, every vehicle produced for sale in the U.S. must, on its own, meet all applicable federal motor vehicle safety standards (FMVSS), but no vehicle produced for sale must, on its own, federal fuel economy standards. Rather, each manufacturer is required to produce a mix of vehicles that, taken together, achieve an average fuel economy level no less than the applicable minimum level.

CAFE Model accounts separately for passenger cars and light trucks, including differentiated standards and compliance.

Attribute-Based Standards: 49 U.S.C. 32902 requires the Secretary of Transportation to define CAFE standards as mathematical functions expressed in terms of one or more vehicle attributes related to fuel economy. This means that for a given manufacturer's fleet of vehicles produced for sale in the U.S. in a given regulatory class and model year, the applicable minimum CAFE requirement (i.e., the numerical value of the requirement) is computed based on the applicable mathematical function, and the mix and attributes of vehicles in the manufacturer's fleet. In the 2012 final rule that first established CO_2 standards, EPA also adopted an attribute-based standard under its broad CAA Section 202(a) authority. The CAFE Model accounts for such functions and vehicle attributes explicitly.

Separately Defined Standards for Each Model Year: 49 U.S.C. 32902 requires the Secretary to set CAFE standards (separately for passenger cars and light trucks) at the maximum feasible levels in each model year. CAA Section 202(a) allows EPA to establish CO_2 standards separately for each model year, and EPA has chosen to do so for this final rule, similar to the approach taken in the previous light-duty vehicle CO_2 standard-setting rules. The CAFE Model represents each model year explicitly, and accounts for the production relationships between model years.[127]

Separate Compliance for Domestic and Imported Passenger Car Fleets: 49 U.S.C. 32904 requires the EPA Administrator to determine CAFE compliance separately for each manufacturers' fleets of domestic passenger cars and imported passenger cars, which manufacturers must consider as they decide how to improve the fuel economy of their passenger car fleets. CAA 202(a) does not preclude the EPA Administrator from determining compliance with CO_2 standards separately for a manufacturer's domestic and imported car fleets, but EPA did not include such a distinction in either the 2010 or 2012 final rules, and EPA did not propose or ask for comment on taking such an approach in the proposal. The CAFE Model is able to account explicitly for this requirement when simulating manufacturers' potential responses to CAFE standards, but combines any given manufacturer's domestic and imported cars into a single fleet when simulating that manufacturer's potential response to CO_2 standards.

Minimum CAFE Standards for Domestic Passenger Car Fleets: 49 U.S.C. 32902 requires that domestic passenger car fleets achieve CAFE levels no less than 92 percent of the industry-wide average level required under the applicable attribute-based CAFE standard, as projected by the Secretary at the time the standard is promulgated. CAA 202(a) does not preclude the EPA Administrator from correspondingly requiring that domestic passenger car fleets achieve CO_2 levels no greater than 108.7 percent (1/0.92 = 1.087) of the projected industry-wide average CO_2 requirement under the attribute-based standard, but the GHG program that EPA designed in the 2010 and 2012 final rules did not include such a distinction, and EPA did not propose or seek

[127] For example, a new engine first applied to given vehicle model/configuration in model year 2020 will most likely be "carried forward" to model year 2021 of that same vehicle model/configuration, in order to reflect the fact that manufacturers do not apply brand-new engines to a given vehicle model every single year.

comment on such an approach in the proposal. The CAFE Model is able to account explicitly for this requirement for CAFE standards, and sets this requirement aside for CO_2 standards.

Civil Penalties for Noncompliance: 49 U.S.C. 32912 prescribes a rate (in dollars per tenth of a mpg) at which the Secretary is to levy civil penalties if a manufacturer fails to comply with a CAFE standard for a given fleet in a given model year, after considering available credits. Some manufacturers have historically demonstrated a willingness to treat CAFE noncompliance as an "economic" choice, electing to pay civil penalties rather than achieving full numerical compliance across all fleets. The CAFE Model calculates civil penalties for CAFE shortfalls and provides means to estimate that a manufacturer might stop adding fuel-saving technologies once continuing to do so would be effectively more "expensive" (after accounting for fuel prices and buyers' willingness to pay for fuel economy) than paying civil penalties. In contrast, the CAA does not authorize the EPA Administrator to allow manufacturers to sell noncompliant fleets and instead only pay civil penalties; manufacturers who choose to pay civil penalties for CAFE compliance tend to employ EPA's more-extensive programmatic flexibilities to meet tailpipe CO_2 emissions standards. Thus, the CAFE Model does not allow civil penalty payment as an option for CO_2 standards.

Dual-Fueled and Dedicated Alternative Fuel Vehicles: For purposes of calculating CAFE levels used to determine compliance, 49 U.S.C. 32905 and 32906 specify methods for calculating the fuel economy levels of vehicles operating on alternative fuels to gasoline or diesel through MY 2020. After MY 2020, methods for calculating alternative fuel vehicle (AFV) fuel economy are governed by regulation. The CAFE Model is able to account for these requirements explicitly for each vehicle model. However, 49 U.S.C. 32902 requires that maximum feasible CAFE standards be set in a manner that does not presume manufacturers can respond by producing new dedicated alternative fuel vehicle (AFV) models. The CAFE model can be run in a manner that excludes the additional application of dedicated AFV technologies in model years for which maximum feasible standards are under consideration. As allowed under NEPA for analysis appearing in EISs informing decisions regarding CAFE standards, the CAFE Model can also be run without this analytical constraint. CAA 202(a) does not preclude the EPA Administrator adopting analogous provisions, but EPA has instead opted through regulation to "count" dual- and alternative fuel vehicles on a CO_2 basis (and through MY 2026, to set aside emissions from electricity generation). The CAFE model accounts for this treatment of dual- and alternative fuel vehicles when simulating manufacturers' potential responses to CO_2 standards. For natural gas vehicles, both dedicated and dual-fueled, EPA is establishing a multiplier of 2.0 for model years 2022-2026.

Creation and Use of Compliance Credits: 49 U.S.C. 32903 provides that manufacturers may earn CAFE "credits" by achieving a CAFE level beyond that required of a given fleet in a given model year, and specifies how these credits may be used to offset the amount by which a different fleet falls short of its corresponding requirement. These provisions allow credits to be "carried forward" and "carried back" between model years, transferred between regulated classes (domestic passenger cars, imported passenger cars, and light trucks), and traded between manufacturers. However, these provisions also impose some specific statutory limits. For example, CAFE compliance credits can be carried forward a maximum of five model years and carried back a maximum of three model years. Also, EPCA/EISA caps the amount of credit that can be transferred between passenger car and light truck fleets, and prohibits manufacturers from applying traded or transferred credits to offset a failure to achieve the applicable minimum standard for domestic passenger cars. The CAFE Model explicitly simulates manufacturers' potential use of credits carried forward from prior model years or transferred from other fleets.[128] 49 U.S.C. 32902 prohibits consideration of manufacturers' potential application of CAFE compliance credits when setting maximum feasible CAFE standards. The CAFE Model can be operated in a manner that excludes the application of CAFE credits after a given model year. CAA 202(a) does not preclude the EPA Administrator adopting analogous provisions. EPA has opted to limit the "life" of compliance credits from most model years to 5 years, and to limit borrowing to 3 years, but has not adopted any limits on transfers (between fleets) or trades (between manufacturers) of compliance credits. The CAFE Model is able to account for the absence of limits on transfers of CO_2 standards. Insofar as the CAFE model can be exercised in a manner that simulates trading of CO_2 compliance credits, such simulations treat trading as unlimited.[129] EPA has considered manufacturers' ability to use credits as part of its decisions on these final standards, and the CAFE model is now able to account for that.

Statutory Basis for Stringency: 49 U.S.C. 32902 requires the Secretary to set CAFE standards at the maximum feasible levels, considering technological feasibility, economic practicability, the need of the Nation to conserve energy, and the impact of other government standards. EPCA/EISA authorizes the Secretary to interpret these factors, and as the Department's interpretation has evolved, NHTSA has continued to expand and refine its qualitative and quantitative analysis. For example, as discussed below in Section VI.B.3, the Autonomie simulations reflect the agencies' judgment that it would not be economically practicable for a manufacturer to "split" an engine shared among many vehicle

---

[128] As explained in Section VI, the CAFE Model does not explicitly simulate the potential that manufacturers would carry CAFE or CO_2 credits back (i.e., borrow) from future model years, or acquire and use CAFE compliance credits from other manufacturers. At the same time, because EPA has elected to not limit credit trading, the CAFE Model can be exercised in a manner that simulates unlimited (a.k.a. "perfect") CO_2 compliance credit trading throughout the industry (or, potentially, within discrete trading "blocs"). The agencies believe there is significant uncertainty in how manufacturers may choose to employ these particular flexibilities in the future: for example, while it is reasonably foreseeable that a manufacturer who over-complies in one year may "coast" through several subsequent years relying on those credits rather than continuing to make technology improvements, it is harder to assume with confidence that manufacturers will rely on future technology investments (that may not pan out as expected, as if market demand for "target-beater" vehicles is lower than expected) to offset prior-year shortfalls, or whether/how manufacturers will trade credits with market competitors rather than making their own technology investments. Historically, carry-back and trading have been much less utilized than carry-forward, for a variety of reasons including higher risk and preference not to "pay competitors to make fuel economy improvements we should be making" (to paraphrase one manufacturer), although the agencies recognize that carry-back and trading are used more frequently when standards require more technology application than manufacturers believe their markets will bear. Given the uncertainty just discussed, and given also the fact that the agencies have yet to resolve some of analytical challenges associated with simulating use of these flexibilities, the agencies consider borrowing and trading to involve sufficient risk that it is prudent to support today's decisions with analysis that sets aside the potential that manufacturers could come to depend widely on borrowing and trading. While compliance costs in real life may be somewhat different from what is modeled today as a result of this analytical decision, that is broadly true no matter what, and the agencies do not believe that the difference would be so great that it would change the policy outcome.

[129] To avoid making judgments (that would invariably turn out to be at least somewhat incorrect) about possible future trading activity, the model simulates trading by combining all manufacturers into a single entity, so that the most cost-effective choices are made for the fleet as a whole.

model/configurations into a myriad of versions each optimized to a single vehicle model/configuration. Also responding to evolving interpretation of these EPCA/EISA factors, the CAFE Model has been expanded to address additional impacts in an integrated manner. For example, the CAFE Model version used for the NPRM analysis included the ability to estimate impacts on labor utilization internally, rather than as an external "off model" or "post processing" analysis. In addition, NEPA requires the Secretary to issue an EIS that documents the estimated impacts of regulatory alternatives under consideration. The EIS accompanying today's notice documents changes in emission inventories as estimated using the CAFE model, but also documents corresponding estimates—based on the application of other models documented in the EIS, of impacts on the global climate, on tropospheric air quality, and on human health. Regarding CO_2 standards, CAA 202(a) provides general authority for the establishment of motor vehicle emissions standards, and the final rule's analysis, like that accompanying the agencies' proposal, addresses impacts relevant to the EPA Administrator's decision making, such as technological feasibility, air quality impacts, costs to industry and consumers, and lead time necessary for compliance.

Other Factors: Beyond these statutory requirements applicable to DOT and/or EPA are a number of specific technical characteristics of CAFE and/or CO_2 regulations that are also relevant to the construction of today's analysis. These are discussed at greater length in Section II.F. For example, EPA has defined procedures for calculating average CO_2 levels, and has revised procedures for calculating CAFE levels, to reflect manufacturers' application of "off-cycle" technologies that increase fuel economy (and reduce CO_2 emissions) in ways not reflected by the long-standing test procedures used to measure fuel economy. Although too little information is available to account for these provisions explicitly in the same way that the agencies have accounted for other technologies, the CAFE Model does include and makes use of inputs reflecting the agencies' expectations regarding the extent to which manufacturers may earn such credits, along with estimates of corresponding costs. Similarly, the CAFE Model includes and makes use of inputs regarding credits EPA has elected to allow manufacturers to earn toward CO_2 levels (not CAFE) based on the use of air conditioner refrigerants with lower global warming potential (GWP), or on the application of technologies to reduce refrigerant leakage. In addition, EPA has elected to provide that through model year 2021, manufacturers may apply "multipliers" to plug-in hybrid electric vehicles, dedicated electric vehicles, fuel cell vehicles, and hydrogen vehicles, such that when calculating a fleet's average CO_2 levels (not CAFE), the manufacturer may, for example, "count" each electric vehicle twice. The CAFE Model accounts for these multipliers, based on either current regulatory provisions or on alternative approaches. Although these are examples of regulatory provisions that arise from the exercise of discretion rather than specific statutory mandate, they can materially impact outcomes. Section VI.B explains in greater detail how today's analysis addresses them.

B. Benefits of Analytical Approach

The agencies' analysis of CAFE and CO_2 standards involves two basic elements: first, estimating ways each manufacturer could potentially respond to a given set of standards in a manner that considers potential consumer response; and second, estimating various impacts of those responses. Estimating manufacturers' potential responses involves simulating manufacturers' decision-making processes regarding the year-by-year application of fuel-saving technologies to specific vehicles. Estimating impacts involves calculating resultant changes in new vehicle costs, estimating a variety of costs (e.g., for fuel) and effects (e.g., CO_2 emissions from fuel combustion) occurring as vehicles are driven over their lifetimes before eventually being scrapped, and estimating the monetary value of these effects. Estimating impacts also involves consideration of the response of consumers—e.g., whether consumers will purchase the vehicles and in what quantities. Both of these basic analytical elements involve the application of many analytical inputs.

As mentioned above, the agencies' analysis uses the CAFE model to estimate manufacturers' potential responses to new CAFE and CO_2 standards and to estimate various impacts of those responses. DOT's Volpe National Transportation Systems Center (often simply referred to as the "Volpe Center") develops, maintains, and applies the model for NHTSA. NHTSA has used the CAFE model to perform analyses supporting every CAFE rulemaking since 2001, and the 2016 rulemaking regarding heavy-duty pickup and van fuel consumption and CO_2 emissions also used the CAFE model for analysis.[130]

NHTSA recently arranged for a formal peer review of the model. In general, reviewers' comments strongly supported the model's conceptual basis and implementation, and commenters provided several specific recommendations. The agency agreed with many of these recommendations and has worked to implement them wherever practicable. Implementing some of the recommendations would require considerable further research, development, and testing, and will be considered going forward. For a handful of other recommendations, the agency disagreed, often finding the recommendations involved considerations (e.g., other policies, such as those involving fuel taxation) beyond the model itself or were based on concerns with inputs rather than how the model itself functioned. A report available in the docket for this rulemaking presents peer reviewers' detailed comments and recommendations, and provides DOT's detailed responses.[131]

As also mentioned above, the agencies use EPA's MOVES model to estimate tailpipe emission factors, use DOE/EIA's NEMS to estimate fuel prices,[132] and use Argonne's GREET model to estimate downstream emissions rates.[133] DOT also sponsored DOE/Argonne to use the

---

[130] While both agencies used the CAFE Model to simulate manufacturers' potential responses to standards, some model inputs differed EPA's and DOT's analyses, and EPA also used the EPA MOVES model to calculate resultant changes in emissions inventories. *See* 81 FR 73478, 73743 (Oct. 25, 2016).

Autonomie full-vehicle modeling and simulation tool to estimate the fuel economy impacts for roughly a million combinations of technologies and vehicle types.[134, 135]

EPA developed two models after 2009, referred to as the "ALPHA" and "OMEGA" models, which provide some of the same capabilities as the Autonomie and CAFE models. EPA applied the OMEGA model to conduct analysis of tailpipe CO_2 emissions standards promulgated in 2010 and 2012, and the ALPHA and OMEGA models to conduct analysis discussed in the above-mentioned 2016 Draft TAR and Proposed and 2017 Initial Final Determinations regarding standards beyond 2021. In an August 2017 notice, the agencies requested comments on, among other things, whether EPA should use alternative methodologies and modeling, including DOE/Argonne's Autonomie full-vehicle modeling and simulation tool and DOT's CAFE model.[136]

Having reviewed comments on the subject and having considered the matter fully, the agencies have determined it is reasonable and appropriate to use DOE/Argonne's model for full-vehicle simulation, and to use DOT's CAFE model for analysis of regulatory alternatives. EPA interprets Section 202(a) of the CAA as giving the agency broad discretion in how it develops and sets CO_2 emissions standards for light-duty vehicles. Nothing in Section 202(a) mandates that EPA use any specific model or set of models for analysis of potential CO_2 standards for light-duty vehicles. EPA weighs many factors when determining appropriate levels for CO_2 standards, including the cost of compliance (*see* Section 202(a)(2)), lead time necessary for compliance (*id.*), safety (*see NRDC v. EPA*, 655 F.2d 318, 336 n. 31 (D.C. Cir. 1981)) and other impacts on consumers,[137] and energy impacts associated with use of the technology.[138] Using the CAFE model allows consideration of a number of factors. The CAFE model explicitly evaluates the cost of compliance for each manufacturer, each fleet, and each model year; it accounts for lead time necessary for compliance by directly incorporating estimated manufacturer production cycles for every vehicle in the fleet, ensuring that the analysis does not assume vehicles can be redesigned to incorporate more technology without regard to lead time considerations; it provides information on safety effects associated with different levels of standards and information about many other impacts on consumers, and it calculates energy impacts (i.e., fuel

---

[134] As part of the Argonne simulation effort, individual technology combinations simulated in Autonomie were paired with Argonne's BatPAC model to estimate the battery cost associated with each technology combination based on characteristics of the simulated vehicle and its level of electrification. Information regarding Argonne's BatPAC model is available at http://www.cse.anl.gov/batpac/.

[135] Furthermore, the impact of engine technologies on fuel consumption, torque, and other metrics was characterized using GT POWER simulation modeling in combination with other engine modeling that was conducted by IAV Automotive Engineering, Inc. (IAV). The engine characterization "maps" resulting from this analysis were used as inputs for the Autonomie full-vehicle simulation modeling. Information regarding GT Power is available at https://www.gtisoft.com/gt-suite-applications/propulsion-systems/gt-power-engine-simulation-software.

[138] *See* George E. Warren Corp. v. EPA, 159 F.3d 616, 623-624 (D.C. Cir. 1998) (ordinarily permissible for EPA to consider factors not specifically enumerated in the Act).

saved or consumed) as a primary function, besides being capable of providing information about many other factors within EPA's broad CAA discretion to consider.

Because the CAFE model simulates a wide range of actual constraints and practices related to automotive engineering, planning, and production, such as common vehicle platforms, sharing of engines among different vehicle models, and timing of major vehicle redesigns, the analysis produced by the CAFE model provides a transparent and realistic basis to show pathways manufacturers could follow over time in applying new technologies, which helps better assess impacts of potential future standards. Furthermore, because the CAFE model also accounts fully for regulatory compliance provisions (now including CO_2 compliance provisions), such as adjustments for reduced refrigerant leakage, production "multipliers" for some specific types of vehicles (e.g., PHEVs), and carried-forward (i.e., banked) credits, the CAFE model provides a transparent and realistic basis to estimate how such technologies might be applied over time in response to CAFE or CO_2 standards.

There are sound reasons for the agencies to use the CAFE model going forward in this rulemaking. First, the CAFE and CO_2 fact analyses are inextricably linked. Furthermore, the analysis produced by the CAFE model and DOE/Argonne's Autonomie addresses the agencies' analytical needs. The CAFE model provides an explicit year-by-year simulation of manufacturers' application of technology to their products in response to a year-by-year progression of CAFE standards and accounts for sharing of technologies and the implications for timing, scope, and limits on the potential to optimize powertrains for fuel economy. In the real world, standards actually are specified on a year-by-year basis, not simply some single year well into the future, and manufacturers' year-by-year plans involve some vehicles "carrying forward" technology from prior model years and some other vehicles possibly applying "extra" technology in anticipation of standards in ensuing model years, and manufacturers' planning also involves applying credits carried forward between model years. Furthermore, manufacturers cannot optimize the powertrain for fuel economy on every vehicle model configuration—for example, a given engine shared among multiple vehicle models cannot practicably be split into different versions for each configuration of each model, each with a slightly different displacement. The CAFE model is designed to account for these real-world factors.

Considering the technological heterogeneity of manufacturers' current product offerings, and the wide range of ways in which the many fuel economy-improving/CO_2 emissions-reducing technologies included in the analysis can be combined, the CAFE model has been designed to use inputs that provide an estimate of the fuel economy achieved for many tens of thousands of different potential combinations of fuel-saving technologies. Across the range of technology classes encompassed by the analysis fleet, today's analysis involves more than a million such estimates. While the CAFE model requires no specific approach to developing these inputs, the National Academy of Sciences (NAS) has recommended, and stakeholders have commented, that full-vehicle simulation provides the best balance between realism and practicality. DOE/Argonne has spent several years developing, applying, and expanding means to use distributed computing to exercise its Autonomie full-vehicle modeling and simulation tool over the scale necessary for realistic analysis of CAFE or average tailpipe CO_2 emissions standards. This scalability and related flexibility (in terms of expanding the set of technologies to be simulated) makes Autonomie well-suited for developing inputs to the CAFE model.

In addition, DOE/Argonne's Autonomie also has a long history of development and widespread application by a much wider range of users in government, academia, and industry. Many of these users apply Autonomie to inform funding and design decisions. These real-world exercises have contributed significantly to aspects of Autonomie important to producing realistic estimates of fuel economy levels and CO_2 emission rates, such as estimation and consideration of performance, utility, and driveability metrics (e.g., towing capability, shift business, frequency of engine on/off transitions). This steadily increasing realism has, in turn, steadily increased confidence in the appropriateness of using Autonomie to make significant investment decisions. Notably, DOE uses Autonomie for analysis supporting budget priorities and plans for programs managed by its Vehicle Technologies Office (VTO). Considering the advantages of DOE/Argonne's Autonomie model, it is reasonable and appropriate to use Autonomie to estimate fuel economy levels and CO_2 emission rates for different combinations of technologies as applied to different types of vehicles.

Commenters have also suggested that the CAFE model's graphical user interface (GUI) facilitates others' ability to use the model quickly—and without specialized knowledge or training—and to comment accordingly.[139] For the NPRM, NHTSA significantly expanded and refined this GUI, providing the ability to observe the model's real-time progress much more closely as it simulates year-by-year compliance with either CAFE or CO_2 standards.[140] Although the model's ability to produce realistic results is independent of the model's GUI, the CAFE model's GUI appears to have facilitated stakeholders' meaningful review and comment during the comment period.

The question of whether EPA's actions should consider and be informed by analysis using non-EPA-staff-developed modeling tools has generated considerable debate over time. Even prior to the NPRM, certain commenters had argued that EPA could not consider, in setting tailpipe CO_2 emissions standards, any information derived from non-EPA-staff-developed modeling. Many of the pre-NPRM concerns focused on inputs used by the CAFE model for

---

[139] From Docket Number EPA–HQ–OAR–2015–0827, *see* Comment by Global Automakers, Docket ID EPA-HQ-OAR-2015-0827-9728, at 34.

[140] The updated GUI provides a range of graphs updated in real time as the model operates. These graphs can be used to monitor fuel economy or CO_2 ratings of vehicles in manufacturers' fleets and to monitor year-by-year CAFE (or average CO_2 ratings), costs, avoided fuel outlays, and avoided CO_2-related damages for specific manufacturers and/or specific fleets (e.g., domestic passenger car, light truck). Because these graphs update as the model progresses, they should greatly increase users' understanding of the model's approach to considerations such as multiyear planning, payment of civil penalties, and credit use.

prior rulemaking analyses.[141, 142, 143] Because inputs are exogenous to any model, they do not determine whether it would be reasonable and appropriate for EPA to use NHTSA's model for analysis. Other concerns focused on certain characteristics of the CAFE model that were developed to align the model better with EPCA and EISA. The model has been revised to accommodate both EPCA/EISA and CAA analysis, as explained further below. Some commenters also argued that use of any models other than ALPHA and OMEGA for CAA analysis would constitute an arbitrary and capricious delegation of EPA's decision-making authority to NHTSA, if NHTSA models are used for analysis instead.[144] As discussed above, the CAFE Model—as with any model—is used to provide analysis, and does not result in decisions. Decisions are made by EPA in a manner that is informed by modeling outputs, sensitivity cases, public comments, any many other pieces of information.

Comments responding to the NPRM's use of the CAFE model and Autonomie rather than also (for CO_2 standards) ALPHA and OMEGA were mixed. For example, the environmental group coalition stated that the CAFE model is aligned with EPCA requirements,[145] but also argued (1) that EPA is legally prohibited from "delegat[ing] technical decision-making to NHTSA;"[146] (2) that "EPA must exercise its technical and scientific expertise" to develop CO_2 standards and "Anything less is an unlawful abdication of EPA's statutory responsibilities;"[147] (3) that EPA staff is much more qualified than DOT staff to conduct analysis relating to standards and has done a great deal of work to inform development of standards;[148] (4) that "The Draft TAR and 2017 Final Determination relied extensively on use of sophisticated EPA analytic tools and methodologies," *i.e.*, the "peer reviewed simulation

---

[141] For example, EDF previously stated that "the data that NHTSA needs to input into its model is sensitive confidential business information that is not transparent and cannot be independently verified,…" and it claimed "the OMEGA model's focus on direct technological inputs and costs—as opposed to industry self-reported data—ensures the model more accurately characterizes the true feasibility and cost effectiveness of deploying greenhouse gas reducing technologies." EDF, EPA-HQ-OAR-2015-0827-9203, at 12. These statements are not correct, as nothing about either the CAFE or OMEGA model either obviates or necessitates the use of CBI to develop inputs.

[142] As another example, CARB previously stated that "another promising technology entering the market was not even included in the NHTSA compliance modeling" and that EPA assumes a five-year redesign cycle, whereas NHTSA assumes a six to seven-year cycle." CARB, EPA-HQ-OAR-2015-0827-9197, at 28. Though presented as criticisms of the models, these comments—at least with respect to the CAFE model—actually concern model inputs. NHTSA did not agree with CARB about the commercialization potential of the engine technology in question ("Atkinson 2") and applied model inputs accordingly. Also, rather than applying a one-size-fits-all assumption regarding redesign cadence, NHTSA developed estimates specific to each vehicle model and applied these as model inputs.

[143] As another example, NRDC has argued that EPA should not use the CAFE model because it "allows manufacturers to pay civil penalties in lieu of meeting the standards, an alternative compliance pathway currently allowed under EISA and EPCA." NRDC, EPA-HQ-OAR-2015-0827-9826, at 37. While the CAFE model can simulate civil penalty payment, NRDC's comment appears to overlook the fact that this result depends on model inputs; the inputs can easily be specified such that the CAFE model will set aside civil penalty payment as an alternative to compliance.

model ALPHA," "the agency's vehicle teardown studies," and the "peer-reviewed OMEGA model to make reasonable estimates of how manufacturers could add technologies to vehicles in order to meet a fleet-wide [CO_2 emissions] standard;"[149] (5) that NHTSA had said in the MYs 2012-2016 rulemaking that the Volpe [CAFE] model was developed to support CAFE rulemaking and incorporates features "that are not appropriate for use by EPA in setting [tailpipe CO_2] standards;"[150] (6) allegations that some EPA staff had disagreed with aspects of the NPRM analysis and had requested that "EPA's name and logo should be removed from the DOT-NHTSA Preliminary Regulatory Impact Analysis document" and stated that "EPA is relying upon the technical analysis performed by DOT-NHTSA for the [NPRM];"[151] (7) that EPA had developed "a range of relevant new analysis" that the proposal "failed to consider," including "over a dozen 2017 and 2018 EPA peer reviewed SAE articles;"[152] (8) that EPA's OMEGA modeling undertaken during NPRM development "found costs *half* that of NHTSA's findings," "Yet NHTSA did not correct the errors in its modeling and analysis, and the published proposal drastically overestimates the cost of complying….;"[153] (9) that some EPA staff had requested that the technology "HCR2" be included in the NPRM analysis, "Yet NHTSA overruled EPA and omitted the technology;"[154] (10) that certain EPA staff had initially "rejected use of the CAFE model for development of the proposed [tailpipe CO_2] standards;"[155] (11) that there are "many specific weaknesses of the modeling results derived in this proposal through use of the Volpe and Autonomie models" and that the CAFE model is "not designed in accordance with" Section 202(a) of the CAA because (A) EPA "is not required to demonstrate that standards are set at the maximum feasible level year-by-year," (B) because EPCA "preclude[s NHTSA] from considering vehicles powered by fuels other than gas or diesel" and EPA is not similarly bound, and (C) because the CAFE model assumed that the value of an overcompliance credit equaled $5.50, the value of a CAFE penalty.[156] Because of all of these things, the environmental group coalition stated that the proposal was "unlawful" and that "Before proceeding with this rulemaking, EPA must consider all relevant materials including these excluded insights, perform its own analysis, and issue a reproposal to allow for public comment."[157]

Some environmental organizations and States contracted for external technical analyses augmenting general comments such as those summarized above. EDF engaged a consultant, Richard Rykowski, for a detailed review of the agencies' analysis.[158] Among Mr. Rykowski's comments, a few specifically involve differences between these two models. Mr. Rykowski recommended NHTSA's CAFE model replace its existing "effective cost" metric (used to

compare available options to add specific technologies to specific vehicles) with a "ranking factor" used for the same purpose. As discussed below in Section VI.A, the model for today's final rule adopts this recommendation. He also states that (1) "EPA has developed a better way to isolate and reject cost ineffective combinations of technologies... [and] includes only these 50 or so technology combinations in their OMEGA model runs;" (2) "NHTSA's arbitrary and rigid designation of leader-follower vehicles for engine, transmission and platform level technologies unrealistically slows the rollout of technology into the new vehicle fleet;" (3) "the Volpe Model is not capable of reasonably simulating manufacturers' ability to utilize CO_2 credits to smooth the introduction of technology throughout their vehicle line-up;" and (4) "the Volpe Model is not designed to reflect the use of these [A/C leakage] technologies and refrigerants."[159]

Mr. Rogers's analysis focuses primarily on the agencies' published analysis, but mentions that some engine "maps" (estimates—used as inputs to full vehicle simulation—of engine fuel consumption under a wide range of engine operating conditions) applied in Autonomie show greater fuel consumption benefits of turbocharging than those applied previously by EPA to EPA's ALPHA model, and these benefits could have caused NHTSA's CAFE model to estimate an unrealistically great tendency toward turbocharged engines (rather than high compression ratio engines).[160] Mr. Rogers also presents alternative examples of year-by-year technology application to specific vehicle models, contrasting these with year-by-year results from the agencies' NPRM analysis, concluding that "that the use of logical, unrestricted technology pathways, with incremental benefits supported by industry-accepted vehicle simulation and dynamic system optimization and calibration, together with publicly-defensible costs, allows cost-effective solutions to achieve target fuel economy levels which meet MY 2025 existing standards."[161]

Mr. Duleep's analysis also focuses primarily on the agencies' published analysis, but does mention that (1) "the Autonomie modeling assumes no engine change when drag and rolling resistance reductions are implemented, as well as no changes to the transmission gear ratios and axle ratios,… [but] the EPA ALPHA model adjusts for this effect;" (2) "baseline differences in fuel economy [between two manufacturers' different products using similar technologies] are carried for all future years and this exaggerates the differences in technology adoption requirements and costs between manufacturers; (3) "assumptions [that most technology changes are best applied as part of a vehicle redesign or freshening] result in unnecessary distortion in technology paths and may bias results of costs for different manufacturers;" and (4) that for the sample results shown for the Chevrolet Equinox "the publicly available EPA lumped parameter model (which was used to support the 2016 rulemaking) and 2016 TAR cost data… results in an estimate of attaining 52.2 mpg for a cost of $2110, which is less than half the cost estimated in the PRIA."[162]

Beyond these comments regarding differences between EPA's models and the Argonne and DOT models applied for the NPRM, these and other technical reviewers had many specific

comments about the agencies' analysis for the NPRM, and these comments are discussed in detail below in Section VI.B.

Manufacturers, on the other hand, supported the agencies' use of Autonomie and the CAFE model rather than, in EPA's case, the ALPHA and OMEGA models. Expressly identifying the distinction between models and model inputs, Global Automakers stated that:

> The agencies provided a new, updated analysis based on the most up-to-date data, using a proven and long-developed modeling tool, known as the Volpe model, and offering numerous options to best determine the right regulatory and policy path for ongoing fuel efficiency improvements in our nation. Now, all stakeholders have an opportunity to come to the table as part of the public process to provide input, data, and information to help shape the final rule.[163]
>
> This NPRM's use of a single model to evaluate alternative scenarios for both programs provides consistency in the technical analysis, and Global Automakers supports the Volpe model's use as it has proven to be a transparent and user-friendly option in this current analysis. The use of the Volpe model has allowed for a broad range of stakeholders, with varying degrees of technical expertise, to review the data inputs to provide feedback on this proposed rule. The Volpe model's accompanying documentation has historically provided a clear explanation of all sources of input and constraints critical to a transparent modeling process. Other inputs have come from modeling that is used widely by other sources, specifically the Autonomie model, allowing for a robust validation, review and reassessment.[164]

The Alliance commented, similarly, that "at least at this time, NHTSA's modeling systems are superior to EPA's" and "as such, we support the Agencies' decision to use NHTSA's modeling tools for this rulemaking and recommend that both Agencies continue on this path. We encourage Agencies to work together to provide input to the single common set of tools."[165]

Regarding the agencies' use of Argonne's Autonomie model rather than EPA's ALPHA model, the Alliance commented that (1) "the benefits of virtually all technologies and their synergistic effects are now determined with full vehicle simulations;" (2) "vehicle categories have been increased to 10 to better recognize the range of 0–60 performance characteristics within each of the 5 previous categories, in recognition of the fact that many vehicles in the baseline fleet significantly exceeded the previously assumed 0–60 performance metrics. This provides better resolution of the baseline fleet and more accurate estimates of the benefits of technology….;" (3) "new technologies (like advanced cylinder deactivation) are included, while unproven combinations (like Atkinson engines with 14:1 compression, cooled EGR, and cylinder deactivation in combination) have been removed;" (4) "Consistent with the recommendation of the National Academy of Sciences and manufacturers, gradeability has been included as a performance metric used in engine sizing. This helps prevent the inclusion of small

[164] Global Automakers, NHTSA-2018-0067-12032, Attachment A, at A-12.
[165] Alliance, NHTSA-2018-0067-12073, at 134.

displacement engines that are not commercially viable and that would artificially inflate fuel savings;" (5) "the Alliance believes NHTSA's tools (Autonomie/Volpe) are superior to EPA's (APLHA[sic]/LPM/OMEGA). This is not surprising since NHTSA's tools have had a significant head start in development….;" (6) "the Autonomie model was developed at Argonne National Lab with funding from the Department of Energy going back to the PNGV (Partnership for Next Generation Vehicles) program in the 1990s. Autonomie was developed from the start to address the complex task of combining 2 power sources in a hybrid powertrain. It is a physics-based, forward looking, vehicle simulator, fully documented with available training," and (7) "EPA's ALPHA model is also a physics-based, forward looking, vehicle simulator. However, it has not been validated or used to simulate hybrid powertrains. The model has not been documented with any instructions making it difficult for users outside of EPA to run and interpret the model."[166]

Regarding the use of NHTSA's CAFE model rather than EPA's OMEGA model, the Alliance stated that (1) NHTSA's model appropriately differentiate between domestic and imported automobiles; (2) in NHTSA's model, "dynamic estimates of vehicle sales and scrappage in response to price changes replace unrealistic static sales and scrappage numbers;" (3) NHTSA's model "has new capability to perform [CO_2 emissions] analysis with [tailpipe CO_2] program flexibilities;" (4) "the baseline fleet [used in NHTSA's model] has been appropriately updated based on both public and manufacturer data to reflect the technologies already applied, particularly tire rolling resistance;" and (5) "some technologies have been appropriately restricted. For example, low rolling resistance tires are no longer allowed on performance vehicles, and aero improvements are limited to maximum levels of 15% for trucks and 10% for minivans."[167] The Alliance continued, noting that "NHTSA's Volpe model also predates EPA's OMEGA model. More importantly, the new Volpe model considers several factors that make its results more realistic."[168] As factors leading the Volpe model to produce results that are more realistic than those produced by OMEGA, the Alliance commented that (1) "The Volpe model includes estimates of the redesign and refresh schedules of vehicles based on historical trends, whereas the OMEGA model uses a fixed, and too short, time interval during which all vehicles are assumed to be fully redesigned….;" (2) "The Volpe model allows users to phase-in technology based on year of availability, platform technology sharing, phase-in caps, and to follow logical technology paths per vehicle….;" (3) "The Volpe model produces a year-by year analysis from the baseline model year through many years in the future, whereas the OMEGA model only analyzes a fixed time interval….;" (4) "The Volpe model recognizes that vehicles share platforms, engines, and transmissions, and that improvements to any one of them will likely extend to other vehicles that use them" whereas "The OMEGA model treats each vehicle as an independent entity….;" (5) "The Volpe model now includes sales and scrappage effects;" and (6) "The Volpe model is now capable of analyzing for CAFE and [tailpipe CO_2] compliance, each with unique program restrictions and flexibilities."[169] The Alliance also

[166] *Id.* at 135.
[167] *Id.* at 134.
[168] *Id.* at 135.
[169] *Id.* at 135-136.

incorporated by reference concerns it raised regarding EPA's OMEGA-based analysis supporting EPA's proposed and prior final determinations.[170]

The Alliance further stated that "For all of the above reasons and to avoid duplicate efforts, the Alliance recommends that the Agencies continue to use DOT's Volpe and Autonomie modeling system, rather than continuing to develop two separate systems. EPA has demonstrated through supporting Volpe model code revisions and by supplying engine maps for use in the Autonomie model that their expertise can be properly represented in the rulemaking process without having to develop separate or new tools."[171]

Some individual manufacturers provided comments supporting and elaborating on the above comments by Global Automakers and the Alliance. For example, FCA commented that "the modeling performed by the agencies should illuminate the differences between the CAFE and [tailpipe CO_2 emissions] programs. This cannot be accomplished when each agency is using different tools and assumptions. Since we believe NHTSA possesses the better set of tools, we support both agencies using Autonomie for vehicle modeling and Volpe (CAFE) for fleet modeling."[172]

Honda stated that "The current version of the CAFE model is reasonably accurate in terms of technology efficiency, cost, and overall compliance considerations, and reflects a notable improvement over previous agency modeling efforts conducted over the past few years. We found the CAFE model's characterization of Honda's "baseline" fleet—critical modeling minutiae that provide a technical foundation of the agencies' analysis—to be highly accurate. We commend NHTSA and Volpe Center staff on these updates, as well as on the overall transparency of the model. The model's graphical user interface (GUI) makes it easier to run, model functionality is thoroughly documented, and the use of logical, traceable input and output files accommodates easy tracking of results."[173] Similarly, in an earlier presentation to the agencies, Honda included the following slide comparing EPA's OMEGA model to DOT's CAFE (Volpe) model, and making recommendations regarding future improvements to the latter:

Modeling Comparison – 2017

Issue	EPA / OMEGA	NHTSA / Volpe
GUI	n/a	Helpful
Documentation	Difficult for users to understand *(or buried in obscure docket)*	Very Good
Technology Interactions	LPM – "Black Box" Difficult to understand	Detailed & Transparent
Efficiency	>10% too optimistic "significantly inaccurate"	Reasonably Accurate
Baseline Input Databases	Independent Analysis	Proactively confirmed inputs with each OEM
Suggested Improvements		• Grid Emissions (upstream) • Turn-off early compliance strategy • Increase speed of runs • Learning based on cumulative volumes • Optional Turn off 30 months compliance • Add Roll05 and Roll15 as tech options

Figure IV-1 – Honda comparison of EPA and NHTSA fleet models[174]

Toyota, in addition to arguing that the agencies' application of model inputs (e.g., an analysis fleet based on MY 2016 compliance data) produced more realistic results than in the draft TAR and in EPA's former proposed and final determinations, also stressed the importance of the CAFE model's year-by-year accounting for product redesigns, stating that this produces more realistic results than the OMEGA-based results shown previously by EPA:

> The modeling now better accounts for factors that limit the rate at which new technologies enter and then diffuse through a manufacturer's fleet. Bringing new or improved vehicles and technologies to market is a several-year, capital-intensive undertaking. Once new designs are introduced, a period of stability is required so investments can be amortized. Vehicle and technology introductions are staggered over time to manage limited resources. Agency modeling now better recognizes the inherent constraints imposed by realities that dictate product cadence. We agree with the agencies' understanding that "the simulation of compliance actions that manufacturers might take is constrained by the pace at which new technologies can be applied in the new vehicle market," and we are encouraged to learn that "agency modeling can now account for the fact that individual vehicle models undergo significant redesigns relatively infrequently." The preamble correctly notes that manufacturers try to keep costs down by applying most major changes mainly during vehicle redesigns and more modest changes during product refresh, and that redesign cycles for vehicle models can range from six to ten years, and eight to ten-years for powertrains. This appreciation for

[174] Honda, NHTSA-2018-0067-12019, at 12.

> standard business practice enables the modeling to more accurately capture the way vehicles share engines, transmissions, and platforms. There are now more realistic limits placed on the number of engines and transmissions in a powertrain portfolio which better recognizes manufacturers must manage limited engineering resources and control supplier, production, and service costs. Technology sharing and inheritance between vehicle models tends to limit the rate of improvement in a manufacturer's fleet.[175]

These comments urging EPA to use NHTSA's CAFE model echo comments provided in response to a 2018 peer review of the model. While identifying various opportunities for improvement, peer reviewers expressed strong overall support for the CAFE model's technical approach and execution. For example, one reviewer, after offering many specific technical recommendations, concluded as follows:

> The model is impressive in its detail, and in the completeness of the input data that it uses. Although the model is complex, the reader is given a clear account of how variables are variously divided and combined to yield appropriate granularity and efficiency within the model. The model tracks well a simplified version of the real-world and manufacturing/design decisions. The progression of technology choices and cost benefit choices is clear and logical. In a few cases, the model simply explains a constraint, or a value assigned to a variable, without defending the choice of the value or commenting on real-world variability, but these are not substantive omissions. The model will lend itself well to future adaptation or addition of variables, technologies and pathways.[176]

Although the peer review charge focused solely on the CAFE model, another peer reviewer separately recommended that EPA "consider opportunities for EPA to use the output from the Volpe Model in place of their OMEGA Model output"[177]

More recently, in response to the NPRM, Dr. Julian Morris, an economist at George Washington University, commented extensively on the superiority of the agencies' NPRM analysis to previous analyses, offering the following overall assessment:

> I have assessed the plausibility of the analyses undertaken by NHTSA and EPA in relation to the proposed SAFE rule. I found that the agencies have undertaken a thorough—one might even say exemplary—analysis, improving considerably on earlier analyses undertaken by the agencies of previous rules relating to CAFE standards and [tailpipe CO_2] emission standards. Of particular note, the agencies included more realistic estimates of the rebound effect, developed a sophisticated model of the

scrappage effect, and better accounted for various factors affecting vehicle fatality rates.[178]

The agencies carefully considered these and other comments regarding which models to apply when estimating potential impacts of each of the contemplated regulatory alternatives. For purposes of estimating the impacts of CAFE standards, even the coalition of environmental advocates observed that the CAFE model reflects EPCA's requirements. As discussed below in Section VI.A, EPCA imposes specific requirements not only on how CAFE standards are to be structured (e.g., including a minimum standard for domestic passenger cars), but also on how CAFE standards are to be evaluated (e.g., requiring that the potential to produce additional AFVs be set aside for the model years under consideration), and the CAFE model reflects these requirements, and the agencies consider the CAFE model to be the best available tool for CAFE rulemaking analysis. Regarding the use of Autonomie to construct fuel consumption (i.e., efficiency) inputs to the CAFE model, the agencies recognize that other vehicle simulation tools are available, including EPA's recently-developed ALPHA model. However, as also discussed in Section VI.B.3, Autonomie has a much longer history of development and refinement, and has been much more widely applied and validated. Moreover, Argonne experts have worked carefully for several years to develop methods for running large arrays of simulations expressly structured and calibrated for use in DOT's CAFE model. Therefore, the agencies consider Autonomie to be the best available tool for constructing such inputs to the CAFE model. While the agencies have also carefully considered potential specific model refinements, as well as the merits of potential changes to model inputs and assumptions, none of these potential refinements and input have led either agency to reconsider using the CAFE model and Autonomie for CAFE rulemaking analysis.

With respect to estimating the impacts of CO_2 standards, even though Argonne and the agencies have adapted Autonomie and the CAFE model to support the analysis of CO_2 standards, environmental groups, California, and other States would prefer that EPA use the models it developed during 2009-2018 for that purpose.[179] Arguments that EPA revert to its ALPHA and OMEGA models fall within three general categories: (1) arguments that EPA's models would have selected what commenters consider better (i.e., generally more stringent) standards, (2) arguments that EPA's models are technically superior, and (3) arguments that the law requires EPA use its own models.

The first of these arguments—that EPA's models would have selected better standards—conflates the analytical tool used to inform decision-making with the action of making the decision. As explained elsewhere in this document and as made repeatedly clear over the past several rulemakings, the CAFE model (or, for that matter, any model) neither sets standards nor dictates where and how to set standards; it simply informs as to the potential effects of setting

---

[178] Morris, J., OAR-2018-0283-4028, at 6-11.
[179] The last-finalized versions of EPA's OMEGA model and ALPHA tools were published in 2016 and 2017, respectively.

different levels of standards. In this rulemaking, EPA has made its own decisions regarding what CO_2 standards would be appropriate under the CAA.

The third of these arguments—that EPA is legally required to use only models developed by its own staff—is also without merit. The CAA does not require the agency to create or use a specific model of its own creation in setting tailpipe CO_2 standards. The fact that EPA's decision may be informed by non-EPA-created models does not, in any way, constitute a delegation of its statutory power to set standards or decision-making authority.[180] Arguing to the contrary would suggest, for example, that EPA's decision would be invalid because it relied on EIA's Annual Energy Outlook for fuel prices for all of its regulatory actions rather than developing its own model for estimating future trends in fuel prices. Yet, all Federal agencies that have occasion to use forecasts of future fuel prices regularly (and appropriately) defer to EIA's expertise in this area and rely on EIA's NEMS-based analysis in the AEO, even when those same agencies are using EIA's forecasts to inform their own decision-making. Similarly, this argument would mean that the agencies could not rely on work done by contractors or other outside consultants, which is contrary to regular agency practice across the entirety of the Federal Government.

The specific claim here that use of the CAFE model instead of ALPHA and OMEGA is somehow illegitimate is similarly unpersuasive. The CAFE and CO_2 rules have, since *Massachusetts v. EPA*, all been issued as joint rulemakings, and, thus are the result of a collaboration between the two agencies. This was true when the rulemakings used separate models for the different programs and continues to be true in today's final rule, where the agencies take the next step in their collaborative approach by now using simply one model to simulate both programs. In 2007, immediately following this Supreme Court decision, the agencies worked together toward standards for model years 2011-2015, and EPA made use of the CAFE model for its work toward possible future CO_2 standards. That the agencies would need to continue the unnecessary and inefficient process of using two separate combinations of models as the joint National Program continues to mature, therefore, runs against the idea that the agencies, over time, would best combine resources to create an efficient and robust regulatory program. For the reasons discussed throughout today's final rule, the agencies have jointly determined that Autonomie and the CAFE model have significant technical advantages, including important additional features, and are therefore the more appropriate models to use to support both analyses.

[180] "[A] federal agency may turn to an outside entity for advice and policy recommendations, provided the agency makes the final decisions itself." U.S. Telecom. Ass'n v. FCC, 359 F.3d 554, 565-66 (D.C. Cir. 2004). To the extent commenters meant to suggest outside parties have a reliance interest in EPA using ALPHA and OMEGA to set standards, EPA and NHTSA do not agree a reliance interest is properly placed on an analytical methodology, which consistently evolves from rule to rule. Even if it were, all parties that closely examined ALPHA and OMEGA-based analyses in the past either also simultaneously closely examined CAFE and Autonomie-based analyses in the past, or were fully capable of doing so, and thus, should face no additional difficulty now they have only one set of models and inputs/outputs to examine.

Further, the fact that Autonomie and CAFE models were initially developed by DOE/Argonne and NHTSA does not mean that EPA has no role in either these models or their inputs. That is, the development process for CAFE and CO_2 standards inherently requires technical and policy examinations and deliberations between staff experts and decision-makers in both agencies. Such engagements are a healthy and important part of any rulemaking activity—and particularly so with joint rulemakings. The Supreme Court stated in *Massachusetts v. EPA* that, "The two obligations [to set CAFE standards under EPCA and to set tailpipe CO_2 emissions standards under the CAA] may overlap, but there is no reason to think the two agencies cannot both administer their obligations and yet avoid inconsistency."[181] When agency experts consider analytical issues and agency decision-makers decide on policy, which is informed (albeit not dictated) by the outcome of that work, they are working together as the Court appears to have intended in 2007, even if legislators' intentions have varied in the decades since EPCA and the CAA have been in place.[182] Regulatory overlap necessarily involves deliberation, which can lead to a more balanced, reasonable, and improved analyses, and better regulatory outcomes. It did here. The existence of deliberation is not *per se* evidence of unreasonableness, even if some commenters believe a different or preferred policy outcome would or should have resulted.[183]

Over the 44 years since EPCA established the requirement for CAFE standards, NHTSA, EPA and DOE career staff have discussed, collaborated on, and debated engineering, economic, and other aspects of CAFE regulation, through focused meetings and projects, informal exchanges, publications, conferences and workshops, and rulemakings.

Part of this expanded exchange has involved full vehicle simulation. While tools such as PSAT (the DOE-sponsored simulation tool that predated Autonomie) were in use prior to 2007, including for discrete engineering studies supporting inputs to CAFE rulemaking analyses, these tools' information and computing requirements were such that NHTSA had determined (and DOE and EPA had concurred) that it was impractical to more fully integrate full vehicle simulation into rulemaking analyses. Since that time, computing capabilities have advanced dramatically, and the agencies now agree that such integration of full vehicle simulation—such as the large-scale exercise of Autonomie to produce inputs to the CAFE Model—can make for more robust CAFE and CO_2 rulemaking analysis. This is not to say, though, that experts always agree on all methods and inputs involved with full vehicle simulation. Differences in approach

---

181 Massachusetts v. EPA, 549 U.S. 497, 532 (2007).

182 For example, when wide-ranging amendments to the CAA were being debated, S. 1630 contained provisions that, if enacted, would have authorized automotive CO_2 emissions standards and prescribed specific average levels to be achieved by 1996 and 2000. In a letter to Senators, then-Administrator William K. Reilly noted that the Bill *"requires for the first time control of emissions of carbon dioxide; this is essentially a requirement to improve fuel efficiency"* and outlined four reasons the H.W. Bush Administration opposed the requirement, including that *"it is inappropriate to add this very complex issue to the Clean Air Act which is already full of complicated and controversial issues."* Reilly, W., Letter to U.S. Senators (January 26, 1990). The CAA amendments ultimately signed into law did not contain these or any other provisions regarding regulation of CO_2 emissions.

183 *See, e.g.*, U.S. House of Representatives, Committee on Oversight and Government Reform, Staff Report, 112th Congress, "A Dismissal of Safety, Choice, and Cost: The Obama Administration's New Auto Regulations," August 10, 2012, at 19-21 and 33-34.

and inputs lead to differences in results. For example, compared to other publicly available tools that can be practicably exercised at the scale relevant to fleetwide analysis needed for CAFE and CO_2 rulemaking analysis, DOE/Argonne's Autonomie model is more advanced, spans a wider range of fuel-saving technologies, and represents them in more specific detail, leaving fewer "gaps" to be filled with other models (risking inconsistencies and accompanying errors). These differences discussed in greater detail below in Section VI.B.3. Perhaps most importantly, the CAFE model considers fuel prices in determining both which technologies are applied and the total amount of technology applied, in the case where market forces demand fuel economy levels in excess of the standards. While OMEGA can apply technology in consideration of fuel prices, OMEGA will apply technology to reach the same level of fuel economy (or CO_2 emissions) if fuel prices are 3, 5, or 20 dollars, which violates the SAB's requirement that the analysis "account for […] future fuel prices."[184] Furthermore, it produces a counterintuitive result. If fuel prices become exorbitantly high, we would expect consumers to place an emphasis on additional fuel efficiency as the potential for extra fuel savings is tremendous.

Moreover, DOE has for many years used Autonomie (and its precursor model, PSAT) to produce analysis supporting fuel economy-related research and development programs involving billions of dollars of public investment, and NHTSA's CAFE model with inputs from DOE/Argonne's Autonomie model has produced analysis supporting rulemaking under the CAA. In 2015, EPA proposed new tailpipe CO_2 standards for MY 2021-2027 heavy-duty pickups and vans, finalizing those standards in 2016. Supporting the NPRM and final rule, EPA relied on analysis implemented by NHTSA using NHTSA's CAFE model, and NHTSA used inputs developed by DOE/Argonne using DOE/Argonne's Autonomie model. CBD questioned this history, asserting that, "EPA conducted a separate analysis using a different iteration of the CAFE model rather than rely on the version which NHTSA used, again resulting and parallel but corroborative modeling results."[185] CBD's comment mischaracterizes EPA's actual use of the CAFE Model. As explained in the final rule, EPA's "Method B" analysis was developed as follows:

> In Method B, the CAFE model from the NPRM was used to project a pathway the industry could use to comply with each regulatory alternative, along with resultant impacts on per-vehicle costs. However, the MOVES model was used to calculate corresponding changes in total fuel consumption and annual emissions for pickups and vans in Method B. Additional calculations were performed to determine corresponding monetized program costs and benefits.[186]

In other words, a version of NHTSA's CAFE Model was used to perform the challenging part of the analysis—that is, the part that involves accounting for manufacturers' fleets, accounting for available fuel-saving technologies, accounting for standards under consideration,

---

[184] *See* SAB Report at 10 ("Constructing each of the scenarios is challenging and involve extensive scientific, engineering, and economic uncertainties. Projecting the baseline requires the agencies to account for a wide range of variables including: the number of new vehicles sold, future fuel prices,… .").
[185] CBD, *et al.*, 2018-0067-12000, Appendix A, at 27.
[186] 81 FR 73478, 73506-07 (October 25, 2016).

and estimating manufacturers' potential responses to new standards—EPA's MOVES model was used to perform "downstream" calculations of fuel consumption and tailpipe emissions, and used spreadsheets to calculate even more straightforward calculations of program costs and benefits. While some stakeholders perceive these differences as evidencing a meaningfully independent approach, in fact, the EPA staff's analysis was, at its core, wholly dependent on NHTSA's CAFE Model, and on that model's use of Autonomie simulations.

Given the above, the only remaining argument for EPA to revert to its previously-developed models rather than relying on Autonomie and the CAFE model would be that the former are so technically superior to the latter that even model refinements and input changes cannot lead Autonomie and the CAFE model to produce appropriate and reasonable results for CO_2 rulemaking analysis. As discussed below, having considered a wide range of technical differences, the agencies find that the Autonomie and CAFE models currently provide the best analytical combination for CAFE and tailpipe CO_2 emissions rulemaking analysis. As discussed below in Section VI.B.3, Autonomie not only has a longer and wider history of development and application, but also DOE/Argonne's interaction with automakers, supplier and academies on continuous bases had made individual sub-models and assumptions more robust. Argonne has also been using research from DOE's Vehicle Technology Office (VTO) at the same time to make continuous improvements in Autonomie.[187] Also, while Autonomie uses engine maps as inputs, and EPA developed engine maps that could have been used for today's analysis, EPA declined to do so, and those engine maps were only used in a limited capacity for reasons discussed below in Section VI.C.1.

As also discussed below in Section VI.A.4, the CAFE model accounts for some important CO_2 provisions that EPA's OMEGA model cannot account for. For example, the CAFE model estimates the potential that any given manufacturer might apply CO_2 compliance credits it has carried forward from some prior model year. While one commenter, Mr. Rykowski, takes issue with how the CAFE model handles credit banking, he does not acknowledge that EPA's OMEGA model, lacking a year-by-year representation of compliance, is altogether incapable of accounting for the earning and use of banked compliance credits. Also, although Mr. Rykowski's comments regarding A/C leakage and refrigerants are partially correct insofar as the CAFE model does not account for leakage-reducing technologies explicitly, the comment is as applicable to OMEGA as it is to the CAFE model and, in any event, data regarding which vehicles have which leakage-reducing technologies was not available for the MY 2016 fleet. Nevertheless, as discussed in Section VI.A.4, NHTSA has refined the CAFE model's accounting for the cost of leakage reduction technologies.

The agencies have also considered Mr. Rykowski's comments suggesting that using OMEGA would be preferable because, rather than selecting from hundreds of thousands of potential combinations of technologies, OMEGA includes only the "50 or so" combinations that EPA has already determined to be cost-effective. The "better way" of making this determination is also effectively a model, but the separation of this model from OMEGA is, as evidenced by

---

[187] U.S. DOE Benefits & Scenario Analysis publications is available at https://www.autonomie.net/publications/fuel_economy_report.html. Last accessed November 14, 2019.

manufacturers' comments, obfuscatory, especially in terms of revealing how specific vehicle model/configurations initial engineering properties are aligned with specific initial technology combinations. By using a full set of technology combinations, the CAFE model makes very clear how each vehicle model/configuration is assigned to a specific initial combination and, hence, how subsequently fuel consumption and cost changes are accounted for. Moreover, EPA's separation of "thinning" process from OMEGA's main compliance simulation makes sensitivity analysis difficult to implement, much less follow. The agencies find, therefore, that the CAFE model's approach of retaining a full set of vehicle simulation results throughout the compliance simulation to be more realistic (e.g., more capable of reflecting manufacturer- and vehicle-specific factors), more responsive to changes in model inputs (e.g., changes to fuel prices, which could impact the relative attractiveness of different technologies), more transparent, and more amenable to independent corroboration the agencies' analysis.

Regarding comments by Messrs. Duleep, Rogers, and Rykowski suggesting that the CAFE model, by tying most technology application to planned vehicle redesigns and freshening, is too restrictive, the agencies disagree. As illustrated by manufacturers' comments cited above, as reinforced by both extensive product planning information provided to the agencies, and as further reinforced by extensive publicly available information, manufacturers tend to not make major changes to a specific vehicle model/configuration in one model year, and then make further major changes to the same vehicle model/configuration the next model year. There is ample evidence that manufacturers strive to avoid such discontinuity, complexity, and waste, and in the agencies' view, while it is impossible to represent every manufacturer's decision-making process precisely and with certainty, the CAFE model's approach of using estimated product design schedules provides a realistic basis for estimating what manufacturers could practicably do. Also, the relevant inputs are simply inputs to the CAFE model, and if it is actually more realistic to assume that a manufacturer can change major technology on all of its products every year, the CAFE model can easily be operated with every model year designated as a redesign year for every product, but as discussed throughout this document, the agencies consider this to be extremely unrealistic. While this means the CAFE model can be run without a year-by-year representation that carries forward technologies between model years, doing so would be patently unrealistic (as reflected in some stakeholders' comments in 2002 on the first version of the CAFE model). Conversely, the OMEGA model cannot be operated in a way that accounts for what the agencies consider to be very real product planning considerations.

However, having also considered Mr. Rykowski's comments about the CAFE model's "effective cost" metric, and having conducted side-by-side testing documented in this FRIA, the agencies are satisfied that an alternative "cost per credit" metric is also a reasonable metric to use for estimating how manufacturers might selected among available options to add specific fuel-saving technologies to specific vehicles.[188] Therefore, NHTSA has revised the CAFE model accordingly, as discussed below in Section VI.A.4.

---

[188] As discussed in the FRIA, results vary with model inputs, among manufacturers, and across model years, but compared to the NPRM's "effective cost" metric, the "cost per credit" metric appears to more frequently produce less expensive solutions than more expensive solutions, at least when simulating compliance with CO_2 standards.

Section VI.C.1 also addresses Mr. Rogers's comments on engine maps used as estimates to full vehicle simulation. In any event, because engine maps are inputs to full vehicle modeling and simulation, the relative merits of specific maps provide no basis to prefer one vehicle simulation modeling system over another. Similarly, Section VI.B.3 also addresses Mr. Duleep's comments preferring EPA's prior approach, using ALPHA, of effectively assuming that a manufacturer would incur no additional cost by reoptimizing every powertrain to extract the full fuel economy potential of even the smallest incremental changes to aerodynamic drag and tire rolling resistance. Mr. Duleep implies that Autonomie is flawed because the NPRM analysis did not apply Autonomie in a way that makes such assumptions. The agencies discuss powertrain sizing and calibration in Section VI.B.3, and note here that such assumptions are not inherent to Autonomie; like engine maps, these are inputs to full vehicle simulation. Therefore, neither of these comments by Mr. Rogers and Mr. Duleep lead the agencies to find reason not to use Autonomie.

None of this is to say that Autonomie and the CAFE model as developed and applied for the NPRM left no room for improvement. In the NPRM and RIA, the agencies discussed plans to continue work in a range of specific technical areas, and invited comment on all aspects of the analysis. As discussed below in Chapter VI, the agencies received extensive comment on the published model, inputs, and analysis, both in response to the NPRM and, for newly-introduced modeling capabilities (estimation of sales, scrappage, and employment effects), in response to additional peer review conducted in 2019. The agencies have carefully considered these comments, refined various specific technical aspects of the CAFE model (like the "effective cost" metric mentioned above), and have also updated inputs to both Autonomie and the CAFE model. Especially given these refinements and updates, as discussed throughout this rule, EPA maintains that for CO_2 rulemaking analysis, Autonomie and the CAFE model have advantages that warrant relying on them rather than on EPA's ALPHA and OMEGA models. Some examples of such advantages include: a longer history of ongong development and application for rulemaking, including by EPA; documentation and model operation stakeholders have found to be comparatively clear and enabling of independent replication of agency analyses; a mechanism to explicitly reflect the fact that manufacturers' product decisions are likely to be informed by fuel prices; better integration of various model functions, enabling efficient sensitivity analysis; and an annual time step that makes it possible to conduct report results on both a calendar year and model year basis, to estimate accruing impacts on vehicle sales and scrappage, and to account for the fact that not every vehicle can be designed in every model year; and other advantages discussed throughout today's notice. Therefore, recognizing that models inform but do not make regulatory decisions, EPA has elected to rely solely on the Autonomie and CAFE models to produce today's analysis of regulatory alternatives for CO_2 standards.

The following sections provide a brief technical overview of the CAFE model, including changes NHTSA made to the model since 2012, and differences between the current analysis, the

---

Differences are more mixed when simulating compliance with CAFE standards, and even when simulating compliance with CO2 standards, results simulating "perfect" trading of CO_2 compliance credits are less intuitive when the "cost per credit metric." Nevertheless, and while less expensive solutions are not necessarily "optimal" solutions (e.g., if gasoline costs $7 per gallon and electricity is free, expensive electrification could be optimal), the agencies consider it reasonable to apply the "cost per credit" metric for the analysis supporting today's rulemaking.

analysis for the 2016 Draft TAR and for the 2017 Proposed Determination/2018 Final Determination, and the 2018 NPRM, before discussing inputs to the model and then diving more deeply into how the model works. For more information on the latter topic, see the CAFE model documentation, available in the docket for this rulemaking and on NHTSA's website.

1. What Assumptions Have Changed Since the 2012 Final Rule?

Any analysis of regulatory actions that will be implemented several years in the future, and whose benefits and costs accrue over decades, requires a large number of assumptions. Over such time horizons, many, if not most, of the relevant assumptions in such an analysis are inevitably uncertain.[189] The 2012 CAFE/CO_2 rule considered regulatory alternatives for model years through MY 2025 (17 model years after the 2008 market information that formed the basis of the analysis) that accrued costs and benefits into the 2060s. Not only was the new vehicle market in 2025 unlikely to resemble the market in 2008, but so, too, were fuel prices. It is natural, then, that each successive CAFE/CO_2 analysis should update assumptions to reflect better the current state of the world and the best current estimates of future conditions.[190] However, beyond the issue of unreliable projections about the future, a number of agency assertions have proven similarly problematic. In fact, Securing America's Future Energy (SAFE) stated in their comments on the NPRM:

> Although the agencies argue "circumstances have changed" and "analytical methods and inputs have been updated," a thorough analysis should provide a side-by-side comparison of the changing circumstances, methods, and inputs used to arrive at this determination… They represent a rapid, dramatic departure from the agencies' previous analyses, without time for careful review and consideration.[191]

We describe in detail (below) the changes to critical assumptions, perspectives, and modeling techniques that have created substantive differences between the current analysis and the analysis conducted in 2012 to support the final rule. To the greatest extent possible, we have calculated the impacts of these changes on the 2012 analysis.

a) The Value of Fuel Savings

The value of fuel savings associated with the preferred alternative in the 2012 final rule is primarily a consequence of two assumptions[192]: the fuel price forecast and the assumed growth in fuel economy in the baseline alternative against which savings are measured. Therefore, as the

---

[189] As often stated, "It's difficult to make predictions, especially about the future." *See, e.g.*, https://quoteinvestigator.com/2013/10/20/no-predict/.

[190] *See, e.g.*, 77 FR 62785 (Oct. 15, 2012) ("If EPA initiates a rulemaking [to revise standards for MYs 2022-2025], it will be a joint rulemaking with NHTSA. …NHTSA's development of its proposal in that later rulemaking will include the making of economic and technology analyses and estimates that are appropriate for those model years and based on then-current information.").

[191] Securing America's Energy Future, NHTSA-2018-0067-12172, at 39.

[192] The value of fuel savings is also affected by the rebound effect assumption, assumed lifetime VMT accumulation, and the simulated penetration of alternative fuel technologies. However, each of these ancillary factors is small compared to the impact of the two factors discussed in this subsection.

value of fuel savings accounted for nearly 80 percent of the total benefits of the 2012 rule, each of these assumptions is consequential. With a lower fuel price projection and an expectation that new vehicle buyers respond to fuel prices, the 2012 rule would have shown much smaller fuel savings attributable to the more stringent standards. Projected fuel prices are considerably lower today than in 2012, the agencies now understand new vehicle buyers to be at least somewhat responsive to fuel prices, and the agencies have therefore updated corresponding model inputs to produce an analysis the agencies consider to be more realistic.

The first of these assumptions, fuel prices, was simply an artifact of the timing of the rule. Following recent periodic spikes in the national average gasoline price and continued volatility after the great recession, the fuel price forecast then produced by EIA (as part of AEO 2011) showed a steady march toward historically high, sustained gasoline prices in the United States. However, the actual series of fuel prices has skewed much lower. As it has turned out, the observed fuel price in the years between the 2012 final rule and this rule has frequently been lower than the "Low Oil Price" sensitivity case in the 2011 AEO, even when adjusted for inflation. The following graph compares fuel prices underlying the 2012 final rule to fuel prices applied in the analysis reported in today's notice, expressing both projections in 2010 dollars. The differences are clear and significant:

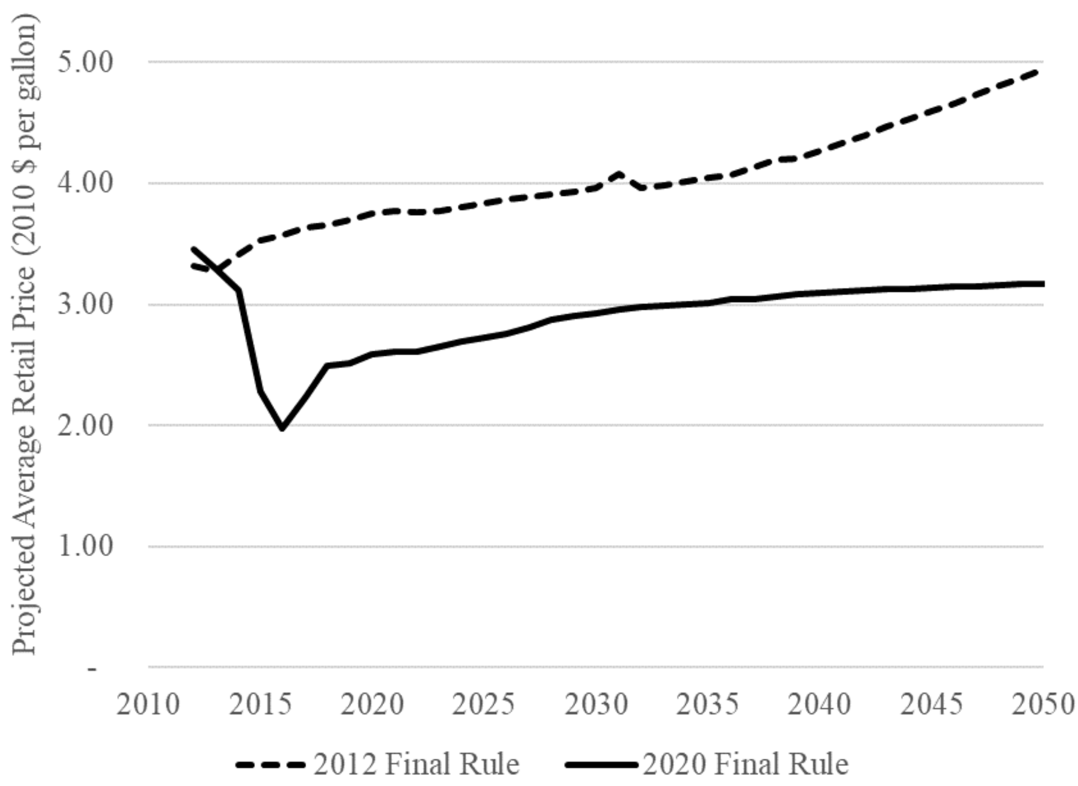

Figure IV-2 – Gasoline Price Projections (in 2010 $/gal.) from 2012 and Current Analyses

The discrepancy in fuel prices is important to the discussion of differences between the current rule and the 2012 final rule, because that discrepancy leads in turn to differences in analytical outputs and thus to differences in what the agencies consider in assessing what levels of standards are reasonable, appropriate, and/or maximum feasible. As an example, the agencies discuss in Sections VI.D.3, Simulating Environmental Impacts of Reglatory Alternatives, and VIII.A.3, EPA's Conclusion that the Final CO_2 Standards are Appropriate and Reasonable, that fuel price projections from the 2012 rule were one assumption, among others, that could have led to overestimates of the health benefits that resulted from reducing criteria pollutant emissions. Yet the agencies caution readers not to interpret this discrepancy as a reflection of negligence on the part of the agencies, or on the part of EIA. Long-term predictions are challenging and the fuel price projections in the 2012 rule were within the range of conventional wisdom *at the time*. However, it does suggest that fuel economy and tailpipe CO_2 regulations set almost two decades into the future are vulnerable to surprises, in some ways, and reinforces the value of being able to adjust course when critical assumptions are proven inaccurate. This value was codified in regulation when EPA bound itself to the mid-term evaluation process as part of the 2012 final rule.[193]

To illustrate this point clearly, substituting the current (and observed) fuel price forecast for the forecast used in the 2012 final rule creates a significant difference in the value of fuel savings. Even under identical discounting methods (see Section 2, below), and otherwise identical inputs in the 2012 version of the CAFE Model, the current (and historical) fuel price forecast reduces the value of fuel savings by *$150 billion*—from $525 billion to $375 billion (in 2009 dollars).

The second assumption employed in the 2012 (as well as the 2010) final rule, that new vehicle fuel economy never improves unless manufacturers are required to increase fuel economy in the new vehicle market by increasingly stringent regulations, is more problematic. Despite the extensive set of recent academic studies showing, as discussed in Section VI.D.1.a)(2), that consumers value at least *some* portion, and in some studies nearly *all*, of the potential fuel savings from higher levels of fuel economy at the time they purchase vehicles, the agencies assumed in past rulemakings that buyers of new vehicles would never purchase, and manufacturers would never supply, vehicles with higher fuel economy than those in the baseline (MY 2016 in the 2012 analysis), regardless of technology cost or prevailing fuel prices in future model years. In calendar year 2025, the 2012 final rule assumed gasoline would cost nearly $4.50/gallon in today's dollars, and continue to rise in subsequent years. Even recognizing that higher levels of fuel economy would be achieved under the augural/existing standards than without them, the assertion that fuel economy and CO_2 emissions would not improve beyond 2016 levels in the presence of nearly $5/gallon gasoline is not supportable. This is highlighted by the observed increased consumer demand for higher-fuel-economy vehicles during the gas price spike of 2008, when average U.S. prices briefly broke $4/gallon. In the 2012 final rule, this assumption—that fuel economy and emissions would never improve absent regulation—created a persistent gap in fuel economy between the baseline and augural standards that grew to 13 mpg (at the industry average, across all vehicles) by MY 2025. In the 2016 Draft TAR, NHTSA's analysis included the assumption that manufacturers would deploy, and consumers would demand, any technology that recovered its own cost in the first year of ownership through

[193] *See* 40 CFR 86-1818-12(h).

avoided fuel costs. However, in both the Draft TAR and the Proposed and Final Determination documents, EPA's analysis assumed that the fuel economy levels achieved to reach compliance with MY 2021 standards would persist indefinitely, regardless of fuel prices or technology costs.

By substituting the conservative assumption that consumers are willing to purchase fuel economy improvements that pay for themselves with avoided fuel expenditures over the first 2.5 years[194] (identical to the assumption in this final rule's central analysis) the gap in industry average fuel economy between the baseline and augural scenarios narrows from 13 mpg in 2025 to 6 mpg in 2025. As a corollary, acknowledging that fuel economy would continue to improve in the baseline under the fuel price forecast used in the final rule erodes the value of fuel savings attributable to the preferred alternative. While each gallon is still worth as much as was assumed in 2012, fewer gallons are consumed in the baseline due to higher fuel economy levels in new vehicles. In particular, the number of gallons saved by the preferred alternative selected in 2012 drops from about 180 billion to 50 billion once we acknowledge the existence of even a moderate market for fuel economy.[195] The value of fuel savings is similarly eroded, as higher fuel prices lead to correspondingly higher demand for fuel economy even in the baseline—reducing the value of fuel savings from $525 billion to $190 billion.

The magnitude of the fuel economy improvement in the baseline is a consequence of both the fuel prices assumed in the 2012 rule (already discussed as being higher than both subsequent observed prices and current projections) and the assumed technology costs. In 2012, a number of technologies were assumed to have negative incremental costs—meaning that applying those technologies to existing vehicles would both improve their fuel economy and reduce the cost to produce them. Asserting that the baseline would experience no improvement in fuel economy without regulation is equivalent to asserting that manufacturers, despite their status as profit maximizing entities, would not apply these cost-saving technologies unless forced to do so by regulation. While this issue is discussed in greater detail in Section VI.B the combination of inexpensive (or free) technology and high fuel prices created a logically inconsistent perspective in the 2012 rule—where consumers never demanded additional fuel economy, despite high fuel costs, and manufacturers never supplied additional fuel economy, despite the availability of inexpensive (or cost saving) technology to do so.

---

[194] Greene, D.L. and Welch, J.G., "Impacts of fuel economy improvements on the distribution of income in the U.S.," Energy Policy, Volume 122, November 2018, pp. 528-41 ("Four nationwide random sample surveys conducted between May 2004 and January 2013 produced payback period estimates of approximately three years, consistent with the manufacturers' perceptions.") (The 2018 article succeeds Greene and Welch's 2017 publication titled "The Impact of Increased Fuel Economy for Light-Duty Vehicles on the Distribution of Income in the U.S.: A Retrospective and Prospective Analysis," Howard H. Baker Jr. Center for Public Policy, March 2017, which Consumers Union, CFA, and ACEEE comments include as Attachment 4, Docket NHTSA-2018-0067-11731).

[195] Readers should note that this is not an estimate of the total amount of fuel that will be consumed or not consumed by the fleet as a whole, but simply the amount of fuel that will be consumed or not consumed *as a direct result of the regulation*. As illustrated in Section VII, light-duty vehicles in the U.S. would continue to consume considerable quantities of fuel and emit considerable quantities of CO_2 even under the baseline/augural standards, and agencies' analysis shows that the standards finalized today will likely increase fuel consumption and CO_2 emissions by a small amount.

Many commenters on earlier rules supported the assumption that fuel economy would not improve at all in the absence of standards. In fact, some commenters still support this position. For example, EDF commented to the NPRM that, "NHTSA set the Volpe model to project that, with CAFE standards remaining flat at MY 2020 levels through MY 2026, automakers would over-comply with the MY 2020 standards by 9 grams/mile of CO_2 for cars and 15 g/mi of CO_2 for light trucks during the 2029-2032 timeframe, plus 1%/year improvements beyond MY 2032. This assumption unreasonably obscures the impacts of the rollback and is not reflective of historical compliance performance."[196]

EDF is mistaken in two different ways: (1) by acknowledging the existence of a well-documented market for fuel economy, rather than erroneously inflating the benefits associated with increasing standards, this assumption serves to isolate the benefits actually attributable to each regulatory alternative, and (2) it is, indeed, reflective of historical compliance performance. While the agencies rely on the academic literature (and comments from companies that build and sell automobiles) to defend the assertion that a market for fuel economy exists, the industry's historical CAFE compliance performance is a matter of public record.[197] As shown in Figure IV-3, Figure IV-4, and Figure IV-5 for more than a decade, the industry average CAFE has exceeded the standard for each regulatory class—by several mpg during periods of high fuel prices.

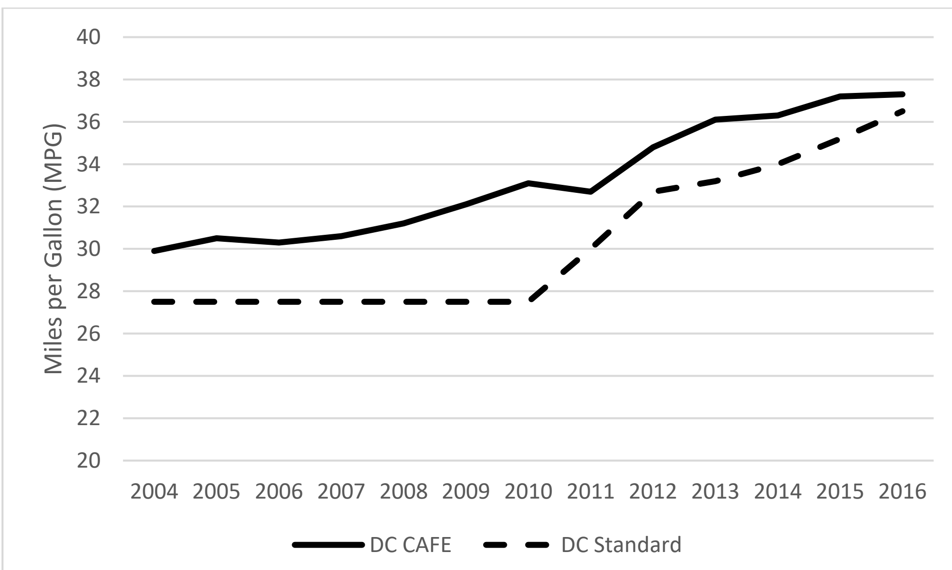

Figure IV-3 – Historical CAFE Compliance, Domestic Cars

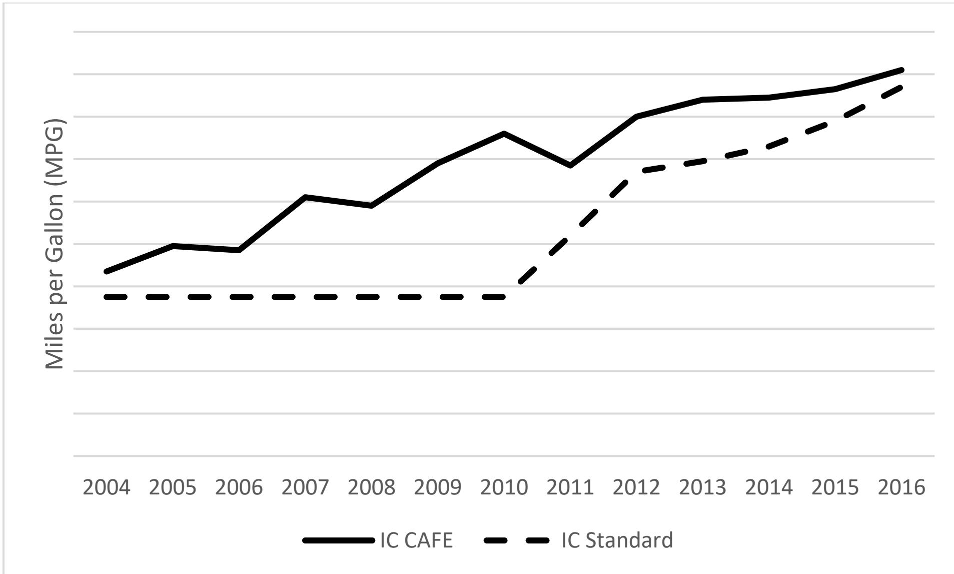

Figure IV-4 – Historical CAFE Compliance, Imported Cars

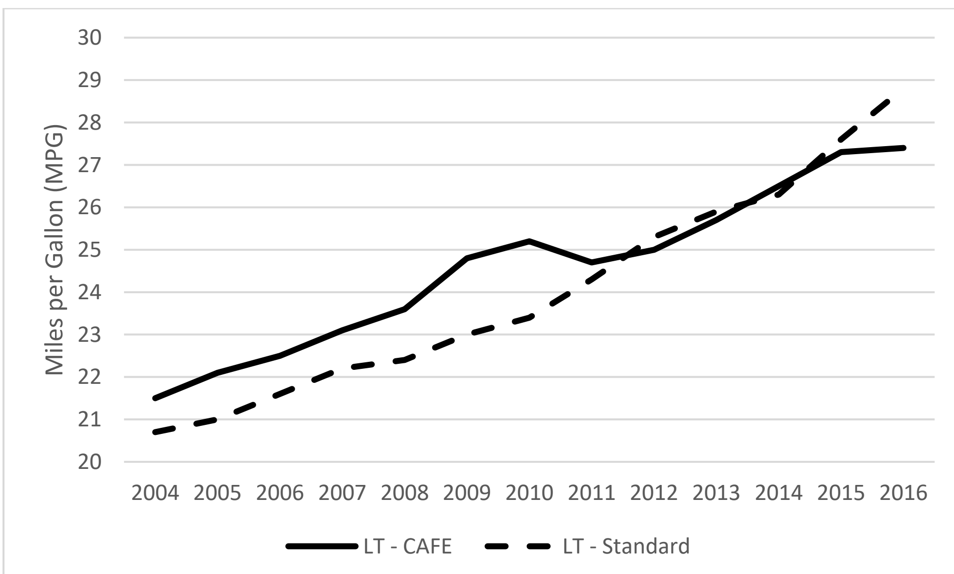

Figure IV-5 – Historical CAFE Compliance, Light Trucks

While this rulemaking has shown the impact of deviations from the 2012 rule assumptions individually, these two assumptions affect the value of fuel savings jointly. Replacing the fuel price forecast with the observed historical and current projected prices, and including any technology that pays for itself in the first 2.5 years of ownership through avoided fuel expenditures, reduces the value of fuel savings from $525 billion in the 2012 rule to $140 billion, all else equal. Interestingly, this reduction in the value of fuel savings is smaller than the result when assuming only that the desired payback period is nonzero. While it may seem counterintuitive, it is entirely consistent.

The number of gallons saved under the preferred alternative is actually higher when modifying both assumptions, compared to only modifying the payback period. Updating both assumptions leads to about 100 billion gallons saved by the preferred alternative in 2012, compared to only 50 billion from changing only the payback period, and 180 billion in the 2012 analysis. This occurs because the fuel economy in the baseline is lower when updating both the fuel price and the payback period—the gap between the augural standards and the baseline grows to 9 mpg, rather than only 6 mpg when updating only the payback period. Despite the existence of inexpensive technology in both cases, with lower fuel prices there are fewer opportunities to apply technology that will pay back quickly. As a consequence, the number of gallons saved by the preferred alternative in 2012 increases—but each gallon saved is worth less because the price of fuel is lower.

b) Technology Cost

While the methods used to identify cost-effective technologies to improve fuel economy in new vehicles have continuously evolved since 2012 (as discussed further in Section IV.B.1), as have the estimated cost of individual technologies, the inclusion of a market response in all scenarios (including the baseline) has changed the total technology cost associated with a given alternative. As also discussed in Section VI.B, acknowledging the existence of a market for fuel economy leads to continued application of the most cost-effective technologies in the baseline—and in other less stringent alternatives—up to the point at which there are no remaining technologies whose cost is fully offset by the value of fuel saved in the first 30 months of ownership. The application of this market-driven technology has implications for fuel economy levels under lower stringencies (as discussed earlier), but also for the incremental technology cost associated with more stringent alternatives. As lower stringency alternatives (including the 2012 baseline) accrue more technology, the incremental cost of more stringent alternatives decreases.

By including a modest market for fuel economy, and preserving all other assumptions from the 2012 final rule, the incremental cost of technology attributable to the preferred alternative decreases from about $140 billion to about $72 billion. This significant reduction in technology cost is somewhat diminished by the associated reduction in the value of fuel savings (a decrease of $385 billion) when acknowledging the existence of a market for fuel economy. Another consequence of these changes is that the incremental cost of fuel economy technology is responsive to fuel price, as it should be. Under higher prices (as were assumed in 2012), consumers demand higher fuel economy in the new vehicle market. Under lower prices (as have occurred since the 2012 rule) consumers demand less fuel economy than would have been consistent with the fuel price assumptions in 2012.[198] Including a market response in the analysis ensures that, in each case, the cost of fuel economy technology within an alternative is consistent with those assumptions. Using the same fuel price forecast that supports this rule, and

[198] This is why dozens of studies examining the ability of fuel taxes (and carbon taxes, which produce the same result for transportation fuels) to reduce CO_2 emissions have found cost-effective opportunities available for those pricing mechanisms.

the same estimate of market demand for fuel economy, the incremental cost of technology in the preferred alternative would rise back up to about $110 billion.

c) The Social Cost of Carbon (SCC) Emissions

As discussed extensively in the NPRM, the agencies' perspective regarding the social cost of carbon has narrowed in focus. While the 2012 final rule considered the net present value of global damages resulting from carbon emitted by vehicles sold in the U.S. between MY 2009 and MY 2025, the NPRM (and this final rule) consider only those damages that occur to the United States and U.S. territories. As a result of this change in perspective, the value of estimated damages per-ton of carbon is correspondingly smaller. Had the 2012 final rule utilized the same perspective on the social cost of carbon, the benefits associated with the preferred alternative would have been about $11 billion, rather than $53 billion. However, the savings associated with carbon damages are a consequence of both the assumed cost per-ton of damages and the number of gallons of fuel saved. As discussed above, the gallons saved in the 2012 final rule were likely inflated as a result of both fuel price forecasts and the assumption that no market exists for fuel economy improvements. Correcting the estimate of gallons saved from the preferred alternative in the 2012 rule and considering only the domestic social cost of carbon further reduces the savings in carbon damages to $6 billion.

d) Safety Neutrality

In the 2012 final rule, the agencies showed a "safety neutral" compliance solution; that is, a compliance solution that assumed no net increase in on-road fatalities for MYs 2017-2025 vehicles as a result of technology changes associated with the preferred alternative. In practice, safety neutrality was achieved by expressly limiting the availability of mass reduction technology to only those vehicles whose usage causes fewer fatalities with decreased mass. This result was discussed as one possible solution, where manufacturers chose technology solutions that limited the amount of mass reduction applied, and concentrated the application on vehicles that improve the safety of other vehicles on the roads (primarily by reducing the mass differential in collisions). However, it implicitly assumed that each and every manufacturer would leave cost-effective technologies unused on entire market segments of vehicles in order to preserve a safety neutral outcome at the fleet level for a given model year (or set of model years) whose useful lives stretched out as far as the 2060s. Removing these restrictions tells a different story.

When mass reduction technology, determined in the model to be a cost-effective solution (particularly in later model years, when more advanced levels of mass reduction were expected to be possible), is unrestricted in its application, the 2012 version of the CAFE Model chooses to apply it to vehicles in all segments. This has a small effect on technology costs, increasing compliance costs in the earliest years of the program by a couple billion dollars, and reducing compliance costs for MYs 2022 – 2025 by a couple billion dollars. However, the impact on safety outcomes is more pronounced.

Also starting with the model and inputs used for the 2012 final rule (and, as an example, focusing on that rule's 2008-based market forecast), removing the restrictions on the application of mass reduction technology results in an additional 3,400 fatalities over the full lives of MYs

2009-2025 vehicles in the baseline,[199] and another 6,900 fatalities over those same vehicle lives under the preferred alternative. The result, a net increase of 3,500 fatalities under the preferred alternative relative to the baseline, also produces a net social cost of $18 billion. The agencies' current treatment of both mass reduction technology, which can greatly improve the effectiveness of certain technology packages by reducing road load, and estimated fatalities and now account for both general exposure (omitted in the 2012 final rule modeling) and fatality risk by age of the vehicle, further changes the story around mass reduction technology application for compliance and its relationship to on-road safety.

2. What Methods Have Changed Since the 2012 Final Rule?

Simulating how manufacturers might respond to CAFE/CO_2 standards requires information about existing products being offered for sale, as well as information about the costs and effectiveness of technologies that could be applied to those vehicles to bring the fleets in which they reside into compliance with a given set of standards. Following extensive additional work and consideration since the 2012 analysis, both agencies now use the CAFE Model to simulate these compliance decisions. This has several practical implications which are discussed in greater detail in Section VI.A. Briefly, this change represents a shift toward including a number of real-world production constraints—such as component sharing across a manufacturer's portfolio—and product cadence, where only a subset of vehicles in a given model year are redesigned (and thus eligible to receive fuel economy technology). Furthermore, the year-by-year accounting ensures a continuous evolution of a manufacturer's product portfolio that begins with the market data of an initial model year (model year 2017, in this analysis) and continues through the last year for which compliance is simulated. Finally, the modeling approach has migrated from one that relied on the simple product of single values to estimate technology effectiveness to a model that relies on full vehicle simulation to determine the effectiveness of any combination of fuel economy technologies. The combination of these changes has greatly improved the realism of simulated vehicle fuel economy for combinations of technologies across vehicle systems and classes.

In addition to these changes to the portions of the analysis that represent the supply of fuel economy (by manufacturer, fleet, and model year) in the new vehicle market, this analysis contains changes to the representation of consumer demand for fuel economy. One such measure was discussed above—the notion that consumers will demand some amount of fuel economy improvement over time, consistent with technology costs and fuel prices. However, another deviation from the 2012 final rule analysis reflects overall demand for new vehicles. Across ten alternatives, ranging from the baseline (freezing future standards at 2016 levels) to scenarios that increased stringency by seven percent per year, from 2017 through 2025, the 2012 analysis showed no response in new vehicle sales, down to the individual model level. This implied that, regardless of changes to vehicle cost or attributes driven by stringency increases, no fewer (or possibly more) units of any single model would be sold in any year, in any alternative. Essentially, that analysis asserted that the new vehicle market does not respond, in any way, to average new vehicle prices across the alternatives—regardless of whether the incremental cost is

[199] Relative to the continuation of vehicle mass from the 2008 model year carried forward into the future.

$1,600/vehicle (as it was estimated to be under the preferred alternative) or nearly $4,000/vehicle (as it was in under the 7 percent alternative). Both the NPRM and this final rule, while not employing pricing models or full consumer choice models to address differentiated demand within brands or manufacturer portfolios, have incorporated a modeled sales response that seeks to quantify what was not quantified in previous rulemakings.

An important accounting method has also changed since the 2012 final rule was published. At the time of that rule, the agencies used an approach to discounting that combined attributes of a private perspective and a social perspective in their respective benefit cost analyses. This approach was logically inconsistent, and further reinforced some of the exaggerated estimates of fuel savings, social benefits (from reduced externalities), and technology costs described above. The old method discounted the value of all incremental quantities, whether categorized as benefits or costs, to the model year of the vehicle to which they accrued. This approach is largely acceptable for use in a private benefit cost analysis, where the costs and benefits accrue to the buyer of a new vehicle (in the case of this policy) who weighs their discounted present values at the time of purchase. However, the private perspective would not include any costs or benefits that are external to the buyer (e.g., congestion or the social cost of carbon emissions). For an analysis that compares benefits and costs from the social perspective, attempting to estimate the relative value of a policy to all of society rather than just buyers of new vehicles, this approach is more problematic.

The discounting approach in the 2012 final rule was particularly distortionary for a few reasons. The fact that benefits and costs occurred over long time periods in the 2012 rule, and the standards isolated the most aggressive stringency increases in the latter years of the program, served to allow benefits that occurred in 2025 (for example) to enter the accounting without being discounted, provided that they accrued to the affected vehicles during their first year of ownership. In a setting where numerous inputs (e.g., fuel price and social cost of carbon) increase over time, benefits were able to grow faster than the discount rate in some cases—essentially making them infinite. The interpretation of discounting for externalities was equally problematic. For example, the discounting approach in the 2012 final rule would have counted a ton of CO_2 not emitted in CY 2025 in multiple ways, despite the fact that the social cost of carbon emissions was inherently tied to the calendar year in which the emissions occurred. Were the ton avoided by a MY 2020 vehicle, which would have been five years old in CY 2025, the value of that ton would have been the social cost of carbon times 0.86, but would have been undiscounted if that same ton had been saved by a MY 2025 vehicle in its initial year of usage.

This approach was initially updated in the 2016 Draft TAR to be consistent with common economic practice for benefit-cost analysis, and this analysis continues that approach. In the social perspective, all benefits and costs are discounted back to the decision year based on the calendar year in which they occur. Had the agencies utilized such an approach in the 2012 final rule, net benefits would have been reduced by about 20 percent, from $465 billion to $374 billion—not accounting for any of the other adjustments discussed above.

3. How Have Conditions Changed Since the 2012 Final Rule Was Published?

The 2012 final rule relied on market and compliance information from model year 2008 to establish standards for model years 2017 – 2025. However, in the intervening years, both the market and the industry's compliance positions have evolved. The industry has undergone a significant degree of change since the MY 2008 fleet on which the 2012FR was based. Entire brands (Pontiac, Oldsmobile, Saturn, Hummer, Mercury, etc.) and companies (Saab, Suzuki, Lotus) have exited the U.S. market, while others (most notably Tesla) have emerged. Several dozen nameplates have been retired and dozens of other created in that time. Overall, the industry has offered a diverse set of vehicle models that have generally higher fuel economy than the prior generation, and an ever-increasing set of alternative fuel powertrains.

As Table IV-1 shows, alternative powertrains have steadily increased under CAFE/CO_2 regulations. Under the standards between 2011 and 2018, the number of electric vehicle offerings in the market has increased from 1 model to 57 models (inclusive of all plug-in vehicles that are rated for use on the highway), and hybrids (like the Toyota Prius) have increased from 20 models to 43 models based on data from DOE's Alternative Fuels Data Center. Fuel efficient diesel vehicles have similarly been on the rise in that period, more than doubling the number of offerings. Flexible fuel vehicles (FFVs), capable of operating on both gasoline and E85 remain readily available in the market, but have been excluded from the table due to both their lower fuel economy and demonstrated consumer reluctance to operate FFVs on E85. They have historically been used to improve a manufacturer's compliance position, rather than other alternative fuel systems that reduce fuel consumption and save buyers money.

Table IV-1 – Alternative Fuel and Diesel Vehicle Offerings

Model Year	**Diesel**	**Electric**	**Hybrid**	**Hydrogen**	**Total**
2008	6	1	16	0	23
2009	12	1	19	0	32
2010	14	1	20	0	35
2011	16	2	29	0	47
2012	17	6	31	0	55
2013	22	15	38	0	76
2014	35	16	43	2	96
2015	39	27	46	3	115
2016	29	29	31	3	92
2017	21	51	44	3	118
2018	38	57	43	3	140

*EVs include plug-in HEVs, but do not include Neighborhood Electric Vehicles, Low Speed Electric Vehicles, or two-wheeled electric vehicles. Only full-sized vehicles sold in the U.S. and capable of 60mph are listed.

Not only have alternative powertrain options proliferated since the 2012 FR, the average fuel economy of new vehicles within each body style has increased. However, the more dramatic effect may lie in the *range* of fuel economies available within each body style. Figure IV-6 shows the distribution of new vehicle fuel economy (in miles per gallon equivalent) by body style for MYs 2008, 2016, and 2020 (simulated). Each box represents the 25th and 75th percentiles, where 25 and 75 percent of new models offered are less fuel efficient than that level. Not only has the median fuel economy improved (the median shows the point at which 50 percent of new models are less efficient) under the CAFE/CO_2 programs, but the range of available fuel economies (determined by the length of the boxes and their whiskers) has increased as well. For example, the 25th percentile of pickup truck fuel economy in 2020 is expected to be significantly more efficient than 75 percent of the pickups offered in 2008. In MY 2008, there were only a few SUVs offered with rated fuel economies above 34MPG. By MY 2020 almost half of the SUVs offered will have higher fuel economy ratings—with almost 20 percent of offerings exceeding 40MPG.

The improvement in passenger car styles has been no less dramatic. As with the other styles, the range of available fuel economies has increased under the CAFE/CO_2 programs and the distribution of available fuel economies skewed higher—with 40 percent of MY 2020 models exceeding 40MPG. The attribute-based standards are designed to encourage manufacturers to improve vehicle fuel economy across their portfolios, and they have clearly done so. Not only have the higher ends of the distributions increased, the lower ends in all body styles have improved as well, where the least fuel efficient 25 percent of vehicles offered in MY 2016 (and simulated in 2020) are more fuel efficient than the most efficient 25 percent of vehicles offered in MY 2008.

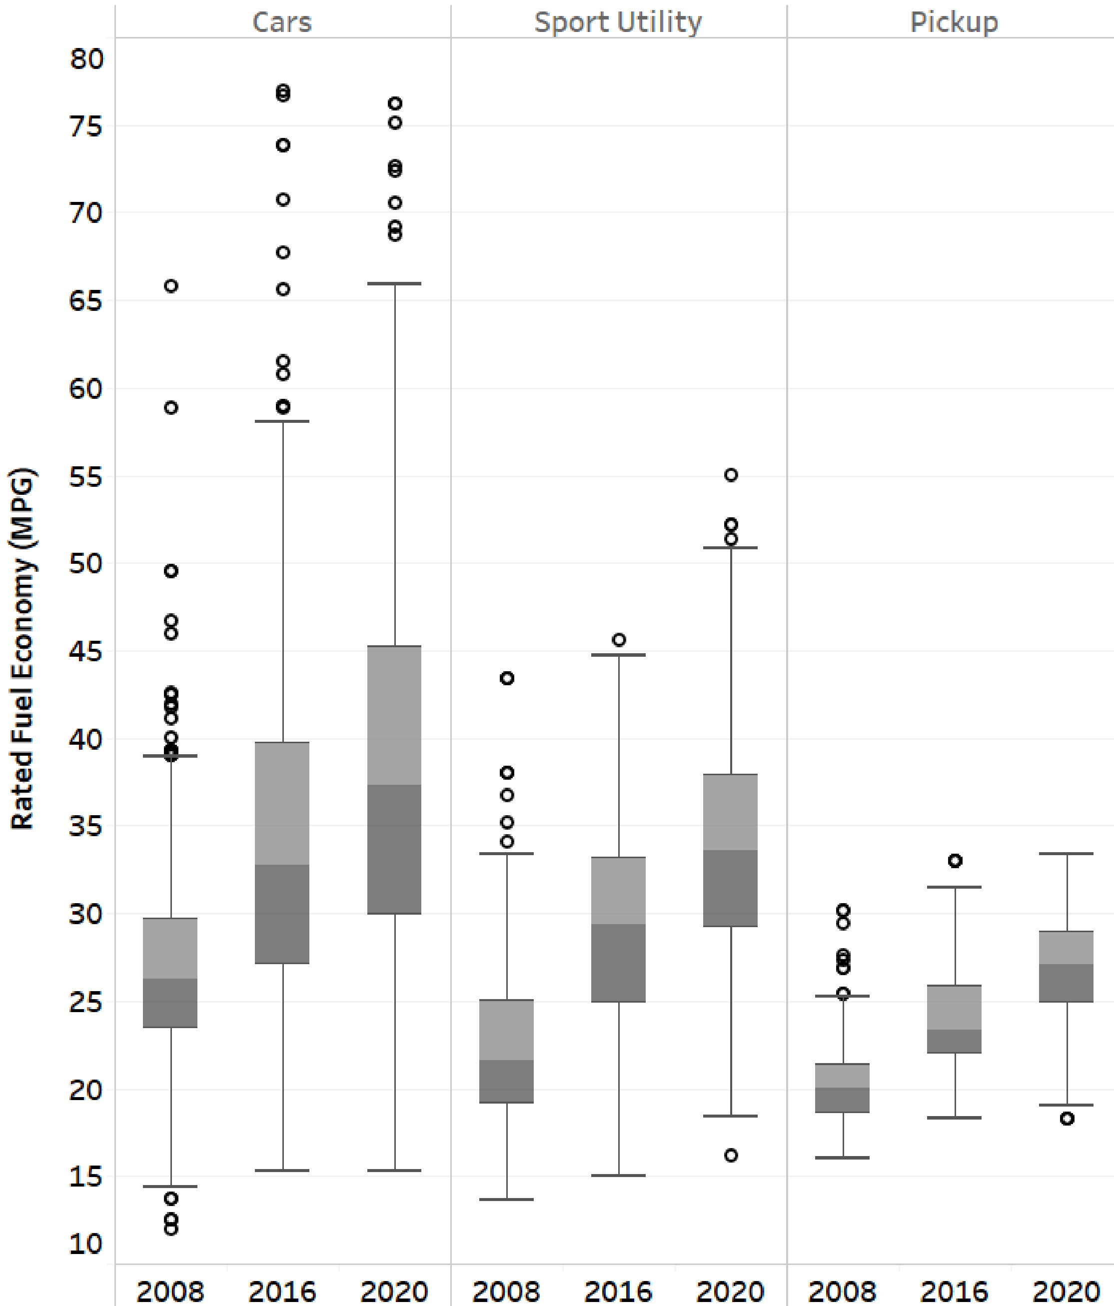

Figure IV-6 – Fuel Economy Distribution[200] of New Vehicle Market by Body Style

Some commenters have argued that consumers will be harmed by any set of standards lower than the baseline (augural) standards because buyers of new vehicles will be forced to spend more on fuel than they would have under the augural standards. However, as Figure IV-6 shows, the range of fuel economies available in the new market is already sufficient to suit the needs of buyers who desire greater fuel economy rather than interior volume or some other

[200] Circles represent specific outlying vehicle models.

attributes. Full size pickup trucks are now available with smaller turbocharged engines paired with 8 and 10-speed transmissions and some mild electrification. Buyers looking to transport a large family can choose to purchase a plug-in hybrid minivan. There were 57 electric models available in 2018, and hybrid powertrains are no longer limited to compact cars (as they once were). Buyers can choose hybrid SUVs with all-wheel and four-wheel drive. While these kinds of highly efficient options were largely absent from some body styles in MY 2008, this is no longer the case. Given that high-MPG vehicles are widely available, consumers must also value other vehicle attributes (e.g., acceleration and load-carrying capacity) that can can also be improved with the same technologies that can be used to improve fuel economy.

Manufacturers have accomplished a portfolio-wide improvement by improving the combustion efficiency of engines (through direct injection and turbocharging), migrating from four and five speed transmissions to 8 and 10 speed transmissions, and electrifying to varying degrees. All of this has increased both production costs and fuel efficiency during a period of economic expansion and low energy prices. While the vehicles offered for sale have increased significantly in efficiency between MY 2008 and MY 2020, the sales-weighted average fuel economy has achieved less improvement. Despite stringency increases of about five percent (year-over-year) between 2012 and 2016, the sales-weighted average fuel economy increased marginally. Figure IV-7 shows an initial increase in average new vehicle fuel economy (the heavy solid line, shown in mpg as indicated on the left *y* axis), followed by relative stagnation as fuel prices (the light dashed lines, shown in dollars per gallon as indicated on the right *y* axis) fell and remained low.[201] It is worth noting that average new vehicle fuel economy observed a brief spike during the year that the Tesla Model 3 was introduced (as a consequence of strong initial sales volumes, as pre-orders were satisfied, and fuel economy ratings that are significantly higher than the industry average), and settled around 27.5 MPG in Fall 2019. Average fuel economy receded further over the next several months to 26.6 MPG in February 2020.[202]

[202] Ward's Automotive, https://wardsintelligence.informa.com/WI964622/Fuel-Economy-Slightly-Down-in-February. Last accessed Mar. 9, 2020.

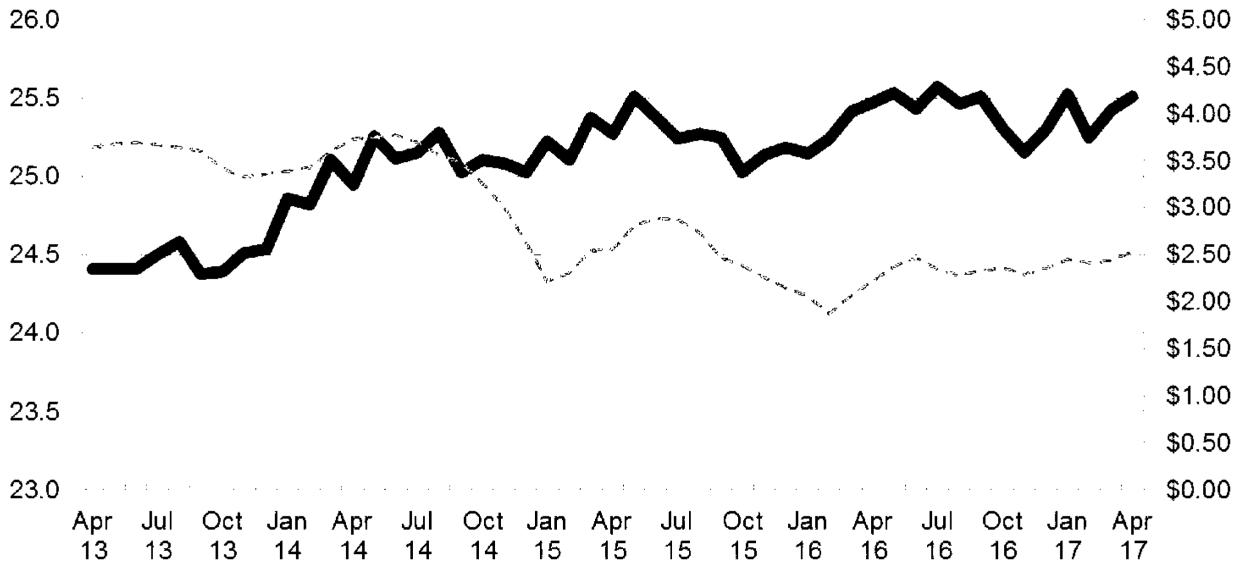

Figure IV-7 – Ward's Automotive Fuel Economy Index, April 2013 – April 2017

In their NPRM comments, manufacturers expressed concern that CAFE standards had already increased to the point where the price increases necessary to recoup manufacturers' increased costs for providing further increases in fuel economy outweigh the value of fuel savings.[203,204] The agencies do not agree that this point has already been reached by previous stringency increases, but acknowledge the reality of diminishing marginal returns to improvements in fuel economy. A driver with a 40MPG vehicle uses about 300 gallons of fuel per year. Increasing the fuel economy of that vehicle to 50MPG, a 25 percent increase, would likely be over $1000 in additional technology cost. However, that driver would only save 25 percent of their annual fuel consumption, or 75 gallons out of 300 gallons. Even at $3/gallon, higher than the current national average, that represents $225 per year in fuel savings. That means that the buyer's $1000 investment in additional fuel economy pays back in just under 4.5 years (undiscounted). The agencies' respective programs have created greater access to high MPG vehicles in all classes and encouraged the proliferation of alternative fuels and powertrains. But if the value of the fuel savings is insufficient to motivate buyers to invest in ever greater levels of fuel economy, manufacturers will face challenges in the market.

While Figure IV-3 through Figure IV-5 illustrate the trends in historical CAFE compliance for the entire industry, the figures contain another relevant fact. After several consecutive years of increasing standards, the achieved and required levels converge. When the standards began increasing again for passenger cars in 2011, the prior year had industry CAFE levels 5.6 mpg and 7.7 mpg in excess of their standards for domestic cars and imported cars, respectively. Yet, by 2016, the consecutive year-over-year increases had eroded the levels of over-compliance. Light trucks similarly exceeded their standard prior to increasing standards,

---

203 NHTSA-2018-0067-12064-25.
204 NHTSA-2018-0067-12073-2.

which began in 2005. Yet, by 2011, after several consecutive years of stringency increases, the industry light-truck average CAFE was merely compliant with the rising standard.

This is largely due to the fact that stringency requirements have increased at a faster rate than achieved fuel economy levels for several years. The attribute-based standards took effect in 2011 for all regulatory classes, although light truck CAFE standards had been increasing since 2005. Since 2004, light truck stringency has increased an average of 2.7 percent per year, while light truck's compliance fuel economy has increased by an average of 1.7 percent over the same period[205]. For the passenger classes, a similar story unfolds over a shorter period of time. Year over year stringency increases have averaged 4.7 percent per year for domestic cars (though increases in the first two years were about 8 percent – with lower subsequent increases), but achieved fuel economy increases averaged only 2.2 percent per year over the same period. Imported passenger cars were similar to domestic cars, with average annual stringency increases of 4.4 percent but achieved fuel economy levels increasing an average of only 1.4 percent per year from 2011 through 2017. Given that each successive percent increase in stringency is harder to achieve than the previous one, long-term discrepancies between required and achieved year-over-year increases cannot be offset indefinitely with existing credit banks, as they have been so far.

With the fuel price increases fresh in the minds of consumers, and the great recession only recently passed, the CAFE stringency increases that began in 2011 (and subsequent CAFE/CO_2 stringency increases after EPA's program was first enforced in MY 2012) had something of a head start. As Figure IV-3 through Figure IV-5 illustrate, the standards were not binding in MY 2011—even manufacturers that had historically paid civil penalties were earning credits for overcompliance. It took two years of stringency increase to catch up to the CAFE levels already present in MY 2011. However, seven consecutive years of increases for passenger cars and a decade of increases for light trucks has changed the credit situation. Figure IV-8 shows CAFE credit performance for regulated fleets—the solid line represents the number of fleets generating shortfalls and the dashed line represents the number of fleets earning credits in each model year.

[205] Both the standards and these calculations are defined in consumption space—gallons per mile—which also translates directly into CO_2 based on the carbon content of the fuel consumed.

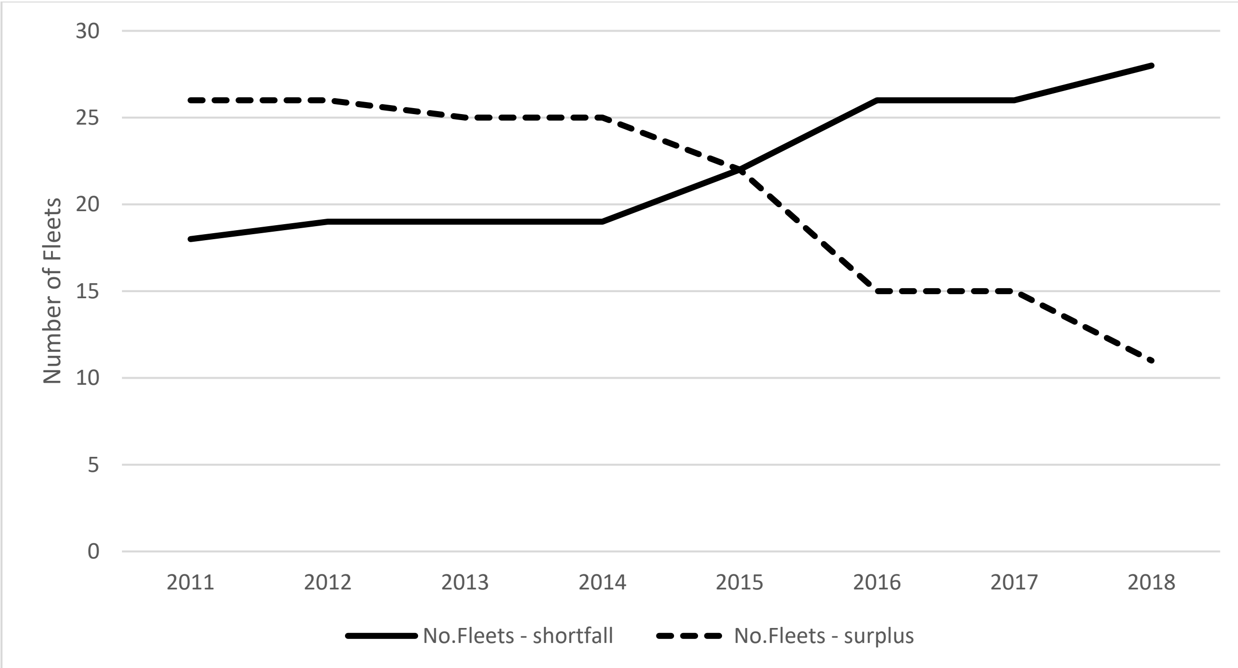

Figure IV-8 – Industry CAFE Credit Performance Over Time

Fewer than half as many fleets earned surplus credits for over-compliance in MY 2017 compared to MY 2011—and this trend is persistent. The story varies from one manufacturer to another, but it seems sufficient to state the obvious—when the agencies conducted the analysis to establish standards through MY 2025 back in 2012, most (if not all) manufacturers had healthy credit positions. That is no longer the case, and each successive increase requires many fleets to not only achieve the new level from the resulting increase, but to resolve deficits from the prior year as well. The large sums of credits, which last five years under both programs, have allowed most manufacturers to resolve shortfalls. But the light truck fleet, in particular, has a dwindling supply of credits available for purchase or trade. The CO_2 program has a provision that allows credits earned during the early years of over-compliance to be applied through MY 2021. This has reduced the compliance burden in the last several years, as intended, but will not mitigate the compliance challenges some OEMs would face if the baseline standards remained in place and energy prices persisted at current levels.

Table IV-2 – CAFE Credits (in millions) Earned by Manufacturer, Fleet, and Model Year

Table IV-2 shows the credits earned by each manufacturer over time[206]. As the table shows, when the agencies considered future standards in 2012, most manufacturers were earning credits in at least one fleet. However, the bold values show years with deficits and even some manufacturers who started out in strong positions, such as Ford's passenger car fleet, have seen growing deficits in recent years. While the initial banks for early-action years eases the burden of CO_2 compliance for many OEMs, the year-to-year compliance story is similar to CAFE, see Table IV-3.

Table IV-3 – CO_2 Credits (MMT) Earned by Manufacturer and Model Year

Manufacturer	MY2009-2011	MY2012	MY2013	MY2014	MY2015	MY2016	MY2017

Credit position and shortfall rates clearly illustrate manufacturers' fleet performance relative to the standards. Recognizing that manufacturers plan compliance over several model years at any given time, sporadic shortfalls may not be evidence of undue difficulty, but sustained, widespread, growing shortfalls should probably be viewed as evidence that standards previously believed to be manageable might no longer be so. While NHTSA is prohibited by statute from considering availability of credits (and thus, size of credit banks) in determining maximum feasible standards, it does consider shortfalls as part of its determination. EPA has no such prohibition under the CAA and is free to consider both credits and shortfalls.

These increasing credit shortfalls are occurring at a time that the industry is deploying more technology than the agencies anticipated when establishing future standards in 2012. The

---

[206] MY 2017 values represent estimated earned credits based on MY 2017 final compliance data.

agencies' projections of transmission technologies were mixed. While the agencies expected the deployment of 8-speed transmissions to about 25 percent of the market by MY 2018, transmissions with eight or more gears account for almost 30 percent of the market. However, the agencies projected no CVT transmissions in future model years, instead projecting high penetration of DCTs. However, CVTs currently make up more than 20 percent of new transmissions. The tradeoff between advanced engines and electrification was also underestimated. While the agencies projected penetration rates of turbocharged engines that are higher than we've observed in the market (45 percent compared to 30 percent), the estimated penetration of electric technologies was significantly lower. The agencies projected a couple percent of strong hybrids—which we've seen—but virtually no PHEVs or EVs. While the volumes of those vehicles are still only a couple percent of the new vehicle market, they are heavily credited under both programs and can significantly improve compliance positions even at smaller volumes. Even lower-level electrification technologies, like stop-start systems, are significantly more prevalent than we anticipated (stop-start systems were projected to be in about 2 percent of the market, compared to over 20 percent in the 2018 fleet). Despite technology deployment that is comparable to 2012 projections, and occasionally more aggressive, passenger car and light truck fleets have slightly lower fuel economy than projected. As fleet volumes have shifted along the footprint curve, the standards have decreased as well (relative to the expectation in 2012), but less so. While compliance deficits have been modest, they have been accompanied by record sales for several years. This has not only depleted existing credit banks, but created significant shortfalls that may be more difficult to overcome if sales recede from record levels.

V. Regulatory Alternatives Considered

Agencies typically consider regulatory alternatives in proposals as a way of evaluating the comparative effects of different potential ways of accomplishing their desired goal. NEPA requires agencies (in this case, NHTSA, but not EPA) to compare the potential environmental impacts of their proposed actions to those of a reasonable range of alternatives. Executive Orders 12866 and 13563 and OMB Circular A-4 also encourage agencies to evaluate regulatory alternatives in their rulemaking analyses. Alternatives analysis begins with a "no-action" alternative, typically described as what would occur in the absence of any regulatory action. This final rule, like the proposal, includes a no-action alternative, described below, as well as seven "action alternatives." The final standards may, in places, be referred to as the "preferred alternative," which is NEPA parlance, but NHTSA and EPA intend "final standards" and "preferred alternative" to be used interchangeably for purposes of this rulemaking.

In the proposal, NHTSA and EPA defined the different regulatory alternatives (other than the no-action alternative) in terms of percent-increases in CAFE and CO_2 stringency from year to year. Percent increases in stringency referred to changes in the standards year over year—as in, standards that become 1 percent more stringent each year. Readers should recognize that those year-over-year changes in stringency are *not* measured in terms of mile per gallon or CO_2 gram per mile differences (as in, 1 percent more stringent than 30 miles per gallon in one year equals 30.3 miles per gallon in the following year), but in terms of shifts in the *footprint functions* that form the basis for the *actual* CAFE and CO_2 standards (as in, on a gallon or gram per mile basis, the CAFE and CO_2 standards change by a given percentage from one model year to the next). Under some alternatives, the rate of change was the same for both passenger cars and light trucks; under others, the rate of change differed. Like the no-action alternative, all of the alternatives considered in the proposal were more stringent than the preferred alternative.

Alternatives considered in the proposal also varied in other significant ways. Alternatives 3 and 7 in the proposal involved a gradual discontinuation of CAFE and average CO_2 adjustments reflecting the use of technologies that improve air conditioner efficiency or otherwise improve fuel economy under conditions not represented by long-standing fuel economy test procedures (off-cycle adjustments, described in further detail in Section IX, although the proposal itself would have retained these flexibilities. Commenters responding to the request for comment on phasing out these flexibilities generally supported maintaining the existing program, as proposed. Some commenters suggested changes to the existing program that were not discussed in the NPRM. Such changes would be beyond the scope of this rulemaking and were not considered. Section IX contains a more thorough summary of these comments and the issues they raise, as well as the agencies' responses. Consistent with the decision to retain these flexibilities in the final rule, alternatives reflecting their phase-out have not been considered in this final rule.

Additionally, in the NPRM for this rule, EPA proposed to exclude the option for manufacturers partially to comply with tailpipe CO_2 standards by generating CO_2-equivalent emission adjustments associated with air conditioning refrigerants and leakage after MY 2020. This approach was proposed in the interest of improved harmonization between the CAFE and tailpipe CO_2 emissions programs because this optional flexibility cannot be available in the CAFE program.[207] Alternatives 1 through 8 excluded this option. EPA requested comment "on whether to proceed with [the] proposal to discontinue accounting for A/C leakage, methane emissions, and nitrous oxide emissions as part of the CO_2 emissions standards to provide for better harmony with the CAFE program, or whether to continue to consider these factors toward compliance and retain that as a feature that differs between the programs."[208] EPA stated that if

---

[207] For the CAFE program, carbon-based tailpipe emissions (including CO_2, HC, and CO) are measured, and fuel economy is calculated using a carbon balance equation. EPA also uses carbon-based emissions (CO_2, HC, and CO, the same as for CAFE) to calculate tailpipe CO_2 for use in determining compliance with its standards. In addition, under the no-action alternative for the proposal and under all alternatives in the final rule, in determining compliance, EPA includes on a CO_2 equivalent basis (using Global Warming Potential (GWP) adjustment) A/C refrigerant leakage credits, at the manufacturer's option, and nitrous oxide and methane emissions. EPA also has separate emissions standards for methane and nitrous oxides. The CAFE program does not include or account for A/C refrigerant leakage, nitrous oxide and methane emissions because they do not impact fuel economy. Under Alternatives 1-8 in the proposal, the standards were closely aligned for gasoline powered vehicles because compliance with the fleet average standard for such vehicles is based on tailpipe CO_2, HC,and CO for both programs and not emissions unrelated to fuel economy, although diesel and alternative fuel vehicles would have continued to be treated differently between the CAFE and CO_2 programs. While such an approach would have significantly improved harmonization between the programs, standards would not have been fully aligned because of the small fraction of the fleet that uses diesel and alternative fuels (as described in the proposal, such vehicles made up approximately four percent of the MY 2016 fleet), as well as differences involving EPCA/EISA provisions EPA has not adopted, such as minimum standards for domestic passenger cars and limits on credit transfers between regulated fleets. The proposal to eliminate flexibilities associated with A/C refrigerants and leakage was not adopted for this final rule, and the reasons for and implications of that decision are discussed further below.

[208] 83 FR at 43193 (Aug. 24, 2018).

EPA were to proceed with excluding A/C refrigerant credits as proposed, "EPA would consider whether it is appropriate to initiate a new rulemaking to regulate these programs independently…."[209] EPA also stated that "[i]f the agency decides to retain the A/C leakage … provisions for CO_2 compliance, it would likely re-insert the current A/C leakage offset and increase the stringency levels for CO_2 compliance by the offset amounts described above (i.e., 13.8 g/mi equivalent for passenger cars and 17.2 g/mi equivalent for light trucks). EPA received comments from a wide range of stakeholders, most of whom opposed the elimination of these flexibility provisions.

Specifically, the two major trade organizations of auto manufacturers, as well as some individual automakers, supported retaining these provisions. Global Automakers commented that "[a]ir conditioning refrigerant leakage . . . should be included for compliance with the EPA standards for all MYs, even if it means a divergence from the NHTSA standards."[210] Global provides several detailed reasons for their comments, including that the existing provisions are "…important to maintaining regulatory flexibility through real [CO_2] emission reductions and would prevent the potential for additional bifurcated, separate programs at the state level."[211] The Alliance similarly commented that it "supports continuation of the full air conditioning refrigerant leakage credits under the [CO_2] standards."[212] Some individual manufacturers, including General Motors,[213] Fiat Chrysler,[214] and BMW,[215] also commented in support of maintaining the current A/C refrigerant and leakage credits.

---

[209] *Id*. at 43194.
[210] Global, NHTSA-2018-0067-12032, Appendix A at A-5.
[211] *Id*. Global also stated that excluding A/C leakage credits would "…greatly limit the ability [of manufacturers] to select the most cost-effective approach for technology improvements and result in a costlier, separate set of regulations that actually relate to the overall GHG standards." Global also expressed concern that issuing separate regulations for A/C leakage could take too long and create a gap in which States might act to separately regulate or even ban refrigerants, and supported continued inclusion of A/C leakage and refrigerant regulation in EPA's GHG program to avoid risk of an ensuing patchwork. Global argued that manufacturers had already invested to meet the existing program, and that "the proposed phase-out also creates another risk that manufacturers will have stranded capital in technologies that are not fully amortized." Global Automakers, EPA-HQ-OAR-2018-0283-5704, Attachment A, at A.43-44.
[212] Alliance, NHTSA-2018-0067-12073, Full Comment Set, at 12. Alliance also expressed concern about stranded capital and risk of patchwork of state regulation if MAC direct credits were not retained in the Federal GHG program. *Id*. at 80-81.
[213] General Motors, NHTSA-2018-0067-11858, Appendix 4, at 1 ("General Motors supports the extensive comments from the Alliance of Automobile Manufacturers regarding flexibility mechanisms, and incorporates them by reference. In particular, the Alliance cites the widening gap between the regulatory standards and actual industry-wide new vehicle average fuel economy that has become evident since 2016, despite the growing use of improvement 'credits' from various flexibility mechanisms, such as off-cycle technology credits, mobile air conditioner efficiency credits, mobile air conditioner refrigerant leak reduction credits and credits from electrified vehicles.")
[214] FCA, NHTSA-2018-0067-11943, at 8. FCA also expressed concern about patchwork in the absence of a federal rule. *Id*.
[215] BMW, EPA-HQ-OAR-2018-4204, at 3. BMW stated that "Today's rules allow flexibilities to be used by the motor vehicle manufacturers for fuel saving technologies and efficiency gains which are not covered in the applicable test procedures. To enhance the future use of these technologies and to reward motor vehicle manufacturer's investments taken for future innovations, the agencies should consider the continuation of current flexibilities for the model years 2021 to 2026."

Auto manufacturing suppliers who addressed A/C refrigerant and leakage credits also generally supported retaining the existing provisions. MEMA commented that "It is essential for supplier investment and jobs, and continuous innovation and improvements in the technologies that the credit programs continue and expand to broaden the compliance pathways. MEMA urges the agencies to continue the current credit and incentives programs…."[216] DENSO also supported maintaining the current provisions.[217] However, BorgWarner supported the proposed removal of A/C refrigerant credits "for harmonization reasons," while encouraging EPA to regulate A/C refrigerants and leakage separately from the CO_2 standards.[218]

The two producers of a lower GWP refrigerant, Chemours and Honeywell, commented extensively in support of continuing to allow A/C refrigerant and leakage credits for CO_2 compliance, making both economic and legal arguments. Both Chemours and Honeywell stated that A/C refrigerant and leakage credits were a highly cost-effective way for OEMs to comply with the CO_2 standards,[219] with Chemours suggesting that OEM compliance strategies are based on the assumption that these credits will be available for CO_2 compliance[220] and that any increase in stringency above the proposal effectively necessitates that the credits remain part of the program.[221] Honeywell stated that all OEMs (and a variety of other parties) supported retaining the credits for CO_2 compliance,[222] and Chemours, Honeywell, and CBD *et al.* all noted that OEMs are already using the credits for low GWP refrigerants in more than 50 percent of the MY 2018 vehicles produced for sale in the U.S.[223] The American Chemistry Council also stated that the "auto industry widely supports the credits, and U.S. chemical manufacturers are at a loss as to why EPA would propose to eliminate such a successful flexible compliance program."[224] In response to NPRM statements expressing concern that the A/C refrigerant and leakage credits could be market distorting, both Chemours and Honeywell disagreed,[225] arguing that the credits were simply a highly cost-effective means of complying with the CO_2 standards,[226] and that

MEMA also expressed concern about stranded capital investments by suppliers and supplier jobs if the direct MAC credits were not available; stated that the credits were an important compliance flexibility and "one of the highest values of any credit offered in the EPA program;" and stated that "Harmonizing the programs does not require making them identical or equivalent. Rather, harmonization can be achieved by better coordinating the two programs to the extent feasible while allowing each agency to implement its separate and distinct mandate." *Id*. at 15-16.

[226] Chemours at 29-30; Honeywell at 13-14.

removal of the credits at this point would, itself, distort the market for refrigerants. Honeywell argued that eliminating the A/C credit program from CO_2 compliance would put the U.S. at a competitive disadvantage with other countries, and would risk U.S. jobs.[227]

Regarding the NPRM's statements that removing the A/C refrigerant and leakage credits from CO_2 compliance would promote harmonization with the CAFE program, these commenters argued that harmonization was not a valid basis for that aspect of the proposal. Chemours, Honeywell, and CBD *et al.* all argued that Section 202(a) creates no obligation to harmonize the [CO_2] program with the CAFE program.[228] Chemours further argued that to the extent disharmonization between the programs existed, it should be addressed via stringency changes (i.e., reducing CAFE stringency relative to CO_2 stringency) rather than "dropping low-cost compliance options."[229]

These commenters also expressed concern that the proposal constituted an EPA decision not to regulate HFC emissions from motor vehicles at all. Commenters argued that the NPRM provided no legal analysis or reasoned explanation for stopping regulation of HFCs,[230] and that *Massachusetts v. EPA* requires any final rule to regulate all greenhouse gases from motor vehicles and not CO_2 alone,[231] suggesting that there was a high likelihood of a lapse in regulation because EPA had not yet proposed a new way of regulating HFC emissions.[232] Because the NPRM provided no specific information about how EPA might regulate non-CO_2 emissions separately, commenters argued that the lack of clarity was inherently disruptive to OEMs.[233] CBD *et al*. argued that any lapse in regulation is "illegal on its face" and that even creating a separate standard for HFC emissions would be "illegal" because it "would increase costs to manufacturers and result in environmental detriment by removing any incentive to use the most aggressive approaches to curtail emissions of these highly potent GHGs."[234]

Environmental organizations,[235] other NGOs, academic institutions, consumer organizations, and state governments[236] also commented in support of continuing the existing provisions.

EPA has considered its proposed approach to A/C refrigerant and leakage credits in light of these comments. EPA believes that maintaining this element of its program is consistent with EPA's authority under Section 202(a) to establish standards for reducing emissions from LDVs.

236 CARB, NHTSA-2018-0067-11873, Detailed Comments, at 120-121; Washington State Department of Ecology, NHTSA-2018-0067-11926, at 6 (HFCs are an important GHG; compliance flexibility is important).

Thus, maintaining the optional HFC credit program is appropriate. In addition, EPA recognizes the value of regulatory flexibility and compliance options, and has concluded that the advantages from retaining the existing A/C refrigerant/leakage credit program and associated offset between the CO_2 and CAFE standards—in terms of providing for a more-comprehensive regulation of emissions from light-duty vehicles—outweigh the disadvantages resulting from the lack of harmonization.

Regarding the comment from BorgWarner about how having a separate A/C refrigerant and leakage regulation would allow for better harmonization between the programs, the agencies accept this to be an accurate statement, but believe the benefits of continued refrigerant regulation as an option for CO_2 compliance outweigh the problems associated with lack of harmonization with the CAFE program.

For these reasons, EPA is not finalizing the proposed provisions, and is making no changes in the A/C refrigerant and leakage-related provisions of the current program. In light of this conclusion, EPA does not need to address the legal arguments made by CBD *et al.* and CARB about regulating refrigerant-related emissions separately, or potential lapses in regulation of refrigerant emissions while such a program could be developed.

As with A/C refrigerant and leakage credits, EPA proposed to exclude nitrous oxide and methane from average performance calculations after model year 2020, thereby removing these optional program flexibilities. Alternatives 1 through 8 excluded this option. EPA sought comment on whether to remove those aspects of the program that allow a manufacturer to use nitrous oxide and methane emissions reductions for compliance with its CO_2 average fleet standards because such a flexibility is not allowed in the NHTSA CAFE program, or whether to retain the flexibilities as a feature that differs between the programs. Further, EPA sought comment on whether to change the existing methane and nitrous oxide standards. Specifically, EPA requested information from the public on whether the existing standards are appropriate, or whether they should be revised to be less stringent or more stringent based on any updated data.

The Alliance in its comments may have misunderstood EPA's proposal to mean that EPA was proposing to eliminate regulation of methane and nitrous oxide emissions altogether. The Alliance commented in support of such a proposal as they understood it, to eliminate the standards to provide better harmony between the two compliance programs.[237] The Alliance commented that "[n]ot only is emission of these two substances from vehicles a relatively minor contribution to GHG emissions, the Alliance has continuing concern regarding measurement and testing technologies for nitrous oxide."[238] The Alliance commented further that if "EPA decides instead to continue to regulate methane and nitrous oxide, the Alliance recommends that EPA re-assess whether the levels of the standards remain appropriate and to retain the current compliance flexibilities. Furthermore, in this scenario, the Alliance also recommends that methane and nitrous oxide standards be assessed as a fleet average and as the average of FTP and

---

[237] Alliance, NHTSA-2018-0067-12073, Full Comment Set, at 13.
[238] *Id*.

HFET test cycles."[239] Several individual manufacturers submitted similar comments, including Ford,[240] FCA,[241] Volvo,[242] and Mazda.[243] Ford also commented that it does not support the proposal to maintain the existing N_2O/CH_4 standards while removing the program flexibilities.[244]

The Alliance further commented that "data from the 2016 EPA report on light-duty vehicle emissions supports the position that CH_4 and N_2O have minimal impact on total GHG emissions, reporting only 0.045 percent in exceedance of the standard. This new information makes it apparent that CH_4 and N_2O contribute a *de minimis* amount to GHG emissions. Additionally, gasoline CH_4 and N_2O performance is within the current standards. Finally, the main producers of CH_4 and N_2O emissions are flex fuel (E85) and diesel vehicles, and these vehicles have been declining in sales as compared to gasoline-fueled vehicles."[245] The Alliance also commented that CH_4 and N_2O have minimal opportunities to be catalytically treated, as N_2O is generated in the catalyst and CH_4 has a low conversion efficiency compared to other emissions. EPA did not intend that additional hardware should be required to comply with the CH_4 or N_2O standards on any vehicle."[246]

Global Automakers commented in support of continuing inclusion of nitrous oxide and methane emissions standards for all MYs, even if it means a divergence from the NHTSA standards for these program elements in the regulations, "because they are complementary to EPA's program, and are better managed through a coordinated federal policy. They are also important to maintaining regulatory flexibility through real [CO_2] emission reductions and would prevent the potential for additional bifurcated, separate programs at the state level."[247] Global Automakers recommended that they remain in place per the existing program but continued to support that the N_2O testing is not necessary. Global Automakers commented that it "strongly recommends reducing the need for N_2O testing or eliminating these test requirements in their entirety. It should be sufficient to allow manufacturers to attest to compliance with the N_2O capped standards based upon good engineering judgment, development testing, and correlation to NO_X emissions. EPA could, however, maintain the option to request testing to be performed

[240] Ford, EPA-HQ-OAR-2018-0283-5691, at 4.
[241] FCA, NHTSA-2018-0067-11943, at 9.
[242] Volvo, NHTSA-2018-0067-12036, at 5.
[243] Mazda, NHTSA-2018-0067-11727, at 3 ("In reality, these emissions are at deminimis levels and have very little, if any, impact on global warming. So, the need to regulate these emissions as part of the GHG program, or separately, is unclear. Although most current engines can comply with the existing requirements, there are some existing and upcoming new technologies that may not be able to fully comply. These technologies can provide substantial CO_2 reductions.")
[244] Ford, at 4 ("Finally, without the ability to incorporate exceedances into CREE, each vehicle will need to employ hardware solutions if they do not comply. We do not believe it was EPA's intent in the original rulemaking to require additional after-treatment, with associated cost increases, explicitly for the control and reduction of an insignificant contributor to GHG emissions. Therefore, we do not support the proposal to maintain the existing N_2O/CH_4 standards while removing the CREE exceedance pathway.")
[245] Alliance, NHTSA-2018-0067-12073, Full Comment Set, at 43.
[246] *Id*. at 44.
[247] Global, NHTSA-2018-0067-12032, at 4, 5.

for new technologies only, which could have unknown impacts on N_2O emissions."[248] Hyundai[249] and Kia[250] submitted similar comments.

Others commented in support of retaining the existing program. MECA commented that it supports the existing standards for methane and nitrous oxide because catalyst technologies provided by MECA members that reduce these climate forcing gases are readily available and cost-effective.[251] MECA also commented that the ability to trade reductions in these pollutants in exchange for CO_2 gives vehicle manufacturers the flexibilities they need to comply with the emission limits by the most cost-effective means.[252] CBD *et al.* commented that the alternative compliance mechanisms currently available in the program exist to provide cost-effective options for compliance, and were considered by manufacturers to be a necessary element of the program for certain types of vehicles.[253] CBD *et al*. further argued that "[e]liminating these flexibilities consequently imposes costs on manufacturers without discernible environmental benefits," and suggested that harmonization with the CAFE program was not a relevant decision factor for EPA.[254] Several other parties commented generally in support of retaining the existing program for A/C leakage credits, discussed above, and N_2O and CH_4 standards.[255]

After considering these comments, EPA is retaining the regulatory provisions related to the N_2O and CH_4 standards with no changes, specifically including the existing flexibilities that accompany those standards. EPA is not adopting its proposal to exclude nitrous oxide and methane emissions from average performance calculations after model year 2020 or any other changes to the program. The standards continue to serve their intended purpose of capping emissions of those pollutants and providing for more-comprehensive regulation of emissions from light-duty vehicles. The standards were intended to prevent future emissions increases, and these standards were generally not expected to result in the application of new technologies or significant costs for manufacturers using current vehicle designs.[256] The program flexibilities are working as intended and all manufacturers are successfully complying with the standards. Most vehicle models are well below the standards and for those that are above the standards, manufacturers have used the flexibilities to offset exceedances with CO_2 improvements to demonstrate compliance. EPA did not receive any data in response to its request for comments supporting potential alternative levels of stringency.

While the Alliance and several individual manufacturers recommended eliminating the standards altogether, EPA did not propose to eliminate the standards, but to eliminate the optional flexibilities, and solicited comment on adjusting the standards to be more or less stringent. Thus, EPA does not believe it would be appropriate to eliminate completely the

standards in this final rule without providing an opportunity for comment on that idea. Furthermore, as noted above, EPA believes the standards are continuing to serve their intended purpose of capping emissions and remain appropriate. Manufacturers have been subject to the standards for several years, and the Alliance acknowledges in their comments that the exceedance of the standards, which is offset by manufacturers using compliance flexibilities, is very small and that most vehicles meet the standards. Regarding the Alliance comments that the standards should be based on a fleet average approach, EPA notes that the purpose of the standards is to cap emissions, not to achieve fleet-wide reductions.[257] The fleet average emissions for N_2O and CH_4 are well below the numerical level of the cap standards and therefore the existing cap standards would not be an appropriate fleet average standard. Adopting a fleet average approach using the same numerical level as the established cap standards would not achieve the intended goal of capping emissions at current levels. If technologies lead to exceedances of the caps, automakers have the opportunity to apply appropriate flexibilities under the current program to achieve GHG emission neutrality. EPA is not aware of any manufacturer that has been prevented from bringing a technology to the marketplace because of the current cap levels or approach. EPA believes it would need to consider all options further, with an opportunity for public comment, before adopting such a significant change to the program.

As explained above, the agencies have changed the alternatives considered for the final rule, partly in response to comments. The basic form of the standards represented by the alternatives—footprint-based, defined by particular mathematical functions—remains the same and as described in the NPRM. For the EPA program, EPA has chosen in this final rule to retain the existing program for regulation of A/C refrigerant leakage, nitrous oxide, and methane emissions as part of the CO_2 standard. This allows manufacturers to continue to rely on this flexibility which they describe as extremely important for compliance, although it results in continued differences between EPA's and NHTSA's programs. This approach also avoids the possibility of gaps in the regulation of HFCs, CH_4, and N_2O while EPA developed a different way of regulating the non-CO_2 emissions as part of or concurrent with the NPRM, and thereby allows EPA to continue to regulate GHE emissions from light-duty vehicles on a more-comprehensive basis. Thus, all alternatives considered in this final rule reflect inclusion of CH_4, N_2O, and HFC in EPA's overall "CO_2" (more accurately, CO_2-equivalent, or CO_2e) requirements. Besides this change, the alternatives considered for the final rule differ from the NPRM in two additional ways: first, alternatives reflecting the phase-out of the A/C efficiency and off-cycle programs have been dropped in response to certain comments and in recognition of the potential real-world benefits of those programs. And second, the preferred alternative for this final rule reflects a 1.5 percent year-over-year increase for both passenger cars and light trucks. These changes will be discussed further below, following a brief discussion of the form of the standards.

---

[257] Relatedly, the Alliance and Global Automakers raised concerns in their comments regarding N_2O measurement and testing burden. EPA did not propose any changes in testing requirements and at this time EPA is not adopting any changes. Manufacturers have been measuring N_2O emissions and have successfully certified vehicles to the N_2O standards for several years and EPA does not believe N_2O measurement is an issue needing regulatory change. EPA continues to believe direct measurement is the best way for manufacturers to demonstrate compliance with the N_2O standards and is more appropriate than an engineering statement without direct measurement.

A. Form of the Standards

As in the CAFE and CO_2 rulemakings in 2010 and 2012, NHTSA and EPA proposed in the NPRM to set attribute-based CAFE and CO_2 standards defined by a mathematical function of vehicle footprint, which has observable correlation with fuel economy and vehicle emissions. EPCA, as amended by EISA, expressly requires that CAFE standards for passenger cars and light trucks be based on one or more vehicle attributes related to fuel economy and be expressed in the form of a mathematical function.[258] While the CAA includes no specific requirements regarding CO_2 regulation, EPA has chosen to adopt attribute-based CO_2 standards consistent with NHTSA's EPCA/EISA requirements in the interest of harmonization and simplifying compliance. Such an approach is permissible under section 202(a) of the CAA, and EPA has used the attribute-based approach in issuing standards under analogous provisions of the CAA. Thus, both the proposed and final standards take the form of fuel economy and CO_2 targets expressed as functions of vehicle footprint (the product of vehicle wheelbase and average track width). Section V.A.2 below discusses the agencies' continued reliance on footprint as the relevant attribute.

Under the footprint-based standards, the function defines a CO_2 or fuel economy performance target for each unique footprint combination within a car or truck model type. Using the functions, each manufacturer thus will have a CAFE and CO_2 average standard for each year that is almost certainly unique to each of its fleets,[259] based upon the footprints and production volumes of the vehicle models produced by that manufacturer. A manufacturer will have separate footprint-based standards for cars and for trucks. The functions are mostly sloped, so that generally, larger vehicles (i.e., vehicles with larger footprints) will be subject to lower CAFE mpg targets and higher CO_2 grams/mile targets than smaller vehicles. This is because, generally speaking, smaller vehicles are more capable of achieving higher levels of fuel economy/lower levels of CO_2 emissions, mostly because they tend not to have to work as hard (and therefore require as much energy) to perform their driving task. Although a manufacturer's fleet average standards could be estimated throughout the model year based on the projected production volume of its vehicle fleet (and are estimated as part of EPA's certification process), the standards to which the manufacturer must comply are determined by its final model year production figures. A manufacturer's calculation of its fleet average standards as well as its fleets' average performance at the end of the model year will thus be based on the production-weighted average target and performance of each model in its fleet.[260]

For passenger cars, consistent with prior rulemakings, NHTSA is defining fuel economy targets as follows:

---

[258] 49 U.S.C. 32902(a)(3)(A).

[259] EPCA/EISA requires NHTSA to separate passenger cars into domestic and import passenger car fleets whereas EPA combines all passenger cars into one fleet.

[260] As discussed in prior rulemakings, a manufacturer may have some vehicle models that exceed their target and some that are below their target. Compliance with a fleet average standard is determined by comparing the fleet average standard (based on the production-weighted average of the target levels for each model) with fleet average performance (based on the production-weighted average of the performance of each model).

$$TARGET_{FE} = \frac{1}{MIN\left[MAX\left(c \times FOOTPRINT + d, \frac{1}{a}\right), \frac{1}{b}\right]}$$

where

TARGET_{FE} is the fuel economy target (in mpg) applicable to a specific vehicle model type with a unique footprint combination,

a is a minimum fuel economy target (in mpg),

b is a maximum fuel economy target (in mpg),

c is the slope (in gallons per mile per square foot, or gpm, per square foot) of a line relating fuel consumption (the inverse of fuel economy) to footprint, and

d is an intercept (in gpm) of the same line.

Here, *MIN* and *MAX* are functions that take the minimum and maximum values, respectively, of the set of included values. For example, *MIN*[40,35] = 35 and *MAX*(40, 25) = 40, such that *MIN*[*MAX*(40, 25), 35] = 35.

For light trucks, also consistent with prior rulemakings, NHTSA is defining fuel economy targets as follows:

$$TARGET_{FE} = MAX\left(\frac{1}{MIN\left[MAX\left(c \times FOOTPRINT + d, \frac{1}{a}\right), \frac{1}{b}\right]}, \frac{1}{MIN\left[MAX\left(g \times FOOTPRINT + h, \frac{1}{e}\right), \frac{1}{f}\right]}\right)$$

where

$TARGET_{FE}$ is the fuel economy target (in mpg) applicable to a specific vehicle model type with a unique footprint combination,

a, *b*, *c*, and *d* are as for passenger cars, but taking values specific to light trucks,

e is a second minimum fuel economy target (in mpg),

f is a second maximum fuel economy target (in mpg),

g is the slope (in gpm per square foot) of a second line relating fuel consumption (the inverse of fuel economy) to footprint, and

h is an intercept (in gpm) of the same second line.

Although the general model of the target function equation is the same for each vehicle category (passenger cars and light trucks) and each model year, the parameters of the function equation differ for cars and trucks. For MYs 2020-2026, the parameters are unchanged, resulting in the same stringency in each of those model years.

Mathematical functions defining the CO_2 targets are expressed as functions that are similar, with coefficients *a-h* corresponding to those listed above.[261] For passenger cars, EPA is defining CO_2 targets mathematically equivalent to the following:

$$TARGET_{CO2} = MIN[b, MAX[a, c \times FOOTPRINT + d]]$$

where

$TARGET_{CO2}$ is the is the CO_2 target (in grams per mile, or g/mi) applicable to a specific vehicle model configuration,

a is a minimum CO_2 target (in g/mi),

b is a maximum CO_2 target (in g/mi),

c is the slope (in g/mi, per square foot) of a line relating CO_2 emissions to footprint, and

d is an intercept (in g/mi) of the same line.

For light trucks, CO_2 targets are defined as follows:

$$TARGET_{CO2} = MIN[MIN\big[b, MAX[a, c \times FOOTPRINT + d]\big], MIN[f, MAX[e, g \times FOOTPRINT + h]]$$

where

$TARGET_{CO2}$ is the is the CO_2 target (in g/mi) applicable to a specific vehicle model configuration,

a, b, c, and *d* are as for passenger cars, but taking values specific to light trucks,

e is a second minimum CO_2 target (in g/mi),

f is a second maximum CO_2 target (in g/mi),

[261] EPA regulations use a different but mathematically equivalent approach to specify targets. Rather than using a function with nested minima and maxima functions, EPA regulations specify requirements separately for different ranges of vehicle footprint. Because these ranges reflect the combined application of the listed minima, maxima, and linear functions, it is mathematically equivalent and more efficient to present the targets as in this Section.

g is the slope (in g/mi per square foot) of a second line relating CO_2 emissions to footprint, and

h is an intercept (in g/mi) of the same second line.

To be clear, as has been the case since the agencies began establishing attribute-based standards, no vehicle need meet the specific applicable fuel economy or CO_2 targets, because compliance with either CAFE or CO_2 standards is determined based on corporate average fuel economy or fleet average CO_2 emission rates. In this respect, CAFE and CO_2 standards are unlike, for example, safety standards and traditional vehicle emissions standards. CAFE and CO_2 standards apply to the average fuel economy levels and CO_2 emission rates achieved by manufacturers' entire fleets of vehicles produced for sale in the U.S. Safety standards apply on a vehicle-by-vehicle basis, such that every single vehicle produced for sale in the U.S. must, on its own, comply with minimum FMVSS. Similarly, criteria pollutant emissions standards are applied on a per-vehicle basis, such that every vehicle produced for sale in the U.S. must, on its own, comply with all applicable emissions standards. When first mandating CAFE standards in the 1970s, Congress specified a more flexible averaging-based approach that allows some vehicles to "under comply" (i.e., fall short of the overall flat standard, or fall short of their target under attribute-based standards) as long as a manufacturer's overall fleet is in compliance.

The required CAFE level applicable to a given fleet in a given model year is determined by calculating the production-weighted harmonic average of fuel economy targets applicable to specific vehicle model configurations in the fleet, as follows:

$$CAFE_{required} = \frac{\sum_i PRODUCTION_i}{\sum_i \frac{PRODUCTION_i}{TARGET_{FE,i}}}$$

where

$CAFE_{required}$ is the CAFE level the fleet is required to achieve,

i refers to specific vehicle model/configurations in the fleet,

$PRODUCTION_i$ is the number of model configuration *i* produced for sale in the U.S., and

$TARGET_{FE,i}$ the fuel economy target (as defined above) for model configuration *i*.

Similarly, the required average CO_2 level applicable to a given fleet in a given model year is determined by calculating the production-weighted average (not harmonic) of CO_2 targets applicable to specific vehicle model configurations in the fleet, as follows:

$$CO2_{required} = \frac{\sum_i PRODUCTION_i \times TARGET_{CO2,i}}{\sum_i PRODUCTION_i}$$

where

$CO2_{required}$ is the average CO_2 level the fleet is required to achieve,

i refers to specific vehicle model/configurations in the fleet,

$PRODUCTION_i$ is the number of model configuration *i* produced for sale in the U.S., and

$TARGET_{CO2,i}$ is the CO_2 target (as defined above) for model configuration *i*.

Section VI.A.1 describes the advantages of attribute standards, generally. Section VI.A.2 explains the agencies' specific decision to use vehicle footprint as the attribute over which to vary stringency for past and current rules. Section VI.A.3 discusses the policy considerations in selecting the specific mathematical function. Section VI.A.4 discusses the methodologies used to develop current attribute-based standards, and the agencies' current proposal to continue to do so for MYs 2021-2026. Section VI.A.5 discusses the methodologies used to reconsider the mathematical function for the proposed standards.

1. Why Attribute-Based Standards, and What Are The Benefits?

Under attribute-based standards, every vehicle model has fuel economy and CO_2 targets, the levels of which depend on the level of that vehicle's determining attribute (for the MYs 2021-2026 standards, footprint is the determining attribute, as discussed below). The manufacturer's fleet average CAFE performance is calculated by the harmonic production-weighted average of those targets, as defined below:

$$Required\ CAFE = \frac{\sum_{i \in OEM\ Fleet} Production_i}{\sum_{i \in OEM\ Fleet} \frac{Production_i}{Target_i}}$$

Here, *i* represents a given model[262] in a manufacturer's fleet, *$Production_i$* represents the U.S. production of that model, and *$Target_i$* represents the target as defined by the attribute-based standards. This means no vehicle is required to meet its target; instead, manufacturers are free to balance improvements however they deem best within (and, given credit transfers, at least partially across) their fleets.

Because CO_2 is on a gram per mile basis rather a mile per gallon basis, harmonic averaging is not necessary when calculating required CO_2 levels:

$$Required\ CO_2 = \frac{\sum_{i \in OEM\ Fleet} Production_i \times Target_i}{\sum_{i \in OEM\ Fleet} Production_i}$$

The idea is to select the shape of the mathematical function relating the standard to the fuel economy-related attribute to reflect the trade-offs manufacturers face in producing more of

[262] If a model has more than one footprint variant, here each of those variants is treated as a unique model, *i*, since each footprint variant will have a unique target.

that attribute over fuel efficiency (due to technological limits of production and relative demand of each attribute). If the shape captures these trade-offs, every manufacturer is more likely to continue adding fuel-efficient technology across the distribution of the attribute within their fleet, instead of potentially changing the attribute—and other correlated attributes, including fuel economy—as a part of their compliance strategy. Attribute-based standards that achieve this have several advantages.

First, assuming the attribute is a measurement of vehicle size, attribute-based standards help to at least partially reduce the incentive for manufacturers to respond to CAFE and CO_2 standards by reducing vehicle size in ways harmful to safety, as compared to "flat," non-attribute based standards.[263] Larger vehicles, in terms of mass and/or crush space, generally consume more fuel and produce more carbon dioxide emissions, but are also generally better able to protect occupants in a crash.[264] Because each vehicle model has its own target (determined by a size-related attribute), properly fitted attribute-based standards reduce the incentive to build smaller vehicles simply to meet a fleet-wide average, because smaller vehicles are subject to more stringent compliance targets.

Second, attribute-based standards, if properly fitted, provide automakers with more flexibility to respond to consumer preferences than do single-valued standards. As discussed above, a single-valued standard encourages a fleet mix with a larger share of smaller vehicles by creating incentives for manufacturers to use downsizing the average vehicle in their fleet (possibly through fleet mixing) as a compliance strategy, which may result in manufacturers building vehicles for compliance reasons that consumers do not want. Under a size-related, attribute-based standard, reducing the size of the vehicle for compliance's sake is a less-viable strategy because smaller vehicles have more stringent regulatory targets. As a result, the fleet mix under such standards is more likely to reflect aggregate consumer demand for the size-related attribute used to determine vehicle targets.

Third, attribute-based standards provide a more equitable regulatory framework across heterogeneous manufacturers who may each produce different shares of vehicles along attributes correlated with fuel economy.[265] An industry-wide single-value CAFE standard imposes disproportionate cost burden and compliance challenges on manufacturers who produce more vehicles with attributes inherently correlated with lower fuel economy—i.e. manufacturers who

---

[263] The 2002 NAS Report described at length and quantified the potential safety problem with average fuel economy standards that specify a single numerical requirement for the entire industry. *See* Transportation Research Board and National Research Council. 2002. *Effectiveness and Impact of Corporate Average Fuel Economy (CAFE) Standards*, Washington, DC: The National Academies Press ("2002 NAS Report") at 5, finding 12, available at https://www.nap.edu/catalog/10172/effectiveness-and-impact-of-corporate-average-fuel-economy-cafe-standards (last accessed June 15, 2018). Ensuing analyses, including by NHTSA, support the fundamental conclusion that standards structured to minimize incentives to downsize all but the largest vehicles will tend to produce better safety outcomes than flat standards.

[264] Bento, A., Gillingham, K., & Roth, K. (2017). The Effect of Fuel Economy Standards on Vehicle Weight Dispersion and Accident Fatalities. NBER Working Paper No. 23340. Available at http://www.nber.org/papers/w23340 (last accessed June 15, 2018).

[265] 2002 NAS Report at 4-5, finding 10.

produce, on average, larger vehicles. As discussed above, retaining flexibility for manufacturers to produce vehicles which respect heterogeneous market preferences is an important consideration. Since manufacturers may target different markets as a part of their business strategy, ensuring that these manufacturers do not incur a disproportionate share of the regulatory cost burden is an important part of conserving consumer choices within the market.

Industry commenters generally supported attribute-based standards, while other commenters questioned their benefits. IPI argued that preserving the current vehicle mix was not necessarily desirable or necessary for consumer welfare, and suggested that some vehicle downsizing in the fleet might be beneficial both for safety and for compliance.[266] IPI also argued that compliance credit trading would "help smooth out any disproportionate impacts on certain manufacturers" and "ensure that manufacturers with relatively efficient fleets still have an incentive to continue improving fuel economy (in order to generate credits)"[267] Similarly, citing Ito and Sallee, Kathryn Doolittle commented that "…Ito and Sallee (2018) have found ABR ["attribute-based regulations"] inefficient in cost when juxtaposed with flat standard with compliance trading."[268]

The agencies have considered these comments. IPI incorrectly characterizes the agencies' prior statements as claims that it is important to preserve the current vehicle mix. EPA and NHTSA have never claimed, and are not today claiming that it is important to preserve the current fleet mix. The agencies have said, and are today reiterating, that it is reasonable to expect that reducing the tendency of standards to distort the market should reduce at least part of the tendency of standards to reduce consumer welfare. Or, more concisely, it is better to work with the market than against it. Single-value (aka flat) CAFE standards in place from the 1970s through 2010 were clearly distortionary. Recognizing this, the National Academy of Sciences recommended in 2002 that NHTSA adopt attribute-based CAFE standards. NHTSA did so in 2006, for light trucks produced starting MY 2008. As mentioned above, in 2007, Congress codified the requirement for attribute-based passenger car and light truck CAFE standards. Agreeing with this history, premise, and motivation, EPA has also adopted attribute-based CO_2 standards. None of this is to say the agencies consider it important to hold fleet mix constant. Rather, the agencies expect that, compared to flat standards, attribute-based standards can allow the market—including fleet mix—to better follow its natural course, and all else equal, consumer acceptance is likely to be greater if the market does so.

The agencies also disagree with comments implying that compliance credit trading can address all of the market distortion that flat standards would entail. Evidence thus far suggests that trading is fragmented, with some manufacturers apparently willing to trade only with some other specific manufacturers. The Ito and Sallee article cited by one commenter is a highly idealized theoretical construction, with the authors noting, *inter alia*, that their model "assumes

---

[266] IPI, NHTSA-2018-0067-12362, at 14-15.
[267] IPI, NHTSA-2018-0067-12362, at 14.
[268] Doolittle, K, NHTSA-2018-0067-7411. *See also* Ito, K and Sallee, J. "The Economics of Attribute-Based Regulation: Theory and Evidence from Fuel Economy Standards." *The Review of Economics and Statistics* (2018), 100(2), pp. 319-36.

perfect competition."[269] Its findings regarding comparative economic efficiency of flat- and attribute-based standards are, therefore, merely hypothetical, and the agencies find little basis in recent transactions to suggest the compliance credit trading market reflects the authors' idealized assumptions. Even if the agencies did expect credit trading markets to operate as in an idealized textbook example, basing the structure of standards on the presumption of perfect trading would not be appropriate. FCA commented that "…when flexibilities are considered while setting targets, they cease to be flexibilities and become simply additional technology mandates," and the Alliance commented, similarly, that "the Agencies should keep 'flexibilities' as optional ways to comply and not unduly assume that each flexibility allows additional stringency of footprint-based standards."[270] Perhaps recognizing this reality, Congress has barred NHTSA from considering manufacturers' ability to use compliance credits (even credits earned and used by the same OEM, much less credits traded between OEMs). As discussed further in Section VIII.A.2, EPA believes that while credit trading may be a useful flexibility to reduce the overall costs of the program, it is important to set standards in a way that does not rely on credit purchasing availability as a compliance mechanism.

Considering these comments and realities, considering EPCA's requirement for attribute-based CAFE standards, and considering the benefits of regulatory harmonization, the agencies are, again, finalizing attribute-based CAFE and CO_2 standards rather than, for either program, finalizing flat standards.

2. Why Footprint as the Attribute?

It is important that the CAFE and CO_2 standards be set in a way that does not unnecessarily incentivize manufacturers to respond by selling vehicles that are less safe. Vehicle size is highly correlated with vehicle safety—for this reason, it is important to choose an attribute correlated with vehicle size (mass or some dimensional measure). Given this consideration, there are several policy and technical reasons why footprint is considered to be the most appropriate attribute upon which to base the standards, even though other vehicle size attributes (notably, curb weight) are more strongly correlated with fuel economy and tailpipe CO_2 emissions.

First, mass is strongly correlated with fuel economy; it takes a certain amount of energy to move a certain amount of mass. Footprint has some positive correlation with frontal surface area, likely a negative correlation with aerodynamics, and therefore fuel economy, but the relationship is less deterministic. Mass and crush space (correlated with footprint) are both important safety considerations. As discussed below, NHTSA's research of historical crash data indicates that holding footprint constant, and decreasing the mass of the largest vehicles, will result in a net positive safety impact to drivers overall, while holding footprint constant and decreasing the mass of the smallest vehicles will result in a net decrease in fleetwide safety. Properly fitted footprint-based standards provide little, if any, incentive to build smaller footprint

[270] FCA, NHTSA-2018-0067-11943, at 6; Alliance, NHTSA-2018-0067-12073, Full Comment Set, at 40, fn. 82

vehicles to meet CAFE and CO_2 standards, and therefore help minimize the impact of standards on overall fleet safety.

Second, it is important that the attribute not be easily manipulated in a manner that does not achieve the goals of EPCA or other goals, such as safety. Although weight is more strongly correlated with fuel economy than footprint, there is less risk of artificial manipulation (i.e., changing the attribute(s) to achieve a more favorable target) by increasing footprint under footprint-based standards than there would be by increasing vehicle mass under weight-based standards. It is relatively easy for a manufacturer to add enough weight to a vehicle to decrease its applicable fuel economy target a significant amount, as compared to increasing vehicle footprint, which is a much more complicated change that typically takes place only with a vehicle redesign.

Further, some commenters on the MY 2011 CAFE rulemaking were concerned that there would be greater potential for such manipulation under multi-attribute standards, such as those that also depend on weight, torque, power, towing capability, and/or off-road capability. As discussed in NHTSA's MY 2011 CAFE final rule,[271] it is anticipated that the possibility of manipulation is lowest with footprint-based standards, as opposed to weight-based or multi-attribute-based standards. Specifically, standards that incorporate weight, torque, power, towing capability, and/or off-road capability in addition to footprint would not only be more complex, but by providing degrees of freedom with respect to more easily adjusted attributes, they could make it less certain that the future fleet would actually achieve the projected average fuel economy and CO_2 levels. This is not to say that a footprint-based system eliminates manipulation, or that a footprint-based system eliminates the possibility that manufacturers will change vehicles in ways that compromise occupant protection, but footprint-based standards achieve the best balance among affected considerations.

Several stakeholders commented on whether vehicular footprint is the most suitable attribute upon which to base standards. IPI commented that "… footprint-based standards may be unnecessary to respect consumer preferences, may negatively impact safety, and may be overall inefficient. Several arguments call into question the footprint-based approach, but a particularly important one is that large vehicles can impose a negative safety externality on other drivers."[272] IPI commented, further, that the agencies should consider the relative merits of other vehicle attributes, including vehicle fuel type, suggesting that it would be more difficult for manufacturers to manipulate a flatter standard or one "differentiated by fuel type."[273] Similarly, Michalek and Whitefoot recommended "that the agencies reexamine automaker response to the footprint-based standards to determine if adjustments should be made to avoid inducing increases to vehicle size."[274]

[271] *See* 74 FR at 14359 (Mar. 30, 2009).
[272] IPI, NHTSA-2018-0067-12362, at 12.
[273] IPI, NHTSA-2018-0067-12362, at 13 *et seq*.
[274] Michalek, J. and Whitefoot, K., NHTSA-2018-0067-11903, at 13.

Conversely, ICCT commented that "the switch to footprint-based CAFE and [CO_2] standards has been widely credited with diminishing safety concerns with efficiency standards. Footprint standards encourage larger vehicles with wider track width, which reduces rollovers, and longer wheelbase, which increases the crush space and reduces deceleration forces for both vehicles in a two-vehicle collision."[275] Similarly, BorgWarner commented that "the use of a footprint standard not only provides greater incentive for mass reduction, but also encourages a larger footprint for a given vehicle mass, thus providing increased safety for a given mass vehicle,"[276] and the Aluminum Association commented footprint based standards drive "fuel-efficiency improvement across all vehicle classes," "eliminate the incentive to shift fleet volume to smaller cars which has been shown to slightly decrease safety in vehicle-to-vehicle collisions," and provide "an incentive for reducing weight in the larger vehicles, where weight reduction is of the most benefit for societal safety," citing Ford's aluminum-intensive F150 pickup truck as an example.[277] NADA urged the agencies to continue basing standards on vehicle footprint, as doing so "serves both to require and allow OEMs to build more fuel-efficient vehicles across the broadest possible light-duty passenger car and truck spectrum,"[278] and UCS commented that footprint-based standards "increase consumer choice, ensuring that the vehicles available for purchase in every vehicle class continue to get more efficient."[279] Furthermore, regarding concerns that footprint-based standards may be susceptible to manipulation, the Alliance commented that "the data above [from Novation Analytics] shows there are no systemic footprint increases (or any type of target manipulation) occurring."[280] While FCA's comments supported this Alliance comment, FCA commented further that, lacking some utility-related vehicle attributes such as towing capability, 4-wheel-drive, and ride height, "it is clear the footprint standard does not fully account for pickup truck capability and the components needed such as larger powertrains, greater mass and frontal area," and requested the agencies "correct LDT standards to reflect the current market preference for capability over efficiency, and introduce mechanisms into the regulation that can adjust for efficiency and capability tradeoffs that footprint standards currently ignore."[281]

When first electing to adopt footprint-based standards, NHTSA carefully considered other alternatives, including vehicle mass and "shadow" (overall width multiplied by overall length). Compared to both of these other alternatives, footprint is much less susceptible to gaming, because while there is some potential to adjust track width, wheelbase is more expensive to change, at least outside a planned vehicle redesign. EPA agreed with NHTSA's assessment, nothing has changed the relative merits of at least these three potential attributes, and nothing in the evolution of the fleet demonstrates that footprint-based standards are leading manufacturers to increase the footprint of specific vehicle models by more than they would in response to customer demand. Also, even if footprint-based standards are encouraging some increases in vehicle size, NHTSA continues to maintain, and EPA to agree, that such increases should tend to

improve overall highway safety rather than degrading it. Regarding FCA's request that the agencies adopt an approach that accounts for a wider range of vehicle attributes related to both vehicle fuel economy and customer-facing vehicle utility, the agencies are concerned that doing so could further complicate already-complex standards and also lead to unintended consequences. For example, it is not currently clear how a multi-attribute approach would appropriately balance emphasis between vehicle attributes (e.g., how much relative fuel consumption should be attributed to, respectively, vehicle footprint, towing capacity, drive type, and ground clearance). Also, basing standards on, in part, ground clearance would encourage manufacturers to increase ride height, potentially increasing the frequency of vehicle rollover crashes. Regarding IPI's recommendation that fuel type be included as a vehicle attribute for attribute-based standards, the agencies note that both CAFE and CO_2 standards already account for fuel type in the procedures for measuring fuel economy levels and CO_2 emission rates, and for calculating fleet average CAFE and CO_2 levels.

Therefore, having considered public comments on the choice of vehicle attributes for CAFE and CO_2 standards, the agencies are finalizing standards that, as proposed, are defined in terms of vehicle footprint.

3. What Mathematical Function Should be Used to Specify Footprint-based Standards?

In requiring NHTSA to "prescribe by regulation separate average fuel economy standards for passenger and non-passenger automobiles based on 1 or more vehicle attributes related to fuel economy and express each standard in the form of a mathematical function," EPCA/EISA provides ample discretion regarding not only the selection of the attribute(s), but also regarding the nature of the function. The CAA provides no specific direction regarding CO_2 regulation, and EPA has continued to harmonize this aspect of its CO_2 regulations with NHTSA's CAFE regulations. The relationship between fuel economy (and CO_2 emissions) and footprint, though directionally clear (*i.e.*, fuel economy tends to decrease and CO_2 emissions tend to increase with increasing footprint), is theoretically vague, and quantitatively uncertain; in other words, not so precise as to *a priori* yield only a single possible curve.

The decision of how to specify this mathematical function therefore reflects some amount of judgment. The function can be specified with a view toward achieving different environmental and petroleum reduction goals, encouraging different levels of application of fuel-saving technologies, avoiding any adverse effects on overall highway safety, reducing disparities of manufacturers' compliance burdens, and preserving consumer choice, among other aims. The following are among the specific technical concerns and resultant policy tradeoffs the agencies have considered in selecting the details of specific past and future curve shapes:

- Flatter standards (i.e., curves) increase the risk that both the size of vehicles will be reduced, potentially compromising highway safety, and reducing any utility consumers would have gained from a larger vehicle.
- Steeper footprint-based standards may create incentives to upsize vehicles, potentially oversupplying vehicles of certain footprints beyond what consumers would naturally demand, and thus increasing the possibility that fuel savings and CO_2 reduction benefits will be forfeited artificially.

- Given the same industry-wide average required fuel economy or CO_2 standard, flatter standards tend to place greater compliance burdens on full-line manufacturers.
- Given the same industry-wide average required fuel economy or CO_2 standard, dramatically steeper standards tend to place greater compliance burdens on limited-line manufacturers (depending of course, on which vehicles are being produced).
- If cutpoints are adopted, given the same industry-wide average required fuel economy, moving small-vehicle cutpoints to the left (*i.e.*, up in terms of fuel economy, down in terms of CO_2 emissions) discourages the introduction of small vehicles, and reduces the incentive to downsize small vehicles in ways that could compromise overall highway safety.
- If cutpoints are adopted, given the same industry-wide average required fuel economy, moving large-vehicle cutpoints to the right (*i.e.*, down in terms of fuel economy, up in terms of CO_2 emissions) better accommodates the design requirements of larger vehicles—especially large pickups—and extends the size range over which downsizing is discouraged.

4. What Mathematical Functions Have Been Used Previously, and Why?

Notwithstanding the aforementioned discretion under EPCA/EISA, data should inform consideration of potential mathematical functions, but how relevant data is defined and interpreted, and the choice of methodology for fitting a curve to that data, can and should include some consideration of specific policy goals. This section summarizes the methodologies and policy concerns that were considered in developing previous target curves (for a complete discussion see the 2012 FRIA).

As discussed below, the MY 2011 final curves followed a constrained logistic function defined specifically in the final rule.[282] The MYs 2012-2021 final standards and the MYs 2022-2025 augural standards are defined by constrained linear target functions of footprint, as shown below:[283]

$$Target = \frac{1}{\min\left(\max\left(c * Footprint + d, \frac{1}{a}\right), \frac{1}{b}\right)}$$

Here, *Target* is the fuel economy target applicable to vehicles of a given footprint in square feet (*Footprint*). The upper asymptote, *a*, and the lower asymptote, *b,* are specified in

[282] *See* 74 Fed. Reg. 14196, 14363-14370 (Mar. 30, 2009) for NHTSA discussion of curve fitting in the MY 2011 CAFE final rule.
[283] The right cutpoint for the light truck curve was moved further to the right for MYs 2017-2021, so that more possible footprints would fall on the sloped part of the curve. In order to ensure that, for all possible footprints, future standards would be at least as high as MY 2016 levels, the final standards for light trucks for MYs 2017-2021 is the maximum of the MY 2016 target curves and the target curves for the give MY standard. This is defined further in the 2012 final rule. *See* 77 Fed. Reg. 62624, at 62699-700 (Oct. 15, 2012).

mpg; the reciprocal of these values represent the lower and upper asymptotes, respectively, when the curve is instead specified in gallons per mile (gpm). The slope, *c*, and the intercept, *d*, of the linear portion of the curve are specified as gpm per change in square feet, and gpm, respectively.

The min and max functions will take the minimum and maximum values within their associated parentheses. Thus, the max function will first find the maximum of the fitted line at a given footprint value and the lower asymptote from the perspective of gpm. If the fitted line is below the lower asymptote it is replaced with the floor, which is also the minimum of the floor and the ceiling by definition, so that the target in mpg space will be the reciprocal of the floor in mpg space, or simply, *a*. If, however, the fitted line is not below the lower asymptote, the fitted value is returned from the max function and the min function takes the minimum value of the upper asymptote (in gpm space) and the fitted line. If the fitted value is below the upper asymptote, it is between the two asymptotes and the fitted value is appropriately returned from the min function, making the overall target in mpg the reciprocal of the fitted line in gpm. If the fitted value is above the upper asymptote, the upper asymptote is returned is returned from the min function, and the overall target in mpg is the reciprocal of the upper asymptote in gpm space, or *b*.

In this way curves specified as constrained linear functions are specified by the following parameters:

$$a = \text{upper limit (mpg)}$$
$$b = \text{lower limit (mpg)}$$
$$c = \text{slope (gpm per sq. ft.)}$$
$$d = \text{intercept (gpm)}$$

The slope and intercept are specified as gpm per sq. ft. and gpm instead of mpg per sq. ft. and mpg because fuel consumption and emissions appear roughly linearly related to gallons per mile (the reciprocal of the miles per gallon).

a) NHTSA in MY 2008 and MY 2011 CAFE (Constrained Logistic)

For the MY 2011 CAFE rule, NHTSA estimated fuel economy levels by footprint from the MY 2008 fleet after normalization for differences in technology,[284] but did not make adjustments to reflect other vehicle attributes (*e.g.*, power-to-weight ratios). Starting with the technology-adjusted passenger car and light truck fleets, NHTSA used minimum absolute deviation (MAD) regression without sales weighting to fit a logistic form as a starting point to develop mathematical functions defining the standards. NHTSA then identified footprints at which to apply minimum and maximum values (rather than letting the standards extend without limit) and transposed these functions vertically (*i.e.*, on a gallons-per-mile basis, uniformly downward) to produce the promulgated standards. In the preceding rule, for MYs 2008-2011 light truck standards, NHTSA examined a range of potential functional forms, and concluded

[284] *See* 74 Fed. Reg. 14196, 14363-14370 (Mar. 30, 2009) for NHTSA discussion of curve fitting in the MY 2011 CAFE final rule.

that, compared to other considered forms, the constrained logistic form provided the expected and appropriate trend (decreasing fuel economy as footprint increases), but avoided creating "kinks" the agency was concerned would provide distortionary incentives for vehicles with neighboring footprints.[285]

b) MYs 2012-2016 Standards (Constrained Linear)

For the MYs 2012-2016 rule, potential methods for specifying mathematical functions to define fuel economy and CO_2 standards were reevaluated. These methods were fit to the same MY 2008 data as the MY 2011 standard. Considering these further specifications, the constrained logistic form, if applied to post-MY 2011 standards, would likely contain a steep mid-section that would provide undue incentive to increase the footprint of midsize passenger cars.[286] A range of methods to fit the curves would have been reasonable, and a minimum absolute deviation (MAD) regression without sales weighting on a technology-adjusted car and light truck fleet was used to fit a linear equation. This equation was used as a starting point to develop mathematical functions defining the standards. Footprints were then identified at which to apply minimum and maximum values (rather than letting the standards extend without limit). Finally, these constrained/piecewise linear functions were transposed vertically (*i.e.*, on a gpm or CO_2 basis, uniformly downward) by multiplying the initial curve by a single factor for each MY standard to produce the final attribute-based targets for passenger cars and light trucks described in the final rule.[287] These transformations are typically presented as percentage improvements over a previous MY target curve.

c) MYs 2017 and Beyond Standards (Constrained Linear)

The mathematical functions finalized in 2012 for MYs 2017 and beyond changed somewhat from the functions for the MYs 2012-2016 standards. These changes were made both to address comments from stakeholders, and to consider further some of the technical concerns and policy goals judged more preeminent under the increased uncertainty of the impacts of finalizing and proposing standards for model years further into the future.[288] Recognizing the concerns raised by full-line OEMs, it was concluded that continuing increases in the stringency of the light truck standards would be more feasible if the light truck curve for MYs 2017 and beyond was made steeper than the MY 2016 truck curve and the right (large footprint) cut-point was extended only gradually to larger footprints. To accommodate these considerations, the 2012 final rule finalized the slope fit to the MY 2008 fleet using a sales-weighted, ordinary least-squares regression, using a fleet that had technology applied to make the technology application across the fleet more uniform, and after adjusting the data for the effects of weight-to-footprint. Information from an updated MY 2010 fleet was also considered to support this decision. As the

A "kink," as used here, is a portion of the curve where a small change in footprint results in a disproportionally large change in stringency.

[287] *See generally* 74 Fed. Reg. at 49491-96; 75 FR at 25357-62.
[288] The MYs 2012-2016 final standards were signed April 1st, 2010—putting 6.5 years between its signing and the last affected model year, while the MYs 2017-2021 final standards were signed August 28th, 2012—giving just more than nine years between signing and the last affected final standards.

curve was vertically shifted (with fuel economy specified as mpg instead of gpm or CO_2 emissions) upwards, the right cutpoint was progressively moved for the light truck curves with successive model years, reaching the final endpoint for MY 2021.

5. Reconsidering the Mathematical Functions for Today's Rulemaking

a) Why is it Important to Reconsider the Mathematical Functions?

By shifting the developed curves by a single factor, it is assumed that the underlying relationship of fuel consumption (in gallons per mile) to vehicle footprint does not change significantly from the model year data used to fit the curves to the range of model years for which the shifted curve shape is applied to develop the standards. However, it must be recognized that the relationship between vehicle footprint and fuel economy is not necessarily constant over time; newly developed technologies, changes in consumer demand, and even the curves themselves could influence the observed relationships between the two vehicle characteristics. For example, if certain technologies are more effective or more marketable for certain types of vehicles, their application may not be uniform over the range of vehicle footprints. Further, if market demand has shifted between vehicle types, so that certain vehicles make up a larger share of the fleet, any underlying technological or market restrictions which inform the average shape of the curves could change. That is, changes in the technology or market restrictions themselves, or a mere re-weighting of different vehicles types, could reshape the fit curves.

For the above reasons, the curve shapes were reconsidered in the proposal using the newest available data from MY 2016. With a view toward corroboration through different techniques, a range of descriptive statistical analyses were conducted that do not require underlying engineering models of how fuel economy and footprint might be expected to be related, and a separate analysis that uses vehicle simulation results as the basis to estimate the relationship from a perspective more explicitly informed by engineering theory was conducted as well. Despite changes in the new vehicle fleet both in terms of technologies applied and in market demand, the underlying statistical relationship between footprint and fuel economy has not changed significantly since the MY 2008 fleet used for the 2012 final rule; therefore, EPA and NHTSA proposed to continue to use the curve shapes fit in 2012. The analysis and reasoning supporting this decision follows.

b) What Statistical Analyses Did EPA and NHTSA Consider?

In considering how to address the various policy concerns discussed above, data from the MY 2016 fleet was considered, and a number of descriptive statistical analyses (i.e., involving observed fuel economy levels and footprints) using various statistical methods, weighting schemes, and adjustments to the data to make the fleets less technologically heterogeneous were performed. There were several adjustments to the data that were common to all of the statistical analyses considered.

With a view toward isolating the relationship between fuel economy and footprint, the few diesels in the fleet were excluded, as well as the limited number of vehicles with partial or full electric propulsion; when the fleet is normalized so that technology is more homogenous, application of these technologies is not allowed. This is consistent with the methodology used in the 2012 final rule.

The above adjustments were applied to all statistical analyses considered, regardless of the specifics of each of the methods, weights, and technology level of the data, used to view the relationship of vehicle footprint and fuel economy. Table V-1, below, summarizes the different assumptions considered and the key attributes of each. The analysis was performed considering all possible combinations of these assumptions, producing a total of eight footprint curves.

Table V-1 – Summary of Assumptions Considered in the Statistical Analysis of the Current Footprint-FE Relationship

Varying Assumptions	**Regression Type**		**Regression Weights**		**Technology Level**	
Alternatives Considered	**OLS**	**MAD**	**Production-weighted**	**Model-weighted**	**Current Technology**	**Max. Technology**
Details	Ordinary Least Squares Regression	Minimum Absolute Deviation Regression	Points weighted by production volumes of each model.	Equal weight for each model; collapses points with similar: footprint, FE, and curb weight.	Current MY 2016 tech., excluding: HEV, PHEV, BEV, and FCV.	Maximum tech. applied, excluding: HEV, PHEV, BEV, and FCV.
Key Attributes	Describes the average relationship between footprint and fuel economy; outliers can skew results.	Describes the median relationship between footprint and fuel economy; does not give outliers as much weight.	Tends towards higher-volume models; may systematically disadvantage manufacturers who produce fewer vehicles.	Tends towards the space of the joint distribution of footprint and FE with the most models; gives low-volume models equal weight.	Describes current market, including demand factors; may miss changes in curve shape due to advanced technology application.	Captures relationship with homogenous technology application; may miss varying demand considerations for different segments.

(1) Current Technology Level Curves

The "current technology" level curves exclude diesels and vehicles with electric propulsion, as discussed above, but make no other changes to each model year fleet. Comparing the MY 2016 curves to ones built under the same methodology from previous model year fleets shows whether the observed curve shape has changed significantly over time as standards have become more stringent. Importantly, these curves will include any market forces which make technology application variable over the distribution of footprint. These market forces will not be present in the "maximum technology" level curves: by making technology levels homogenous, this variation is removed. The current technology level curves built using both regression types and both regression weight methodologies from the MY 2008, MY 2010, and MY 2016 fleets, shown in more detail in Chapter 4.4.2.1 of the PRIA, support the curve slopes finalized in the 2012 final rule. The curves built from most methodologies using each fleet generally shift, but remain very similar in slope. This suggests that the relationship of footprint to fuel economy, including both technology and market limits, has not significantly changed.

(2) Maximum Technology Level Curves

As in prior rulemakings, technology differences between vehicle models were considered to be a significant factor producing uncertainty regarding the relationship between fuel consumption and footprint. Noting that attribute-based standards are intended to encourage the application of additional technology to improve fuel efficiency and reduce CO_2 emissions across the distribution of footprint in the fleet, approaches were considered in which technology application is simulated for purposes of the curve fitting analysis in order to produce fleets that are less varied in technology content. This approach helps reduce "noise" (i.e., dispersion) in the plot of vehicle footprints and fuel consumption levels and identify a more technology-neutral relationship between footprint and fuel consumption. The results of updated analysis for maximum technology level curves are also shown in Chapter 4.4.2.2 of the PRIA. Especially if vehicles progress over time toward more similar size-specific efficiency, further removing variation in technology application both better isolates the relationship between fuel consumption and footprint and further supports the curve slopes finalized in the 2012 final rule.

c) What Other Methodologies Were Considered?

The methods discussed above are descriptive in nature, using statistical analysis to relate observed fuel economy levels to observed footprints for known vehicles. As such, these methods are clearly based on actual data, answering the question "how does fuel economy appear to be related to footprint?" However, being independent of explicit engineering theory, they do not answer the question "how might one expect fuel economy to be related to footprint?" Therefore, as an alternative to the above methods, an alternative methodology was also developed and applied that, using full-vehicle simulation, comes closer to answering the second question, providing a basis either to corroborate answers to the first, or suggest that further investigation could be important.

As discussed in the 2012 final rule, several manufacturers have confidentially shared with the agencies what they described as "physics-based" curves, with each OEM showing significantly different shapes for the footprint-fuel economy relationships. This variation suggests that manufacturers face different curves given the other attributes of the vehicles in their fleets (i.e., performance characteristics) and/or that their curves reflected different levels of technology application. In reconsidering the shapes of the proposed MYs 2021-2026 standards, a similar estimation of physics-based curves leveraging third-party simulation work form Argonne National Laboratories (Argonne) was developed. Estimating physics-based curves better ensures that technology and performance are held constant for all footprints; augmenting a largely statistical analysis with an analysis that more explicitly incorporates engineering theory helps to corroborate that the relationship between fuel economy and footprint is in fact being characterized.

Tractive energy is the amount of energy it will take to move a vehicle.[289] Here, tractive energy effectiveness is defined as the share of the energy content of fuel consumed which is converted into mechanical energy and used to move a vehicle—for internal combustion engine (ICE) vehicles, this will vary with the relative efficiency of specific engines. Data from Argonne simulations suggest that the limits of tractive energy effectiveness are approximately 25 percent for vehicles with internal combustion engines which do not possess integrated starter generator, other hybrid, plug-in, pure electric, or fuel cell technology.

A tractive energy prediction model was also developed to support today's proposal. Given a vehicle's mass, frontal area, aerodynamic drag coefficient, and rolling resistance as inputs, the model will predict the amount of tractive energy required for the vehicle to complete the Federal test cycle. This model was used to predict the tractive energy required for the average vehicle of a given footprint[290] and "body technology package" to complete the cycle. The body technology packages considered are defined in Table V-2, below. Using the absolute tractive energy predicted and tractive energy effectiveness values spanning possible ICE engines, fuel economy values were then estimated for different body technology packages and engine tractive energy effectiveness values.

Table V-2 – Summary of Body Technology Packages Considered for Tractive Energy Analysis

Body Tech. Package	Mass Reduction Level	Aerodynamics Level	Roll Resistance Level
1	0%	0%	0%
2	0%	10%	10%
3	10%	10%	10%
4	10%	15%	20%
5	15%	20%	20%

Chapter 6 of the PRIA show the resultant CAFE levels estimated for the vehicle classes Argonne simulated for this analysis, at different footprint values and by vehicle "box." Pickups are considered 1-box, hatchbacks and minivans are 2-box, and sedans are 3-box. These estimates are compared with the MY 2021 standards finalized in 2012. The general trend of the simulated data points follows the pattern of the previous MY 2021 standards for all technology packages and tractive energy effectiveness values presented in the PRIA. The tractive energy curves are intended to validate the curve shapes against a physics-based alternative, and the analysis suggests that the curve shapes track the physical relationship between fuel economy and tractive energy for different footprint values.

---

[289] Thomas, J. "Drive Cycle Powertrain Efficiencies and Trends Derived from EPA Vehicle Dynamometer Results," *SAE Int. J. Passeng. Cars - Mech. Syst.* 7(4):2014, doi:10.4271/2014-01-2562. Available at https://www.sae.org/publications/technical-papers/content/2014-01-2562/ (last accessed June 15, 2018).

[290] The mass reduction curves used elsewhere in this analysis were used to predict the mass of a vehicle with a given footprint, body style box, and mass reduction level. The 'Body style Box' is 1 for hatchbacks and minivans, 2 for pickups, and 3 for sedans, and is an important predictor of aerodynamic drag. Mass is an essential input in the tractive energy calculation.

Physical limitations are not the only forces manufacturers face; their success is dependent upon producing vehicles that consumers desire and will purchase. For this reason, in setting future standards, the analysis will continue to consider information from statistical analyses that do not homogenize technology applications in addition to statistical analyses which do, as well as a tractive energy analysis similar to the one presented above.

The relationship between fuel economy and footprint remains directionally discernable but quantitatively uncertain. Nevertheless, each standard must commit to only one function. Approaching the question "how is fuel economy related to footprint" from different directions and applying different approaches has given EPA and NHTSA confidence that the function applied here appropriately and reasonably reflects the relationship between fuel economy and footprint.

The agencies invited comments on this conclusion and the supporting analysis. IPI raised concerns that "…several dozen models (mostly subcompacts and sports cars) fall in the 30-40 square feet range, which are all subject to the same standards" and that "manufacturers of these models may have an incentive to decrease footprints as a compliance strategy, since doing so would not trigger more stringent standards."[291] NHTSA and EPA agree that, all else equal, downsizing the smallest cars (e.g., Chevrolet Spark, Ford Fiesta, Mini Cooper, Mazda MX-5, Porsche 911, Toyota Yaris) would most likely tend to degrade overall highway safety. At the same time, as discussed above, the agencies recognize that small vehicles do appear attractive to some market segments (although obviously the Ford Fiesta and Porsche 911 compete in different segments). Therefore, there is a tension between on one hand, avoiding standards that unduly encourage safety-eroding downsizing and, on the other, avoiding standards that unduly penalize the market for small vehicles. The agencies examined this issue, and note that the market for the smallest vehicles has not evolved at all as estimated in the analysis supporting the 2012 final rule, and attribute this more to fuel prices and consumer demand for larger vehicles than to attribute-based CAFE and CO_2 standards. For example, the market for vehicles with footprints less than 40 square foot was about 45 percent smaller in MY 2017 than in MY 2010. The agencies also found that among the smallest vehicle models produced throughout MYs 2010-2017, most have become larger, not smaller. For example, while the Mazda MX-5's footprint decreased by 0.1 square foot (0.3 percent) during that time, the MY 2017 versions of the Mini Cooper, Smart fortwo, Porsche 911, and Toyota Yaris had larger footprints than in MY 2010. With the market for very small vehicles shrinking, and with manufacturers not evidencing a tendency to make the smallest vehicles even smaller, the agencies are satisfied that it would be unwise to change the target functions such that targets never stop becoming more stringent as vehicle footprint becomes ever smaller, because doing so could further impede an already-shrinking market.

[291] IPI, NHTSA-2018-0067-12362, p. 14.

B. No-action Alternative

As in the proposal, the No-Action Alternative applies the augural CAFE and final CO_2 targets announced in 2012 for MYs 2021-2025.[292] For MY 2026, this alternative applies the same targets as for MY 2025. The carbon dioxide equivalent of air conditioning refrigerant leakage credits, nitrous oxide, and methane emissions are included for compliance with the EPA standards for all model years under the no-action alternative.[293]

[292] https://www.govinfo.gov/content/pkg/CFR-2014-title40-vol19/pdf/CFR-2014-title40-vol19-sec86-1818-12.pdf
[293] EPA regulations use a different but mathematically equivalent approach to specify targets. Rather than using a function with nested minima and maxima functions, EPA regulations specify requirements separately for different ranges of vehicle footprint. Because these ranges reflect the combined application of the listed minima, maxima, and linear functions, it is mathematically equivalent and more efficient to present the targets as in this Section.

In comments on the DEIS, CBD *et al*. indicated that it was appropriate for NHTSA to use the augural CAFE standards as the baseline No Action regulatory alternative.[294] However, CARB commented that the baseline regulatory alternative should include CARB's ZEV mandate, in part because EPA must consider "other regulations promulgated by EPA or other government entities," and, according to CARB, there will be much more vehicle electrification in the future as manufacturers respond to market demand and also work to comply with the ZEV mandate.[295] Similarly, EPA's Science Advisory Board recommended—despite the action taken in the One National Program Action—that the baseline include state ZEV mandates "to be consistent with policies that would prevail in the absence of the rule change."[296] EPA's Science Advisory Board further recommended including sensitivity analyses with different penetration rates of ZEVs.

On the other hand, arguing for consideration of standards less stringent than those proposed in the NPRM, Walter Kreucher commented that rather than using the augural standards as the baseline, "a better approach would be to assume a clean sheet of paper and start from the existing 2016MY fleet and its associated standards as the baseline using 0%/year increases for both passenger cars and light trucks for MYs 2017-2026."[297] Similarly, AVE argued that because previously-promulgated standards for MYs 2018-2021 already present a significant challenge that "will likely require almost every automaker to continue using credits for compliance,... AVE believes this rulemaking should reset …the current compliance baseline for cars and light trucks at MY 2018…"[298] BorgWarner commented similarly that "Beginning in MY 2018, standards should be reset to the levels the industry actually achieved. For MY 2018 and beyond, succeeding model year targets should be set with an annual rate of improvement defined by the slope of improvement the industry has achieved over the last six years.… Based on these data, our analysis suggests the most reasonable and logical rate of improvement falls between 2.0% to 2.6% for cars and trucks. Additionally, a single rate of improvement for the combined fleet should be considered."[299]

The No-Action Alternative represents expectations regarding the world in the absence of a proposal, accounting for applicable laws already in place. Although manufacturers are already making significant use of compliance credits toward compliance with even MY 2017 standards, the agencies are obligated to evaluate regulatory alternatives against the standards already in place through MY 2025. Similarly, even though manufacturers are already producing electric vehicles, EPA and NHTSA appropriately excluded California's ZEV mandate from the No-Action alternative for the NPRM, for several reasons. First, the ZEV mandate is not Federal law; second, as described in the proposal and subsequently finalized in regulatory text, the ZEV mandate is expressly and impliedly preempted by EPCA; third, EPA proposed to withdraw the waiver of CAA preemption in the NPRM and subsequently finalized this withdrawal. Accordingly, the agencies have, therefore, appropriately excluded the ZEV mandate from the

No-Action alternative. However, as discussed below, the agencies' analysis does account for the potential that under every regulatory alternative, including the No-Action Alternative, vehicle electrification could increase in the future, especially if batteries become less expensive as gasoline becomes more expensive.

C. Action Alternatives

1. Alternatives in Final Rule

Table V-5 below shows the different alternatives evaluated in today's notice.

Table V-5 – Regulatory Alternatives Currently under Consideration

Alternative	Change in stringency
Baseline/ No-Action	MY 2021 standards remain in place; MYs 2022-2025 augural CAFE standards are finalized and CO_2 standards remain unchanged; MY 2026 standards are set at MY 2025 levels
1 (Proposed)	Existing standards through MY 2020, then 0%/year increases for both passenger cars and light trucks, for MYs 2021-2026
2	Existing standards through MY 2020, then 0.5%/year increases for both passenger cars and light trucks, for MYs 2021-2026
3 (Preferred)	Existing standards through MY 2020, then 1.5%/year increases for both passenger cars and light trucks, for MYs 2021-2026
4	Existing standards through MY 2020, then 1%/year increases for passenger cars and 2%/year increases for light trucks, for MYs 2021-2026
5	Existing standards through MY 2021, then 1%/year increases for passenger cars and 2%/year increases for light trucks, for MYs 2022-2026
6	Existing standards through MY 2020, then 2%/year increases for passenger cars and 3%/year increases for light trucks, for MYs 2021-2026
7	Existing standards through MY 2021, then 2%/year increases for passenger cars and 3%/year increases for light trucks, for MYs 2022-2026

With one exception, the alternatives considered in the NPRM included the changes in stringency for the above alternatives. Alternative 3, the preferred alternative, is newly included for today's notice.[300]

Regulations regarding implementation of NEPA requires agencies to "rigorously explore and objectively evaluate all reasonable alternatives, and for alternatives which were eliminated from detailed study, briefly discuss the reasons for their having been eliminated."[301] This does not amount to a requirement that agencies evaluate the widest conceivable spectrum of alternatives. For example, a State considering adding a single travel lane to a preexisting section

[300] As the agencies indicated in the NPRM, they were considering and taking comment "on a wide range of alternatives and have specifically modeled eight alternatives." 83 FR at 42990 (Aug. 24, 2018). The preferred alternative in this final rule was within the range of alternatives considered in the proposal, although it was not specifically modeled at that time. This issue is discussed in further detail below.
[301] 40 CFR 1502.14.

of highway would not be required to consider adding three lanes, or to consider dismantling the highway altogether.

Among thousands of individual comments that mentioned the proposed standards very generally, some comments addressed the range and definition of these regulatory alternatives in specific terms, and these specific comments include comments on the stringency, structure, and particular provisions defining the set of regulatory alternatives under consideration.

As discussed throughout today's notice, the agencies have updated and otherwise revised many aspects of the analysis. The agencies have also reconsidered whether the set of alternatives studied in detail should be expanded to include standards less stringent than the proposal's preferred alternative, or to include standards more stringent than the proposal's no-action alternative. On one hand, comments from Walter Kreucher and AVE cited above indicate the agencies should consider relaxing standards below MY 2020 levels, and CEI challenged the agencies' failure to include less-stringent alternatives in the following comments on this question:

> DOT failed to consider the possibility of freezing CAFE at an even more lenient standard than currently exists, nor did it consider making its proposed freeze take effect sooner than MY 2020. However, as DOT's own analysis strongly indicates, doing so would lead to even greater benefits and an even greater reduction in CAFE-related deaths and injuries. In short, DOT's failure to consider this possibility is arbitrary and capricious. It has an opportunity to remedy this in its final rule, and it should do so by selecting a standard that is even more lenient than the one it proposed.… It should have gone beyond its original set of alternatives and examined less stringent ones as well – until it found one that, for some reason or another, failed to produce greater safety benefits or failed to meet the statutory factors.[302]

On the other hand, a coalition of ten environmental advocacy organizations stated that the agencies should consider alternatives more stringent than those defining the baseline no action alternative, arguing that in light of CEQ guidance and the 2018 IPCC report on climate change, "the increasing danger, increasing urgency, and increasing importance of vehicle emissions all rationally counsel for strengthening emission standards."[303] CBD *et al.* observe that "none of these alternatives [considered in the NPRM] increases fuel economy in comparison with the No Action Alternative, none conserves energy…" and go on to assert that "none represents maximum feasible CAFE standards."[304] Similarly, EDF commented that "…given its clear statutory directive to maximize fuel savings, NHTSA should have considered a range of alternatives that would be more protective than the existing standards,"[305] and three State

agencies in Minnesota commented that "more stringent standards are consistent with EPCA's purpose of energy conservation and the CAA's purpose of reducing harmful air pollutants."[306] The North Carolina Department of Environmental Quality acknowledged the agencies' determination in the proposal that alternatives beyond the augural standards might be economically impracticable, but nevertheless argued that "alternatives that exceed the stringency of the current standards are consistent with EPCA's purpose"[307] In oral testimony before the agencies, the New York State Attorney General also indicated that the agencies should consider alternatives more stringent than the augural standards.[308] A coalition of States and cities commented that "at a minimum, the existing standards should be left in place, but EPA should also consider whether to make the standards more stringent, not less, just as it has done in prior proposals."[309] More specifically, through International Mosaic, some individuals commented that the agencies must "fully and publicly consider a few options that require at least a seven annual percent [sic] improvement in vehicle fleet mileage."[310] In comments on the DEIS, CBD, *et al.* went further, commenting that "NHTSA's most stringent alternative must be set at no lower than a 9 percent improvement per year."[311] Most manufacturers who commented on stringency did not identify specific regulatory alternatives that the agencies should consider, although Honda suggested that standards be set to increase in stringency at 5 percent annually for both passenger cars and light trucks throughout model years 2021-2026.[312,313]

The agencies carefully considered these comments to expand the range of stringencies to be evaluated as possible candidates for promulgation. To inform this consideration, the agencies used the CAFE model to examine a progression of stringencies extending outside the range presented in the proposal and draft EIS, and as a point of reference, using a case that reverts to MY 2018 standards starting in MY 2021. Scenarios included in this initial screening exercise ranged as high as increasing annually at 9.5 percent during MYs 2021-2026, reaching average CAFE and CO_2 requirements of 66 mpg and 120 g/mi, respectively. Results of this analysis are presented in the following tables and charts. Focusing on MY 2029, the tables show average required and achieved CAFE (as mpg) and CO_2 (as g/mi) levels for each scenario, along with average per-vehicle costs (in 2018 dollars, relative to retaining MY 2017 technologies). The proposed (0%/0%), final (1.5%/1.5%), and baseline augural standards are shown in bold type. The charts present the same results on a percentage basis, relative to values shown below for the scenario that reverts to MY 2018 standards starting in MY 2021.

[312] Honda, NHTSA-2018-0067-12019, EPA-HQ-OAR-2018-0283, at 54.
[313] In model year 2021, the baseline standards for passenger cars and light trucks increase by about 4% and 6.5%, respectively, relative to standards for model year 2020. Depending on the composition of the future new vehicle fleet (i.e., the footprints and relative market shares of passenger cars and light trucks), this amounts to an overall average stringency increase of about 5.5% relative to model year 2020.

For example, reverting to the MY 2018 CAFE standards starting in MY 2021 yields an average CAFE requirement of 35 mpg by MY 2029, with the industry exceeding that standard by 5 mpg at an average cost of $1,255 relative to MY 2017 technology. Under the augural standards, the MY 2029 requirement increases to 47 mpg, the average compliance margin falls to 1 mpg, and the average cost increases to $2,770. In other words, compared to the scenario that reverts to MY 2018 stringency starting in MY 2021, the augural standards increase stringency by 34 percent (from 35 to 47 mpg), increase average fuel economy by 20 percent (from 40 to 48 mpg), and increase costs by 121 percent (from $1,255 to $2,770).

As indicated in the following two charts, the reality of diminishing returns clearly applies in both directions. On one hand, relaxing stringency below the proposed standards by reverting to MY 2018 or MY 2019 standards reduces average MY 2029 costs by only modest amounts ($54-$121). As discussed in Section VIII, the agencies' updated analysis indicates that the proposed standards would not be maximum feasible considering the EPCA/EISA statutory factors, and would not be appropriate under the CAA after considering the appropriate factors. If further relaxation of standards appeared likely to yield more significant cost reductions, it is conceivable that such savings could outweigh further foregoing of energy and climate benefits. However, this screening analysis does not show dramatic cost reductions. Therefore, the agencies did not include these two less stringent alternatives in the detailed analysis presented in Section VII.

On the other hand, increases in stringency beyond the baseline augural standards show relative costs continuing to accrue much more rapidly than relative CAFE and CO_2 improvements. As discussed below in Section VIII, even the no action alternative is already well beyond levels that can be supported under the CAA and EPCA. If further stringency increases appeared likely to yield more significant additional energy and environmental benefits, it is conceivable that these could outweigh these significant additional cost increases. However, this screening analysis shows no dramatic relative acceleration of energy and environmental benefits. Therefore, the agencies did not include stringencies beyond the augural standards in the detailed analysis presented in Section VII.

Table V-6 – Average MY 2029 Required and Achieved CAFE Levels (mpg) and Average MY 2029 Per-Vehicle Costs (2018 $) under a Range of Stringency Increases

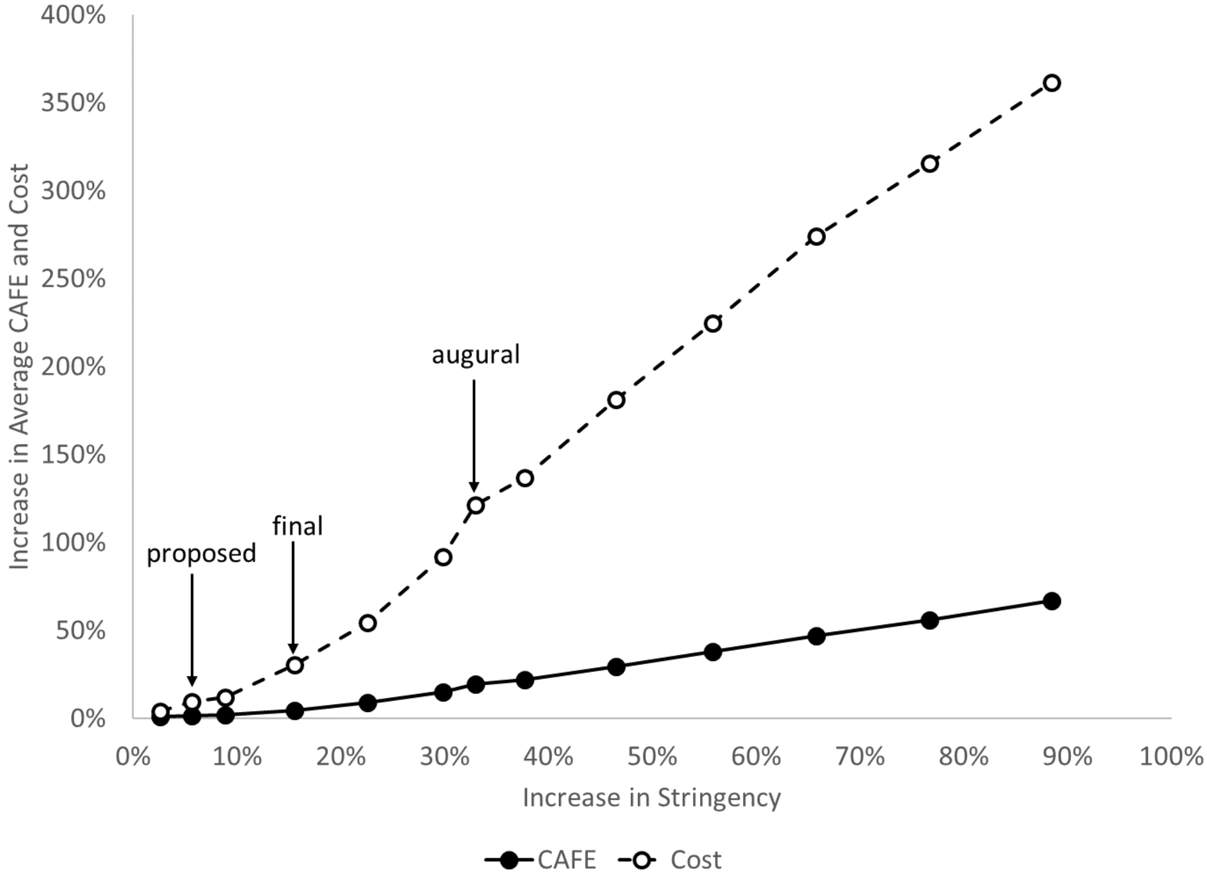

Figure V-1 – Decrease in Average CO_2 and Increase in Cost (MY 2029) versus Increase in Stringency (as Average Required g/mi in MY 2029) of CO_2 Standards

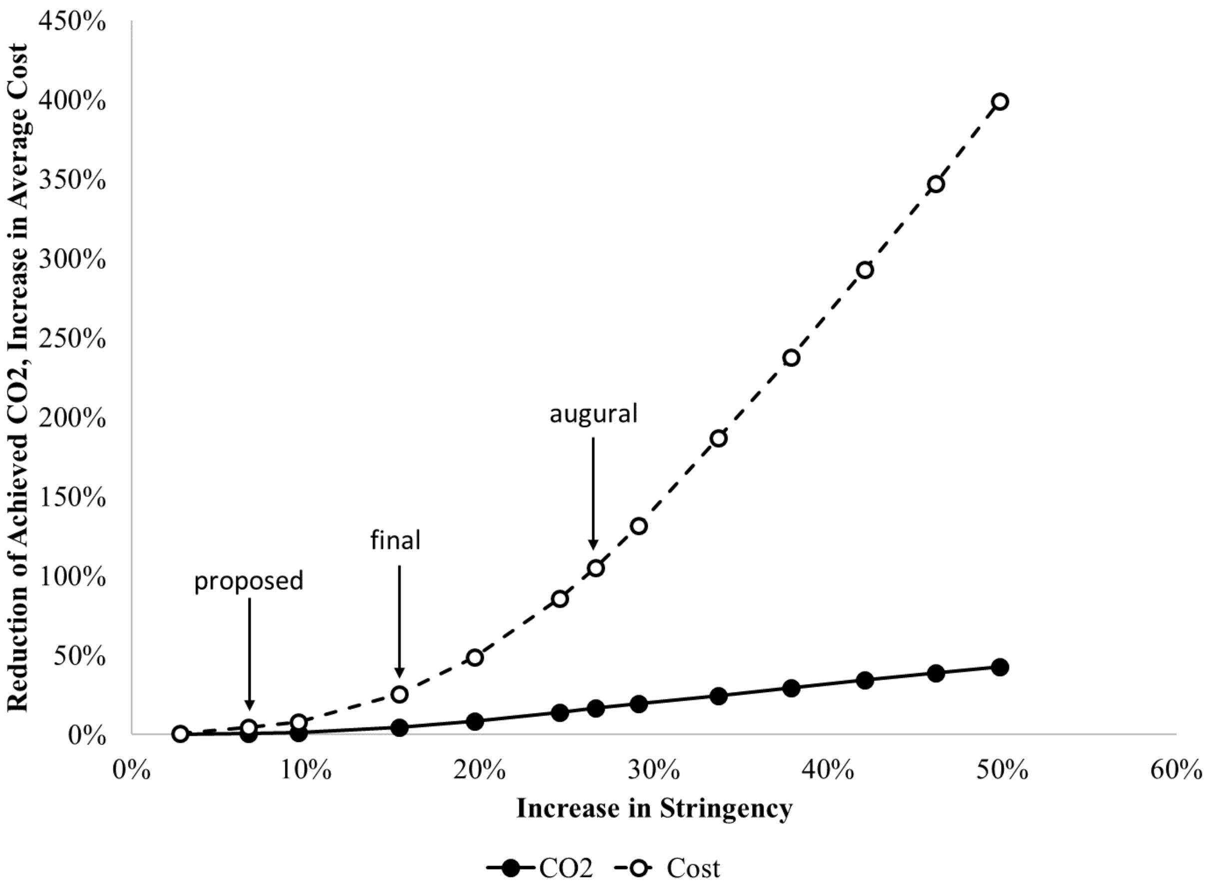

Figure V-2 – CO_2 Reduction and Cost Increases versus (MY 2029) Increase in Stringency

Specific to model year 2021, some commenters argued that EPCA's lead time requirement prohibits NHTSA from revising CAFE standards for model year 2021.[314] Regarding the revision of standards for model year 2021, NHTSA did consider EPCA's lead time requirement, and determined that while the agency would need to finalize a stringency increase at least 18 months before the beginning of the first affected model year, the agency can finalize a stringency decrease closer (or even after) the beginning of the first affected model year. The agency's reasoning is explained further in Section VIII. Therefore, NHTSA did not change regulatory alternatives to avoid any relaxation of stringency in model year 2021.

The Auto Alliance stated that "the truck increase rate should be no greater than the car rate of increase and should be the 'equivalent task' per fleet."[315] Supporting these Alliance comments, FCA elaborated by commenting that "(1) in MY2017, the latest data we have available, most trucks have a larger gap to standards than cars, and (2) all of the truck segments

---

[314] State of California, et al., NHTSA-2018-0067-11735, at 78.; CBD, et al., NHTSA-2018-0067-12000, Appendix A, at 66.; National Coalition for Advanced Transportation, NHTSA-2018-0067-11969, at 46.
[315] Alliance, NHTSA-2018-0067-12073, at 7-8

are challenged because consumers are placing a greater emphasis on capability than fuel economy."[316] Similarly, Ford commented that "… the rates of increase in the stringency of the standards should remain equivalent between passenger cars and light duty trucks."[317] Other commenters expressed general support for equalizing the rates at which the stringencies of passenger car and light truck standards increase.[318]

For the final rule, the agencies have added an alternative in which stringency for both cars and trucks increases at 1.5 percent. This is consistent with comments received requesting that both fleets' standards increase in stringency by the same amount, and 1.5 percent represents a rate of increase within the range of rates of increase considered in the NPRM.

Throughout the NPRM, the agencies described their consideration as covering a range of alternatives.[319] The preferred alternative for this final rule, an increase in stringency of 1.5 percent for both cars and trucks, falls squarely within the range of alternatives proposed by the agencies.

The NPRM alternatives were bounded on the upper end by the baseline/no action alternative, and the proposed alternative on the lower end (0 percent per year increase in stringency for both cars and trucks). For passenger cars, the agencies considered a range of stringency increases between 0 percent and 2 percent per year for passenger cars, in addition to the baseline/no action alternative. For light trucks, the agencies considered a range of stringency increases between 0 percent and 3 percent per year, in addition to the baseline/no action alternative.

The agencies considered the same range of alternatives for this final rule. As with the proposal, the alternatives for stringency are bounded on the upper end by the baseline/no action alternative and on the lower end by 0 percent per year increases for both passenger cars and light trucks. Consistent with the proposal, for this final rule, the agencies considered stringency increases of between 0 and 2 percent per year for passenger cars and between 0 and 3 percent per year for light trucks, in addition to the baseline/no action alternative.

[319] 83 FR at 42986 (Aug. 24, 2018) (explaining, in "Summary" section of NPRM, that "comment is sought on a range of alternatives discussed throughout this document"); *id.* at 42988 (stating that the agencies are "taking comment on a wide range of alternatives, including different stringencies and retaining existing CO_2 standards and the augural CAFE standards"); 42990 ("As explained above, the agencies are taking comment on a wide range of alternatives and have specifically modeled eight alternatives (including the proposed alternative) and the current requirements (i.e., baseline/no action)."); 43197 ("[T]oday's notice also presents the results of analysis estimating impacts under a range of other regulatory alternatives the agencies are considering."); 43229 (explaining that "technology availability, development and application, if it were considered in isolation, is not necessarily a limiting factor in the Administrator's selection of which standards are appropriate within the range of the Alternatives presented in this proposal."); 43369 ("As discussed above, a range of regulatory alternatives are being considered.").

While it was not specifically modeled in the NPRM, the new preferred alternative of an increase in stringency of 1.5 percent for both cars and trucks was well within the range of alternatives considered. The proposal described the alternatives specifically modeled as options for the agencies, but also gave notice that they did not limit the agencies in selecting from among the range of alternatives under consideration.[320]

The agencies explained in the proposal that they were "taking comment on a wide range of alternatives and have specifically modeled eight alternatives."[321] As with the proposal, for the final rule, the agencies specifically modeled the upper and lower bounds of the baseline/no action alternative and 0 percent per year stringency increases for both passenger cars and light trucks. In both the proposal and the final rule, the agencies also modeled a stringency increase of 2 percent per year for passenger cars and 3 percent per year for light trucks, as well as a variety of other specific increases between 0 and 2 percent for passenger cars and 0 and 3 percent for light trucks.

The specific alternatives the agencies modeled for the final rule reflect their consideration of public comments. As discussed above, multiple commenters expressed support for equalizing the rates at which the stringencies of passenger car and light truck standards increase. To help the agencies evaluate alternatives that include the same stringency increase for passenger cars and light trucks, three of the seven alternatives (in addition to the baseline/no action alternative) that the agencies specifically modeled for the final rule included the same stringency increase for passenger cars and light trucks. This includes the new preferred alternative of an increase in stringency of 1.5 percent for both cars and trucks. This alternative, and all others specifically modeled for the final rule, falls within the range of alternatives for stringency considered by the agencies in the proposal.

Beyond these stringency provisions discussed in the NPRM, the agencies also sought comment on a number of additional compliance flexibilities for the programs, as discussed in Section IX.

2. Additional Alternatives Suggested by Commenters

Beyond the comments discussed above regarding the shapes of the functions defining fuel economy and CO_2 targets, regarding the inclusion of non-CO_2 emissions, and regarding the stringencies to be considered, the agencies also received a range of other comments regarding regulatory alternatives.

---

[320] *See, e.g.*, 83 FR at 43003 (Aug. 24, 2018) ("These alternatives were examined because they will be considered as options for the final rule. The agencies seek comment on these alternatives, seek any relevant data and information, and will review responses. That review could lead to the selection of one of the other regulatory alternatives for the final rule or some combination of the other regulatory alternatives (e.g., combining passenger cars standards from one alternative with light truck standards from a different alternative)."); *id.* at 43229 (describing a factor relevant to "the Administrator's selection of which standards are appropriate within the range of the Alternatives presented in this proposal").
[321] 83 FR at 42990 (Aug. 24, 2018).

Some of these additional comments involved how CAFE and CO_2 standards compare to one another for any given regulatory alternative. With a view toward maximizing harmonization of the standards, the Alliance, supported by some of its members' individual comments, indicated that "to the degree flexibilities and incentives are not completely aligned between the CAFE and [CO_2] programs, there must be an offset in the associated footprint-based targets to account for those differences. Some areas of particular concerns are air conditioning refrigerant credits, and incentives for advanced technology vehicles. The Alliance urges the Agencies to seek harmonization of the standards and flexibilities to the greatest extent possible…."[322]

On the other hand, discussing consideration of compliance credits but making a more general argument, the NYU Institute for Policy Integrity commented that "…EPA is not allowed to set lower standards just for the sake of harmonization; to the contrary, full harmonization may be inconsistent with EPA's statutory responsibilities."[323] Similarly, ACEEE argued that "any consideration of an extension or expansion of credit provisions under the [carbon dioxide] or CAFE standards program should take as a starting point the assumption that the additional credits will allow the stringency of the standards to be increased."[324]

EPCA's requirement that NHTSA set standards at the maximum feasible levels is separate and "wholly independent" from the CAA's requirement, per *Massachusetts v. EPA*, that EPA issue regulations addressing pollutants that EPA has determined endanger public health and welfare.[325] Nonetheless, as recognized by the Supreme Court, "there is no reason to think the two agencies cannot both administer their obligations and yet avoid inconsistency."[326] This conclusion was reached despite the fact that EPCA has a range of very specific requirements about how CAFE standards are to be structured, how manufacturers are to comply, what happens when manufacturers are unable to comply, and how NHTSA is to approach setting standards, and despite the fact that the CAA has virtually no such requirements. This means that while nothing about either EPCA or the CAA, much less the combination of the two, guarantees "harmonization" defining "One National Program," the agencies are expected to be able to work out the differences.

Since tailpipe CO_2 standards are *de facto* fuel economy standards, the more differences there are between CO_2 and CAFE standards and compliance provisions, the more challenging it is for manufacturers to plan year-by-year production that responses to both, and the more difficult it is for affected stakeholders and the general public to understand regulation in this space. Therefore, even if the two statutes, taken together, do not guarantee "full harmonization," steps toward greater harmonization help with compliance planning and transparency—and meet the expectations set forth by the Supreme Court that the agencies avoid inconsistencies.

326 *Id*.

The agencies have taken important steps toward doing so. For example, EPA has adopted separate footprint-based CO_2 standards for passenger cars and light trucks, and has redefined CAFE calculation procedures to introduce recognition for the application of real-world fuel-saving technology that is not captured with traditional EPA two-cycle compliance testing. Detailed aspects of both sets of standards and corresponding compliance provisions are discussed at length in Section IX. The agencies never set out with the primary goal of achieving "full harmonization," such that both sets of standards would lead each manufacturer to respond in exactly the same way in every model year.[327] For example, EPA did not adopt the EPCA requirement that domestic passenger car fleets each meet a minimum standard, or the EPCA cap on compliance credit transfers between passenger car fleets. On the other hand, EPA also did not adopt the EPCA civil penalty provisions that have allowed some manufacturers to pay civil penalties as an alternative method of meeting EPCA obligations. These and other differences provide that even if CAFE and CO_2 standards are "mathematically" harmonized, for any given manufacturer, the two sets of standards will not be identically burdensome in each model year. Inevitably, one standard will be more challenging than the other, varying over time, between manufacturers, and between fleets. This means manufacturers need to have compliance plans for both sets of standards.

In 2012, recognizing that EPCA provides no clear basis to address HFC, CH_4, or N_2O emissions directly, the agencies "offset" CO_2 targets from fuel economy targets (after converting the latter to a CO_2 basis) by the amounts of credit EPA anticipated manufacturers would, on average, earn in each model years by reducing A/C leakage and adopting refrigerants with reduced GWPs. In 2012, EPA assumed that by 2021, all manufacturers would be earning the maximum available credit, and EPA's analysis assumed that all manufacturers would make progress at the same rate. However, as discussed above, data highlighted in comments by Chemours, Inc., demonstrate that actual manufacturers' adoption of lower-GWP refrigerants thus far ranges widely, with some manufacturers (e.g., Nissan) having taken no such steps to move toward lower-GWP refrigerants, while others (e.g., JLR) have already applied lower-GWP refrigerants to all vehicles produced for sale in the U.S. Therefore, at least in practice, HFC provisions thus far continue to leave a gap (in terms of harmonization) between the two sets of standards. The proposal would have taken the additional step of decoupling provisions regarding HFC (i.e., A/C leakage credits), CH_4, and N_2O emissions from CO_2 standards, addressing these in separate regulations to be issued in a new proposal. As discussed above, EPA did not finalize this proposal. Accordingly, for the regulatory alternatives considered today, EPA has reinstated offsets of CO_2 targets from fuel economy targets, reflecting the assumption that all manufacturers will be earning the maximum available A/C leakage credit by MY 2021.

In addition to general comments on harmonization, the agencies received a range of comments on specific provisions—especially involving "flexibilities"—that may or may not impact harmonization. With a view toward encouraging further electrification, NCAT proposed

[327] Full harmonization would mean that, for example, if Ford would do some set of things over time in response to CAFE standards in isolation, it would do exactly the same things on exactly the same schedule in response to CO_2 standards in isolation.

that EPA extend indefinitely the exclusion of upstream emissions from electricity generation, and also extend and potentially restructure production multipliers for PHEVs, EVs, and FCVs.[328] On the other hand, connecting its comments back to the stringency of standards, NCAT also commented that "…expansion of compliance flexibilities in the absence of any requirement to improve [CO_2] reduction or fuel economy (as under the agencies' preferred option) could result in an effective deterioration of existing [CO_2] and fuel economy performance, as well as little or no effective support for advanced vehicle technology development or deployment."[329] Global Automakers indicated that the final rule "should include a package of programmatic elements that provide automakers with flexible compliance options that promote the full breadth of vehicle technologies," such options to include the extension of "advanced technology" production multipliers through MY 2026, the indefinite exclusion of emissions from electricity generation, the extension to passenger cars of credits currently granted for the application of "game changing" technologies (e.g., HEVs) only to full-size pickup trucks, an increase (to 15 g/mi) of the cap on credits for off-cycle technologies, an updated credit "menu" of off-cycle technologies, and easier process for handling applications for off-cycle credits.[330] The Alliance also called for expanded sales multipliers and a permanent exclusion of emissions from electricity generation.[331] Walter Kreucher recommended the agencies consider finalizing the proposed standards but also keeping the augural standards as "voluntary targets" to " provide compliance with the statutes and an aspirational goal for manufacturers."[332]

The agencies have carefully considered these comments, and have determined that the current suite of "flexibilities" generally provide ample incentive more rapidly to develop and apply advanced technologies and technologies that produce fuel savings and/or CO_2 reductions that would otherwise not count toward compliance. The agencies also share some stakeholders' concern that expanding these flexibilities could increase the risk of "gaming" that would make compliance less transparent and would unduly compromise energy and environmental benefits. Nevertheless, as discussed in Section IX, EPA is adopting new multiplier incentives for natural gas vehicles. EPA is also finalizing some changes to procedures for evaluating applications for off-cycle credits, and expects these changes to make this process more accurate and more efficient. Also, EPA is revising its regulations to not require manufacturers to account for upstream emissions associated with electricity use for electric vehicles and plug-in hybrid electric vehicles through model year 2026; compliance will instead be based on tailpipe emissions performance only and not include emissions from electricity generation until model year 2027. As discussed below, even with this change, and even accounting for continued increases in fuel prices and reductions in battery prices, BEVs are projected in this final rule analysis to continue to account for less than 5 percent of new light vehicle sales in the U.S. through model year 2026. To the extent that this projection turns out to reflect reality, this means that the impact of upstream emissions from electricity use on the projected CO_2 reductions associated with these standards would likely remain small. Regarding comments

suggesting that the augural standards should be finalized as "voluntary targets," the agencies have determined that having such targets exist alongside actual regulatory requirements would be, at best, unnecessary and confusing.

Beyond these additional proposals, some commenters' proposals clearly fell outside authority provided under EPCA or the CAA. Ron Lindsay recommended the agencies "consider postponing the rule changes until the U.S. can establish a legally binding national and international carbon budget and a binding mechanism to adhere to it."[333] EPCA requires NHTSA to issue standards for MY 2022 by April 1, 2020, and previously-issued EPA regulations commit EPA to revisiting MY 2021-2025 standards on a similar schedule. These statutory and regulatory provisions do not include a basis to delay decisions pending an international negotiation for which prospects and schedules are both unknown.

SCAQMD, supported by Shyam Shukla, indicated that the agencies should consider an alternative that keeps the waiver for California's CO_2 standards in place.[334] NCAT and the North Carolina DEQ offered similar comments and CBD, *et al.* commented that "among the set of more stringent alternatives that NEPA requires the agency to consider, NHTSA must include action alternatives that retain the standards California and other states have lawfully adopted."[335] As discussed above, the agencies recently issued a final rule addressing the issue of California's authority. NEPA does not require NHTSA to include action alternatives that cannot be lawfully realized.

International Mosiac commented that NHTSA's DEIS "is fatally flawed…because it does not consider any market-based alternatives (e.g., a 'cap and trade' type option)."[336] While EPCA/EISA does include very specific provisions regarding trading of CAFE compliance credits, the statute provides no authority for a broad-based cap-and-trade program involving other sectors. Similarly, Michalek, *et al.* wrote that "a more economically efficient approach of, taxing emissions and fuel consumption at socially appropriate levels would allow households to determine whether to reduce fuel consumption and emissions by driving less, by buying a vehicle with more fuel saving technologies, or by buying a smaller vehicle—or, alternatively, not to reduce fuel consumption and emissions at all but rather pay a cost based on the damages they cause. Forcing improvements only through one mechanism (fuel-saving technologies) increases the cost of achieving these outcomes."[337] While some economists would agree with these comments, Congress has provided no clear authority for NHTSA or EPA to implement either an emissions tax or a broad-based cap-and-trade program in which motor vehicles could participate.

3. Details of Alternatives Considered in Final Rule

a) Alternative 1

Alternative 1 holds the stringency of targets constant and MY 2020 levels through MY 2026.

Table V-8 – Characteristics of Alternative 1 – Passenger Cars

EPCA, as amended by EISA, requires that any manufacturer's domestically-manufactured passenger car fleet must meet the greater of either 27.5 mpg on average, or 92 percent of the average fuel economy projected by the Secretary for the combined domestic and non-domestic passenger automobile fleets manufactured for sale in the U.S. by all manufacturers in the model year, which projection shall be published in the Federal Register when the standard for that model year is promulgated in accordance with 49 U.S.C. 32902(b).[338] Any time NHTSA establishes or changes a passenger car standard for a model year, the MDPCS for that model year must also be evaluated or re-evaluated and established accordingly. Thus, this final rule establishes the applicable MDPCS for MYs 2021-2026. Table V-22 lists the minimum domestic passenger car standards.

VI. Analytical Approach as Applied to Regulatory Alternatives

A. Overview of Methods

Like analyses accompanying the NPRM and past CAFE and CAFE/CO_2 rulemakings, the analysis supporting today's notice spans a range of technical topics, uses a range of different types of data and estimates, and applies several different types of computer models. The purpose of the analysis is not to determine the standards, but rather to provide information for consideration in doing so. The analysis aims to answer the question "what impacts might each of these regulatory alternatives have?"

Over time, NHTSA's and, more recently, NHTSA's and EPA's analyses have expanded to address an increasingly wide range of types of impacts. Today's analysis involves, among other things, estimating how the application of various combinations of technologies could

[338] 49 U.S.C. 32902(b)(4).

impact vehicles' costs and fuel economy levels (and CO_2 emission rates), estimating how vehicle manufacturers might respond to standards by adding fuel-saving technologies to new vehicles, estimating how changes in new vehicles might impact vehicle sales and operation, and estimating how the combination of these changes might impact national-scale energy consumption, emissions, highway safety, and public health. In addition, the EIS accompanying today's notice addresses impacts on air quality and climate. The analysis of these factors informs and supports both NHTSA's application of the statutory requirements governing the setting of "maximum feasible" fuel-economy standards under EPCA, including, among others, technological feasibility and economic practicability, and EPA's application of the CAA requirements for tailpipe emissions.

Supporting today's analysis, the agencies have brought to bear a variety of different types of data, a few examples of which include fuel economy compliance reports, historical sales and average characteristics of light-duty vehicles, historical economic and demographic measures, historical travel demand and energy prices and consumption, and historical measures of highway safety. Also supporting today's analysis, the agencies have applied several different types of estimates, a few examples of which include projections of the future cost of different fuel-saving technologies, projections of future GDP and the number of households, estimates of the "gap" between "laboratory" and on-road fuel economy, and estimates of the social cost of CO_2 emissions and petroleum "price shocks."

With a view toward transparency, repeatability, and efficiency, the agencies have used a variety of computer models to conduct the majority of today's analysis. For example, the agencies have applied DOE/EIA's National Energy Modeling System (NEMS) to estimate future energy prices, EPA's MOVES model to estimate tailpipe emission rates for ozone precursors and other criteria pollutants, DOE/Argonne's GREET model to estimate emission rates for "upstream" processes (*e.g.*, petroleum refining), and DOE/Argonne's Autonomie simulation tool to estimate the fuel consumption impacts of different potential combinations of fuel-saving technology. In addition, the EIS accompanying today's notice applies photochemical models to estimate air quality impacts, and applies climate models to estimate climate impacts of overall emissions changes.

Use of these different types of data, estimates, and models is discussed further below in the most closely relevant sections. For example, the agencies' use of NEMS is discussed below in the portion of Section VI that addresses the macroeconomic context, which includes fuel prices, and the agencies use of Autonomie is discussed in the portion of Section VI.B.3 that addresses the agencies' approach to estimating the effectiveness of various technologies (in reducing fuel consumption and CO_2 emissions).

Providing an integrated means to estimate both vehicle manufacturers' potential responses to CAFE or CO_2 standards and, in turn, many of the different potential direct results (*e.g.*, changes in new vehicle costs) and indirect impacts (*e.g.*, changes in rates of fleet turnover) of those responses, the CAFE Model plays a central role in the agencies' analysis supporting today's notice. The agencies used the specific models mentioned above to develop inputs to the CAFE model, such as fuel prices and emission factors. Outputs from the CAFE Model are discussed in Sections VII and VIII of this FRIA. The EIS accompanying today's notice makes use of the CAFE Model's estimates of changes in total emissions from light-duty vehicles, as well as corresponding changes in upstream emissions. These changes in emissions are included in the set of inputs to the models used to estimate air quality and climate impacts.

The remainder of this overview focuses on the CAFE Model. The purpose of this overview is not to provide a comprehensive technical description of the model,[339] but rather to give an overview of the model's functions, to explain some specific aspects not addressed elsewhere in today's notice, and to discuss some model aspects that were the subject of significant public comment. Some model functions and related comments are addressed in other parts of today's notice. For example, the model's handling of Autonomie-based fuel consumption estimates is addressed in the portion of Section VI.B.3 that discusses the agencies' application of Autonomie. The model documentation accompanying today's notice provides a comprehensive and detailed description of the model's functions, design, inputs, and outputs.

1. Overview of CAFE Model

The basic design of the CAFE Model is as follows: the system first estimates how vehicle manufacturers might respond to a given regulatory scenario, and from that potential compliance solution, the system estimates what impact that response will have on fuel consumption, emissions, and economic externalities. A regulatory scenario involves specification of the form, or shape, of the standards (*e.g.*, flat standards, or linear or logistic attribute-based standards), scope of passenger car and truck regulatory classes, and stringency of the CAFE and CO_2 standards for each model year to be analyzed.

Manufacturer compliance simulation and the ensuing effects estimation, collectively referred to as compliance modeling, encompass numerous subsidiary elements. Compliance simulation begins with a detailed user-provided initial forecast of the vehicle models offered for sale during the simulation period. The compliance simulation then attempts to bring each manufacturer into compliance with the standards defined by the regulatory scenario contained within an input file developed by the user. For example, a regulatory scenario may define CAFE or CO_2 standards that increase in stringency by 4 percent per year for 5 consecutive years.

The model applies various technologies to different vehicle models in each manufacturer's product line to simulate how each manufacturer might make progress toward compliance with the specified standard. Subject to a variety of user-controlled constraints, the model applies technologies based on their relative cost-effectiveness, as determined by several input assumptions regarding the cost and effectiveness of each technology, the cost of compliance (determined by the change in CAFE or CO_2 credits, CAFE-related civil penalties, or value of CO_2 credits, depending on the compliance program being evaluated and the effective-cost mode in use), and the value of avoided fuel expenses. For a given manufacturer, the compliance simulation algorithm applies technologies either until the manufacturer runs out of cost-effective technologies, until the manufacturer exhausts all available technologies, or, if the

[339] The CAFE Model is available at https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system with documentation and all inputs and outputs supporting today's notice.

manufacturer is assumed to be willing to pay civil penalties, until paying civil penalties becomes more cost-effective than increasing vehicle fuel economy. At this stage, the system assigns an incurred technology cost and updated fuel economy to each vehicle model, as well as any civil penalties incurred by each manufacturer. This compliance simulation process is repeated for each model year available during the study period.

This point marks the system's transition between compliance simulation and effects calculations. At the conclusion of the compliance simulation for a given regulatory scenario, the system contains multiple copies of the updated fleet of vehicles corresponding to each model year analyzed. For each model year, the vehicles' attributes, such as fuel types (*e.g.*, diesel, electricity), fuel economy values, and curb weights have all been updated to reflect the application of technologies in response to standards throughout the study period. For each vehicle model in each of the model year specific fleets, the system then estimates the following: lifetime travel, fuel consumption, carbon dioxide and criteria pollutant emissions, the magnitude of various economic externalities related to vehicular travel (*e.g.*, noise), and energy consumption (*e.g.*, the economic costs of short-term increases in petroleum prices). The system then aggregates model-specific results to produce an overall representation of modeling effects for the entire industry.

Different categorization schemes are relevant to different types of effects. For example, while a fully disaggregated fleet is retained for purposes of compliance simulation, vehicles are grouped by type of fuel and regulatory class for the energy, carbon dioxide, criteria pollutant, and safety calculations. Therefore, the system uses model-by-model categorization and accounting when calculating most effects, and aggregates results only as required for efficient reporting.

2. Representation of the Market

As a starting point, the model needs enough information to represent each manufacturer covered by the program. As discussed below in Section VI.B.1, the MY 2017 analysis fleet contains information about each manufacturer's:

- Vehicle models offered for sale—their current (*i.e.*, MY 2017) production volumes, manufacturer suggested retail prices (MSRPs), fuel saving technology content and other attributes (curb weight, drive type, assignment to technology class and regulatory class);
- Production considerations—product cadence of vehicle models (*i.e.*, schedule of model redesigns and "freshenings"), vehicle platform membership, degree of engine and/or transmission sharing (for each model variant) with other vehicles in the fleet; and
- Compliance constraints and flexibilities—preference for full compliance or penalty payment/credit application, willingness to apply additional cost-effective fuel saving technology in excess of regulatory requirements, projected applicable flexible fuel credits, and current credit balance (by model year and regulatory class) in first model year of simulation.

3. Representation of Fuel-Saving Technologies

The modeling system defines technology pathways for grouping and establishing a logical progression of technologies that can be applied to a vehicle. Technologies that share similar characteristics form cohorts that can be represented and interpreted within the CAFE Model as discrete entities. The following Table VI-1 shows the technologies available within the modeling system used for this final rule. Each technology is discussed in detail below. However, an understanding of the technologies considered and how they are defined in the model (*e.g.*, a 6-speed manual transmission is defined as “MT6”) is helpful for the following explanation of the compliance simulation and the inputs required for that simulation.

Table VI-1 – CAFE Model Technologies

Technology	Technology Description	Technology	Technology Description
SOHC	Single Overhead Camshaft Engine	CVT	Continuously Variable Transmission
DOHC	Double Overhead Camshaft Engine	CVTL2	CVT, Level 2
EFR	Improved Engine Friction Reduction	EPS	Electric Power Steering
VVT	Variable Valve Timing	IACC	Improved Accessories
VVL	Variable Valve Lift	CONV	Conventional Powertrain (Non-Electric)
SGDI	Stoichiometric Gasoline Direct Injection	SS12V	12V Micro-Hybrid (Stop-Start)
DEAC	Cylinder Deactivation	BISG	Belt Mounted Integrated Starter/Generator
TURBO1	Turbocharging and Downsizing, Level 1 (1.5271 bar)	SHEVP2	P2 Strong Hybrid/Electric Vehicle
TURBO2	Turbocharging and Downsizing, Level 2 (2.0409 bar)	SHEVPS	Power Split Strong Hybrid/Electric Vehicle
CEGR1	Cooled Exhaust Gas Recirculation, Level 1 (2.0409 bar)	P2HCR0	SHEVP2 with HCR0 Engine
ADEAC	Advanced Cylinder Deactivation	P2HCR1	SHEVP2 with HCR1 Engine
HCR0	High Compression Ratio Engine, Level 0	P2HCR2	SHEVP2 with HCR2 Engine
HCR1	High Compression Ratio Engine, Level 1	PHEV20	20-mile Plug-In Hybrid/Electric Vehicle with HCR Engine
HCR2	High Compression Ratio Engine, Level 2	PHEV50	50-mile Plug-In Hybrid/Electric Vehicle with HCR Engine
VCR	Variable Compression Ratio Engine	PHEV20T	20-mile Plug-In Hybrid/Electric Vehicle with Turbo Engine
VTG	Variable Turbo Geometry	PHEV50T	50-mile Plug-In Hybrid/Electric Vehicle with Turbo Engine
VTGE	Variable Turbo Geometry (Electric)	PHEV20H	PHEV20 with HCR Engine
TURBOD	Turbocharging and Downsizing with DEAC	PHEV50H	PHEV50 with HCR Engine
TURBOAD	Turbocharging and Downsizing with ADEAC	BEV200	200-mile Electric Vehicle
ADSL	Advanced Diesel	BEV300	300-mile Electric Vehicle
DSLI	Diesel Engine Improvements	FCV	Fuel Cell Vehicle

Technology	Technology Description	Technology	Technology Description
DSLIAD	Diesel Engine Improvements with ADEAC	LDB	Low Drag Brakes
CNG	Compressed Natural Gas Engine	SAX	Secondary Axle Disconnect
MT5	5-Speed Manual Transmission	ROLL0	Baseline Tires
MT6	6-Speed Manual Transmission	ROLL10	Low Rolling Resistance Tires, Level 1 (10% Reduction)
MT7	7-Speed Manual Transmission	ROLL20	Low Rolling Resistance Tires, Level 2 (20% Reduction)
AT5	5-Speed Automatic Transmission	AERO0	Baseline Aero
AT6	6-Speed Automatic Transmission	AERO5	Aero Drag Reduction, Level 1 (10% Reduction)
AT6L2	6-Speed Automatic Transmission, Level 2	AERO10	Aero Drag Reduction, Level 1 (10% Reduction)
AT7L2	7-Speed Automatic Transmission, Level 2	AERO15	Aero Drag Reduction, Level 1 (10% Reduction)
AT8	8-Speed Automatic Transmission	AERO20	Aero Drag Reduction, Level 2 (20% Reduction)
AT8L2	8-Speed Automatic Transmission, Level 2	MR0	Baseline Mass
AT8L3	8-Speed Automatic Transmission, Level 3	MR1	Mass Reduction, Level 1 (5% Reduction in Glider Weight)
AT9L2	9-Speed Automatic Transmission, Level 2	MR2	Mass Reduction, Level 2 (7.5% Reduction in Glider Weight)
AT10L2	10-Speed Automatic Transmission, Level 2	MR3	Mass Reduction, Level 3 (10% Reduction in Glider Weight)
AT10L3	10-Speed Automatic Transmission, Level 3	MR4	Mass Reduction, Level 4 (15% Reduction in Glider Weight)
DCT6	6-Speed Dual Clutch Transmission	MR5	Mass Reduction, Level 5 (20% Reduction in Glider Weight)
DCT8	8-Speed Dual Clutch Transmission	MR6	Mass Reduction, Level 6 (28.2% Reduction in Glider Weight)

These entities are then laid out into pathways (or paths), which the system uses to define relations of mutual exclusivity between conflicting sets of technologies. For example, as presented in the next section, technologies on the Turbo Engine path are incompatible with those on the HCR Engine or the Diesel Engine paths. As such, whenever a vehicle uses a technology from one pathway (*e.g.*, turbo), the modeling system immediately disables the incompatible technologies from one or more of the other pathways (*e.g.*, HCR and diesel).

In addition, each path designates the direction in which vehicles are allowed to advance as the modeling system evaluates specific technologies for application. Enforcing this directionality within the model ensures that a vehicle that uses a more advanced or more efficient technology (*e.g.*, AT8) is not allowed to "downgrade" to a less efficient option (*e.g.*, AT5). Visually, as portrayed in the charts in the sections that follow, this is represented by an arrow leading from a preceding technology to a succeeding one, where vehicles begin at the root of each path, and traverse to each successor technology in the direction of the arrows.

The modeling system incorporates twenty technology pathways for evaluation as shown below. Similar to individual technologies, each path carries an intrinsic application level that denotes the scope of applicability of all technologies present within that path, and whether the pathway is evaluated on one vehicle at a time, or on a collection of vehicles that share a common platform, engine, or transmission.

Table VI-2 – Technology Pathways

Technology Pathway	Application Level
Engine Configuration Path	Engine
Engine Improvements Path	Engine
Basic Engine Path	Engine
Turbo Engine Path	Engine
Advanced Cylinder Deactivation (ADEAC) Engine Path	Engine
High Compression Ratio (HCR) Engine Path	Engine
Variable Compression Ratio (VCR) Engine Path	Engine
Variable Turbo Geometry (VTG) Engine Path	Engine
Advanced Turbo Engine Path	Engine
Diesel Engine Path	Engine
Alternative Fuel Engine Path	Engine
Manual Transmission Path	Transmission
Automatic Transmission Path	Transmission
Electric Improvements Path	Vehicle
Electrification Path	Vehicle
Hybrid/Electric Path	Vehicle
Dynamic Load Reduction (DLR) Path	Vehicle
Low Rolling Resistance Tires (ROLL) Path	Vehicle
Aerodynamic Improvements (AERO) Path	Vehicle
Mass Reduction (MR) Path	Platform

Even though technology pathways outline a logical progression between related technologies, all technologies available to the system are evaluated concurrently and independently of each other. Once all technologies have been examined, the model selects a solution deemed to be most cost-effective for application on a vehicle. If the modeling system applies a technology that resides later in the pathway, it will subsequently disable all preceding technologies from further consideration to prevent a vehicle from potentially downgrading to a less advanced option. Consequently, the system skips any technology that is already present on a vehicle (either those that were available on a vehicle from the input fleet or those that were previously applied by the model). This "parallel technology" approach, unlike the "parallel path" methodology utilized in the preceding versions of the model, allows the system always to consider the entire set of available technologies instead of foregoing the application of potentially more cost-effective options that happen to reside further down the pathway.[340] This revised approach addresses comments summarized below, and allows the system to analyze all available technology options concurrently and independently of one other without having to first apply one or more "predecessor" technologies. For example, if model inputs are such that a 7-speed transmission is cost-effective, but not as cost-effective as an 8-speed transmission, the revised approach enables the model to skip over the 7-speed transmission entirely, whereas the NPRM version of the model might first apply the 7-speed transmission and then consider whether to proceed immediately to the 8-speed transmission. As such, the model's choices for evaluation of new technology solutions becomes slightly less restrictive, allowing it immediately to consider and apply more advanced options, and increasing the likelihood that the a globally optimum solution is selected.

Some commenters supported the agencies' use of such pathways in the simulation of manufacturers' potential application of technologies. As one of a dozen examples of CAFE model design elements that lead to the transparent representation of real-world factors, the Alliance highlighted "recognition of the need for manufacturers to follow 'technology' pathways that retain capital and implementation expertise, such as specializing in one type of engine or transmission instead of following an unconstrained optimization that would cause manufacturers to leap to unrelated technologies and show overly optimistic costs and benefits."[341] Similarly, Toyota commented that "the inertia of capital investments and engineering expertise dedicated to one compliance technology or set of technologies makes it unreasonable for manufacturers to immediately switch to another technology path."[342]

Other commenters cited the use of technology pathways as inherently overly restrictive. For example, as an example of "arbitrary model constraints," a coalition of commenters cited the fact the model "prohibit[s] manufacturers from switching vehicle technology pathways."[343] Also, EDF, UCS, and CARB cited the combination of technology pathways, decision making criteria, and model inputs as producing unrealistic results.[344] Regarding the technology pathways, specifically, EDF's consultant argued that the technology paths are not transparent, and cited the potential that specific paths may not necessarily be arranged in progression from least to most cost-effective—that "NHTSA ignores the cost of the technology when developing this list."[345] Relatedly, as EDF's consultant commented:

---

[340] Previous versions of the CAFE Model followed a "low-cost" first approach where the system would stop evaluating technologies residing within a given pathway as soon as the first cost-effective option within that path was reached.
[341] Alliance, NHTSA-2018-0067-12073, at 9.
[342] Toyota, NHTSA-2018-0067-12098, at 7.
[343] CBD, et al., NHTSA-2018-0067-12057, at 3.
[344] EDF, NHTSA-2018-0067-12108, Appendix A, at 57 *et seq.*; UCS, NHTSA-2018-0067-12039, Appendix, at 25 *et seq.*; Roush Industries, NHTSA-2018-0067-11984, at 5.
[345] EDF, NHTSA-2018-0067-12108, Appendix B, at 69.

> [T]he Volpe Model is not designed to look backwards along its technology paths. Thus, the opportunity to recover the expenditure of inefficient technology is missed. NHTSA might argue that a manufacturer will not invest in 10-speed transmissions, for example, and then return to an older design. Whether or not this is true in real life, such a view would put too much stake in the Volpe Model projections. The model simply projects what could be done, not what will be. Anyone examining the progression of technology and noting the reversion of transmission technology could easily modify the model inputs to avoid this. Also, if NHTSA evaluated combinations of technologies prior to entering them in the model piecemeal, it would automatically avoid such apparent problems.[346]

The agencies also received additional public comments on specific paths and specific interactions between paths (*e.g.*, involving engines and hybridization). These comments are addressed below.

The agencies have carefully considered these comments and the approach summarized below reflects some corresponding revision. As mentioned above, the CAFE model now approaches the technology paths in a such way that, faced with two cost-effective technologies on the same path, the model can proceed directly to the more advanced technology if that technology is the more cost effective of the two.

However, the agencies reject assertions that the model's use of technology paths is not transparent. The agencies provided extensive explanatory text, figures, model documentation, and model source code specifically addressing these paths (and other model features). This transparency appears evident in that commenters (sometimes while claiming that a specific feature of the model is not transparent) presented analytical results involving changes to corresponding inputs that required a detailed understanding of that feature's operation.

Regarding comments that the technology paths should be arranged in order of cost-effectiveness, the agencies note that such comments presume, without merit, that costs, fuel consumption impacts, and other inputs (*e.g.*, fuel prices) that logically impact manufacturers' decision-making are not subject to uncertainty. These inputs are all subject to uncertainty, and the CAFE Model's arrangement of technologies into several paths is responsive to these uncertainties. Nevertheless, the agencies maintain that some technologies *do* reflect a higher level of advancement than others (e.g., 10-speed transmissions vs. 5-speed transmissions), and while manufacturers may, in practice, occasionally revert to less advanced technologies, it is appropriate and reasonable to conduct the agencies' analysis in a manner that assumes manufacturers will continue to make forward progress. As observed by EDF's consultant's remarks, the CAFE Model "simply projects what could be done, not what will be." While no model, much less any model relying on information that can be made publicly available, can hope to represent precisely each manufacturers' actual detailed constrains related to product development and planning, such constraints are real and important. The agencies agree that the

---

[346] *Ibid*., at 70.

CAFE Model's representation of such constraints—including the Model's use of technology paths—provides a reasonable means of accounting for them.

4. Compliance Simulation

The CAFE model provides a way of estimating how vehicle manufacturers could attempt to comply with a given CAFE standard by adding technology to fleets that the agencies anticipate they will produce in future model years. This exercise constitutes a simulation of manufacturers' decisions regarding compliance with CAFE or CO_2 standards.

This compliance simulation begins with the following inputs: (a) the analysis fleet of vehicles from model year 2017 discussed below in Section VI.B.1, (b) fuel economy improving technology estimates discussed below in Section VI.C, (c) economic inputs discussed below in Section VI.D, and (d) inputs defining baseline and potential new CAFE or CO_2 standards discussed above in Section V. For each manufacturer, the model applies technologies in both a logical sequence and a cost-optimizing strategy in order to identify a set of technologies the manufacturer could apply in response to new CAFE or CO_2 standards. The model applies technologies to each of the projected individual vehicles in a manufacturer's fleet, considering the combined effect of regulatory and market incentives while attempting to account for manufacturers' production constraints. Depending on how the model is exercised, it will apply technology until one of the following occurs:

(1) The manufacturer's fleet achieves compliance[347] with the applicable standard and adding additional technology in the current model year would be attractive neither in terms of stand-alone (*i.e.*, absent regulatory need) cost-effectiveness nor in terms of facilitating compliance in future model years;

(2) The manufacturer "exhausts" available technologies;[348] or

(3) For manufacturers assumed to be willing to pay civil penalties (in the CAFE program), the manufacturer reaches the point at which doing so would be more cost-effective (from the manufacturer's perspective) than adding further technology.

The model accounts explicitly for each model year, applying technologies when vehicles are scheduled to be redesigned or freshened and carrying forward technologies between model

---

[347] When determining whether compliance has been achieved in the CAFE program, existing CAFE credits that may be carried over from prior model years or transferred between fleets are also used to determine compliance status. For purposes of determining the effect of maximum feasible CAFE standards, however, EPCA prohibits NHTSA from considering these mechanisms for years being considered (though it does so for model years that are already final) and the agency runs the CAFE model without enabling these options. 49 U.S.C. 32902(h)(3).

[348] In a given model year, it is possible that production constraints cause a manufacturer to "run out" of available technology before achieving compliance with standards. This can occur when: (a) an insufficient volume of vehicles are expected to be redesigned, (b) vehicles have moved to the ends of each (relevant) technology pathway, after which no additional options exist, or (c) engineering aspects of available vehicles make available technology inapplicable (*e.g.*, secondary axle disconnect cannot be applied to two-wheel drive vehicles).

years once they are applied (until, if applicable, they are superseded by other technologies). The model then uses these simulated manufacturer fleets to generate both a representation of the U.S. auto industry and to modify a representation of the entire light-duty registered vehicle population. From these fleets, the model estimates changes in physical quantities (gallons of fuel, pollutant emissions, traffic fatalities, etc.) and calculates the relative costs and benefits of regulatory alternatives under consideration.

The CAFE model accounts explicitly for each model year, in turn, because manufacturers actually "carry forward" most technologies between model years, tending to concentrate the application of new technology to vehicle redesigns or mid-cycle "freshenings," and design cycles vary widely among manufacturers and specific products. Comments by manufacturers and model peer reviewers strongly support explicit year-by-year simulation. Year-by-year accounting also enables accounting for credit banking (*i.e.*, carry-forward), as discussed above, and at least four environmental organizations recently submitted comments urging the agencies to consider such credits, citing NHTSA's 2016 results showing impacts of carried-forward credits.[349] Moreover, EPCA/EISA requires that NHTSA make a year-by-year determination of the appropriate level of stringency and then set the standard at that level, while ensuring ratable increases in average fuel economy through MY 2020. The multi-year planning capability, simulation of "market-driven overcompliance," and EPCA credit mechanisms (again, for purposes of modeling the CAFE program) increase the model's ability to simulate manufacturers' real-world behavior, accounting for the fact that manufacturers will seek out compliance paths for several model years at a time, while accommodating the year-by-year requirement. This same multi-year planning structure is used to simulate responses to standards defined in grams CO_2/mile, and utilizing the set of specific credit provisions defined under EPA's program.

After the light-duty rulemaking analysis accompanying the 2012 final rule that finalized NHTSA's standards through MY 2021, NHTSA began work on changes to the CAFE model with the intention of better reflecting constraints of product planning and cadence for which previous analyses did not account. This involves accounting for expected future schedules for redesigning and "freshening" vehicle models, and accounting for the fact that a given engine or transmission is often shared among more than one vehicle model, and a given vehicle production platform often includes more than one vehicle model. These real product planning considerations are explained below.

Like earlier versions, the current CAFE model provides the capability for integrated analysis spanning different regulatory classes, accounting both for standards that apply separately to different classes and for interactions between regulatory classes. Light vehicle CAFE and CO_2 standards are specified separately for passenger cars and light trucks. However, there is considerable sharing between these two regulatory classes, where a single engine, transmission, or platform can appear in both the passenger car and light truck regulatory class. For example, some sport-utility vehicles are offered in 2WD versions (classified as passenger

---

[349] Comment by Environmental Law & Policy Center, Natural Resources Defense Council (NRDC), Public Citizen, and Sierra Club, Docket ID EPA-HQ-OAR-2015-0827-9826, at 28-29.

cars for compliance purposes) and 4WD versions (classified as light trucks for compliance purposes). Integrated analysis of manufacturers' passenger car and light truck fleets provides the ability to account for such sharing and reduces the likelihood of finding solutions that could involve introducing impractical and unrealistic levels of complexity in manufacturers' product lines. In addition, integrated fleet analysis provides the ability to simulate the potential that manufacturers could earn CAFE and CO_2 credits by over complying with the standard in one fleet and use those credits toward compliance with the standard in another fleet (*i.e.*, to simulate credit transfers between regulatory classes).[350]

The CAFE model also accounts for EPCA's requirement that compliance be determined separately for fleets of domestic passenger cars and fleets of imported passenger cars. The model accounts for all three CAFE regulatory classes simultaneously (*i.e.*, in an integrated way) yet separately: domestic passenger cars, imported passenger cars, and light trucks. The model further accounts for two related specific statutory requirements specifically involving this distinction between domestic and imported passenger cars. First, EPCA/EISA requires that any given fleet of domestic passenger cars meet a minimum standard, irrespective of any available compliance credits. Second, EPCA/EISA requires compliance with the standards applicable to the domestic passenger car fleet without regard to traded or transferred credits.[351]

However, the CAA has no such limitation regarding compliance by domestic and imported vehicles; EPA did not adopt provisions similar to the aforementioned EPCA/EISA requirements and is not doing so today. Therefore, the CAFE model determines compliance for manufacturers' overall passenger car and light truck fleets for EPA's program.

Each manufacturer's regulatory requirement represents the production-weighted harmonic mean of their vehicle's targets in each regulated fleet. This means that no individual vehicle has a "standard," merely a target, and each manufacturer is free to identify a compliance strategy that makes the most sense given its unique combination of vehicle models, consumers, and competitive position in the various market segments. As the CAFE model provides flexibility when defining a set of regulatory standards, each manufacturer's requirement is dynamically defined based on the specification of the standards for any simulation and the distribution of footprints within each fleet.

Given this information, the model attempts to apply technology to each manufacturer's fleet in a manner that, given product planning and engineering-related considerations, optimizes the selected cost-related metric. The metric supported by the NPRM version of the model is termed "effective cost." The effective cost captures more than the incremental cost of a given technology; it represents the difference between their incremental cost and the value of fuel savings to a potential buyer over the first 30 months of ownership.[352] In addition to the

---

[350] Note, however, that EPCA prohibits NHTSA from considering the availability of such credit trading when setting maximum feasible fuel economy standards. 49 U.S.C. 32902(h)(3).
[351] 49 U.S.C. 32903(f)(2) and (g)(4).
[352] The length of time over which to value fuel savings in the effective cost calculation is a model input that can be modified by the user. This analysis uses 30 months' worth of fuel savings in the effective cost calculation, using the price of fuel at the time of vehicle purchase.

technology cost and fuel savings, the effective cost also includes the change in CAFE civil penalties from applying a given technology and any estimated welfare losses associated with the technology (*e.g.*, earlier versions of the CAFE model simulated low-range electric vehicles that produced a welfare loss to buyers who valued standard operating ranges between re-fueling events). Comments on this metric are discussed below, as are model changes responding to these comments.

This construction allows the model to choose technologies that both improve a manufacturer's regulatory compliance position and are most likely to be attractive to its consumers. This also means that different assumptions about future fuel prices will produce different rankings of technologies when the model evaluates available technologies for application. For example, in a high fuel price regime, an expensive but very efficient technology may look attractive to manufacturers because the value of the fuel savings is sufficiently high both to counteract the higher cost of the technology and, implicitly, to satisfy consumer demand to balance price increases with reductions in operating cost.

In general, the model adds technology for several reasons but checks these sequentially. The model then applies any "forced" technologies. Currently, only variable valve timing (VVT) is forced to be applied to vehicles at redesign since it is the root of the engine path and the reference point for all future engine technology applications.[353] The model next applies any inherited technologies that were applied to a leader vehicle on the same vehicle platform and carried forward into future model years where follower vehicles (on the shared system) are freshened or redesigned (and thus eligible to receive the updated version of the shared component). In practice, very few vehicle models enter without VVT, so inheritance is typically the first step in the compliance loop. Next, the model evaluates the manufacturer's compliance status, applying all cost-effective technologies regardless of compliance status.[354] Then the model applies expiring overcompliance credits (if allowed to do so under the perspective of either the "unconstrained" or "standard setting" analysis, for CAFE purposes).[355] At this point, the model checks the manufacturer's compliance status again. If the manufacturer is still not compliant (and is unwilling to pay civil penalties, again for CAFE modeling), the model will add technologies that are not cost-effective until the manufacturer reaches compliance. If the manufacturer exhausts opportunities to comply with the standard by improving fuel economy/reducing emissions (typically due to a limited percentage of its fleet being redesigned in that year), the model will apply banked CAFE or CO_2 credits to offset the remaining deficit. If no credits exist to offset the remaining deficit, the model will reach back in time to alter technology solutions in earlier model years.

---

[353] As a practical matter, this affects very few vehicles. More than 95 percent of vehicles in the market file either already have VVT present or have surpassed the basic engine path through the application of hybrids or electric vehicles.

[354] For further explanation of how the CAFE model considers the effective cost of applying different technologies see the CAFE Model Documentation for the final rule, at S5.3 Compliance Simulation Algorithm.

[355] As mentioned above, EPCA prohibits consideration of available credits when setting maximum feasible fuel economy standards. 49 U.S.C. 32902(h)(3).

The CAFE model implements multi-year planning by looking back, rather than forward. When a manufacturer is unable to comply through cost-effective (*i.e.*, producing effective cost values less than zero) technology improvements or credit application in a given year, the model will "reach back" to earlier years and apply the most cost-effective technologies that were not applied at that time and then carry those technologies forward into the future and re-evaluate the manufacturer's compliance position. The model repeats this process until compliance in the current year is achieved, dynamically rebuilding previous model year fleets and carrying them forward into the future, and accumulating CAFE or CO_2 credits from over-compliance with the standard wherever appropriate.

In a given model year, the model determines applicability of each technology to each vehicle platform, model, engine, and transmission. The compliance simulation algorithm begins the process of applying technologies based on the CAFE or CO_2 standards specified during the current model year. This involves repeatedly evaluating the degree of noncompliance, identifying the next "best" technology (ranked by the effective cost discussed earlier) available on each of the parallel technology paths described above and applying the best of these. The algorithm combines some of the pathways, evaluating them sequentially instead of in parallel, to ensure appropriate incremental progression of technologies.

The algorithm first finds the best next applicable technology in each of the technology pathways and then selects the best among these. For CAFE purposes, the model applies the technology to the affected vehicles if a manufacturer is either unwilling to pay penalties or if applying the technology is more cost-effective than paying penalties. Afterwards, the algorithm reevaluates the manufacturer's degree of noncompliance and continues application of technology. Once a manufacturer reaches compliance (*i.e.*, the manufacturer would no longer need to pay penalties), the algorithm proceeds to apply any additional technology determined to be cost-effective (as discussed above). Conversely, if a manufacturer is assumed to prefer to pay penalties, the algorithm only applies technology up to the point where doing so is less costly than paying penalties. The algorithm stops applying additional technology to this manufacturer's products once no more cost-effective solutions are encountered. This process is repeated for each manufacturer present in the input fleet. It is then repeated for each model year. Once all model years have been processed, the compliance simulation algorithm concludes. The process for CO_2 standard compliance simulation is similar, but without the option of penalty payment, such that technologies are applied until compliance (accounting for any modeled application of credits) is achieved. For both CAFE and CO_2 standards, the model also applies any additional (*i.e.*, beyond required for compliance) technology that "pays back" within a specified period (for the NPRM and today's analysis, 30 months).

Some commenters argued that the CAFE model applies constraints that excessively limit options manufacturers have to add technology, causing the model to overestimate costs to achieve a given level of improvement.[356] Some of these commenters further argued that the agencies should assume greater potential to apply technologies that contribute to compliance by

[356] NHTSA-2018-0067-12057, CBD, et. al, p. 3.

improving air conditioner efficiency or otherwise reducing "off cycle" fuel consumption and CO_2 emissions.[357] Other commenters argued that such constraints, while warranting some refinements, help the model to simulate manufacturers' decision making realistically and to estimate technology effectiveness and costs reasonably.[358, 359]

Some commenters questioned the "effective cost" metric the model uses to decide among available options, claiming that the metric also causes the model to avoid selection of pathways that are not always economically optimal.[360] One of these commenters recommended the agencies modify the effective cost metric for CO_2 compliance by removing the term placing a monetary value on progress toward compliance, and instead dividing the remaining net cost (*i.e.*, the increase in technology costs minus a portion of the fuel outlays expected to be avoided) by the additional CO_2 credits earned.[361] Another of these commenters claimed on one hand, that the effective cost metric "does not include a measurement of the technology's reduction in fuel consumption or CO_2 emissions" and, on the other, that the metric inappropriately places a value on avoided fuel consumption.[362]

One commenter claimed that the model inappropriately allows earned credits (including CO_2 program credits for which EPA has granted a one-time exemption from carry-forward limits) to expire while also showing undue degrees overcompliance with standards, and further proposed that the model be modified to simulate both credit "carry back" (aka "borrowing") and credit trading between manufacturers.[363]

In addition, some commenters indicated that the agencies' analysis (impliedly, its modeling) should account for some States' mandates that manufacturers sell minimum quantities of "Zero Emission Vehicles" (ZEVs).[364, 365]

Regarding the model's representation of engineering and product planning constraints, the agencies maintain that having such constraints produces more realistic potential (as mentioned above, not "predicted") pathways forward from manufacturers' current fleets than would be the case were these constraints removed. For example, while manufacturers' product plans are protected as confidential business information (CBI), some manufacturers' public comments demonstrate year-by-year balancing such as the CAFE model emulates.[366] Also, even manufacturers that have invested in technologies such as hybrid electric powertrains and Atkinson cycle engines have commented that a manufacturers' past investments will constrain

the pathways it can practicably take.[367] Therefore, the agencies have retained the model's basic structural constraints, have updated and expanded the model's technology paths (and, as discussed, the model's logic for approaching these paths), and have updated inputs defining the range of manufacturer-, technology-, and product-specific constraints. These updates are discussed below at greater length.

The agencies have also reconsidered opportunities manufacturers may have to expand the application of technologies that contribute to compliance by improving air conditioner efficiency or otherwise reducing "off cycle" fuel consumption and CO_2 emissions, or to earn credit toward CO_2 compliance by using refrigerants with lower global warming potential (GWP) or reducing the potential for refrigerant leaks. The version of the model used for the proposal accommodates inputs that, for each of these adjustments or credits, applies the same value to every model year. The agencies have revised the model to accommodate inputs that specify the degree of adjustment or credit separately for each model year, and have applied inputs that assume manufacturers will increase application of these improvements to the highest levels reported within the industry.

Regarding comments on the effective cost metric the model uses to compare and select among available options to add technology, the agencies have considered changes such as those mentioned above. Given the myriad of factors that manufacturers can consider, any weighing to be conducted using publicly-available information will constitute a simplified representation. Nevertheless, within the model's context, it is obvious that any weighing of options should, at a minimum, consider some measure of each option's costs and benefits. Since this aspect of the model involves simulating manufacturers' decisions, it is also clearly appropriate that these costs and benefits be considered from a manufacturer perspective rather than a social perspective.

The effective cost metric used for the NPRM version of the model represents the cost of a given option as the cost to apply a given technology to a given set of vehicles, and represents the benefit of the same option as the extent to which the manufacturer might expect buyers would be willing to pay for fuel economy (as represented by a portion of the projected fuel savings), combined with any reduction in CAFE civil penalties that the manufacturer might ultimately need to pass along to buyers. The reduction in CAFE civil penalties places a value on progress made toward compliance with CAFE standards. The CAA provides no direction regarding CO_2 standards, so the model accepts inputs specifying an analogous basis for valuing changes in the quantity of CO_2 credits earned from (or required by) a manufacturer's fleet. Because each of these three components (technology cost, fuel benefit, and compliance benefit) is expressed in dollars, subtracting benefits from costs produces a net cost, and after dividing net costs by the number of affected vehicles, it is logical to, at each step, select the option that produces the most negative net unit cost. This approach can be interpreted as maximizing net benefits (to the manufacturer).

As an alternative, the agencies considered a simpler metric that considers only the cost of the option and the extent to which the option increases the quantity of earned credits, and does

[367] Toyota, Attachment 1, p. 10.

not require input assumptions regarding how to value progress toward compliance. Such a metric is expressed in dollars per ton or dollars per gallon such that seeking options that produce the smallest (positive) values can be interpreted as maximizing cost effectiveness (of progress toward compliance). However, simply comparing technology costs to corresponding compliance improvements would implicitly assume that manufacturers do not respond at all to fuel prices. This assumption is clearly unrealistic. For example, if diesel fuel costs $5 per gallon and gasoline costs $2 per gallon, manufacturers will be reluctant to respond to stringent CAFE or CO_2 standards by replacing gasoline engines with diesel engines. Manufacturers' comments credibly assert that fuel prices matter, and in the agencies' judgment, simulations of decisions between available options should continue to account for avoided fuel outlays.

On the other hand, while any metric should incorporate some measure of progress toward compliance, it is not obvious that this progress must be expressed in monetary terms. While the CAFE civil penalty provisions provide a logical basis for doing so with respect to CAFE, the recently-introduced (through EISA) option to trade credit between manufacturers adds an alternative basis that is undefined and uncertain, in part because terms of past trades are not known to the agencies. Also, as mentioned above, EPCA/EISA's civil penalty provisions are not applicable to noncompliance with CO_2 standards.

Therefore, for the purpose of selecting among available options to add technology, the agencies consider it reasonable to use the degree of compliance improvement in "raw" (*i.e.*, not monetized) form, and to divide net costs (*i.e.*, technology costs minus a portion of expected avoided fuel outlays) by this improvement. Under a range of side-by-side tests, this change to the effective cost metric most frequently produced lower overall estimates of compliance costs. However, differences vary among manufacturers, model years, and regulatory alternatives, and also depend on other model inputs. For example, at high fuel prices, the new metric tends to select more expensive pathways than the NPRM's metric, and with the new metric, a case simulating "perfect trading" of CO_2 compliance credits tends to show such trading increasing compliance costs rather than, as expected, decreasing such costs.

The version of the model used for the proposal simulates the potential that, for a given fleet in a given model year, a manufacturer might be able to use credits from an earlier model year or a different fleet. This version of the model did not explicitly simulate the potential that, for a given fleet in a given model year, a manufacturer might be to use credits from a future model year or a different manufacturer. However, the agencies did apply model inputs that reflected assumptions regarding possible trading of credits actually earned prior to model year 2016 (the earliest represented in detail in the agencies' analysis), and the agencies did examine a case (included in the sensitivity analysis) involving hypothetical "perfect" trading of CO_2 credits among manufacturers by treating the industry as a single "manufacturer." Although past versions of the CAFE Model had included code under development with a view toward eventually simulating one or both of these provisions, this code had never proceeded beyond preliminary experimentation, and had never been the focus of peer reviews or application in published analyses.

Nevertheless, the agencies considered expanding the model to simulate credit "carry back" (or "borrowing") and trading (explicitly, rather than in an idealized hypothetical way). The agencies closely examined the corresponding model revisions proposed by UCS and determined that such methods would not produce repeatable results. This is because the approach proposed by UCS "randomly swaps items in list to minimize trading bias."[368]

Even if such revisions could be modified to produce non-random results, including credit banking and trading would introduce highly speculative elements into the agencies' analysis. While manufacturers have occasionally indicated plans to carry back credits from future model years, those plans have sometimes backfired when projected credits have failed to materialize, *e.g.*, by misjudging consumer demand for more efficient vehicles. In the agencies' judgment, it would be inappropriate to set standards based on an analysis that relies on the type of borrowing that has been known to fail. To rely also on credit trading during the model years included in the analysis would compound this undue speculation. For example, including credit borrowing and trading throughout the analysis, as some commenters proposed, would lead to an analysis that depends on the potential that, in order to comply with the MY 2022 standard for light trucks, FCA could use credits it expects to be able to buy from another manufacturer in MY 2025. Even if the agencies' analysis had knowledge of and made use of manufacturers' actual product plans, expectations about the ability to borrow others' unearned credits would necessarily be considered risky and unreliable. Within an analysis that, to provide for public disclosure, extrapolates forward many years from the most recent observed fleet, such transactions would add an unreasonable level of speculation. Therefore, the agencies have declined to introduce credit borrowing and trading into the model's logic.

The analysis presented in the proposal applied inputs reflecting potential application of credits earned earlier than the first year modeled explicitly. However, as observed by some commenters, those inputs did not fully account for the one-time exemption from the 5-year limit on the extent to which manufacturers may carry forward CO_2 credits. The agencies have updated the analysis fleet to MY 2017 and, in doing so, have updated inputs specifying how credits earned to MY 2017 might be applied. These updates implement a reasonably full accounting of these "legacy" credits, including of the one-time exemption from the credit life limit.

As mentioned above, some commenters also indicated that the model is unrealistically "reluctant" to apply credits carried forward from early model years. As explained in the proposal and in the model documentation, the model's application of carried-forward credits is partially controlled by model inputs, which, for the proposal, were set to assume that manufacturers would tend to retain credits as long as possible. This assumption is entirely consistent with manufacturers' past practice and logical in a context wherein the stringency of standards is generally increasing over time. Even though using credits in some model years might seem initially advantageous, doing so means foregoing actual improvements likely to be needed in later model years.

Regarding the model's treatment of mandates and credits for the sale of ZEVs, as indicated in the model documentation accompanying the proposal, these capabilities were

---

[368] UCS, NHTSA-2018-0067-12039, Technical Appendix, at 84-87.

experimental in that version of the model. The reference case analysis for today's notice, like that for the proposal, does not simulate compliance with ZEV mandates.[369]

For the NPRM, the CAFE model was exercised with inputs extending this explicit simulation of technology application through MY 2032, as the agencies anticipated this was sufficiently beyond MY 2026 that nearly all multiyear planning attributable to MY 2026 standards should be accounted for, and any compliance credits carried forward from MY 2026 would have expired. The analysis met this expectation, and the agencies presented analysis of the resultant estimated impacts over the useful lives of vehicles produced prior to MY 2030. The agencies invited comment on all aspects of the analysis, and relevant to this aspect of the analysis—*i.e.*, its perspective and temporal span—EDF stated that that these led the agencies to overstate the proposal's positive impacts on safety, in part because by explicitly representing vehicle model years only through 2032, the agencies had failed to account for the impact of distant model years prices and fuel economy levels on the retention and scrappage of vehicles produced through MY 2029.[370] For example, some vehicles produced in MY 2026 will likely still be on the road during calendar years (CY) 2033-2050 and the rates at which these MY 2026 vehicles will be scrapped during CYs 2033-2050 will be impacted by the prices and fuel economy levels of vehicles produced during MYs 2033-2050.

The agencies have addressed this comment by expanding model inputs to extend the explicit simulation of technology application through MY 2050. Most of these expanded model inputs involve the analysis fleet and inputs defining the cost and availability of various fuel-saving technologies. These inputs are discussed below. The agencies also made minor modifications to the model in order to extend model outputs to cover this wider span and to carry forward each regulatory alternative's standards automatically through the last year to be modeled (*e.g.*, extending standards without change from MY 2032 through MY 2050). The model documentation discusses these minor changes.[371] In addition, although the agencies published detailed model output files documenting all estimated annual impacts through calendar year 2089, the notice and PRIA both emphasized the above-mentioned "model year" perspective, as in past regulatory analyses supporting CAFE and CO_2 standards. Recognizing that an alternative "calendar year" perspective is of interest to EDF and, perhaps other stakeholders, the agencies have expanded the presentation of results in today's notice and FRIA by presenting some physical impacts (*e.g.*, fuel consumption and CO_2 emissions) as well as monetized benefits, costs, and net benefits for each of CYs 2017-2050. All of these results appear in the model output files published with today's notice, as do corresponding results for more specific impacts (*e.g.*, year-by-year components of monetized social costs).[372]

---

369 The agencies note their finalization of the One National Program Final Action, in which EPA partially withdrew a waiver of CAA preemption previously granted to the State of California relating to its ZEV mandate, and NHTSA finalized regulations providing that State ZEV mandates are impliedly and expressly preempted by EPCA. This joint action is available at 84 FR 51310.

5. Calculation of Physical Impacts

Once it has completed the simulation of manufacturers' potential application of technology in response to CAFE/CO_2 standards and fuel prices, the CAFE Model calculates impacts of the resultant changes in new vehicle fuel economy levels and prices. This involves several steps.

The model calculates changes in the total quantity of new vehicles sold in each model year as well as the relative shares passenger cars and light trucks comprise of the overall new vehicle market. The agencies received many comments on the estimation of sales impacts, and as discussed below, today's analysis applies methods and corresponding estimates that reflect careful consideration of these comments. Related to these calculations, the model now operates in an iterated fashion with a view toward obtaining sales impacts that are balanced with changes in vehicle prices and fuel economy levels. This involves solving for compliance, calculating sales impacts, re-solving for compliance, and repeating these steps as many times as specified in model inputs. For today's analysis, the agencies operated the model with four iterations, as early testing suggested three iterations should be sufficient for fleetwide results to converge between iterations. The model documentation describes the procedures for iteration in detail.

The impacts on outlays for new vehicles occur coincident with the sale of these vehicles so the model can simply calculate and record these for each model year included in the analysis. However, virtually all other impacts result from vehicle operation that extends long after a vehicle is produced. Like other models (including, *e.g.*, NEMS), the CAFE Model includes procedures (sometimes referred to as "stock models" or as models of fleet turnover) to estimate annual rates at which new vehicles are used and subsequently scrapped. The agencies received many comments on procedures for estimating vehicle scrappage and on procedures for estimating annual quantities of highway travel, accounting for the elasticity of travel demand with respect to per-mile costs for fuel. Below, Section VI.D.1 discusses these comments and reviews procedures and corresponding estimates that also reflect careful consideration of these comments.

For each vehicle model in each model year, these procedures result in estimates of the number of vehicles remaining in service in each calendar year, as well as the annual mileage accumulation (*i.e.*, vehicle miles traveled, or VMT) in each calendar year. As mentioned above, most of the physical impacts of interest derive from this vehicle operation. Also discussed above, the simulated application of technology results in "initial" and "final" estimates of the cost, fuel type, fuel economy, and fuel share (for, in particular, PHEVs that can run on gasoline or electricity) applicable to each vehicle model in each model year. Together with quantities of travel, and with estimates of the "gap" between "laboratory" and "on-road" fuel economy, these enable calculation of quantities of fuel consumed in each year during the useful life of each vehicle model produced in each model year.[373] The model documentation provides specific procedures and formulas implementing these calculations.

As for the NPRM, the model calculates emissions of CO_2 and other air pollutants, reporting emissions both from vehicle tailpipes and from upstream processes (*e.g.*, petroleum refining) involved in producing and supplying fuels. Section VI.D.3 below reviews methods, models, and estimates used in performing these calculations. The model also calculates impacts on highway safety, accounting for changes in travel demand, changes in vehicle mass, and continued past and expected progress in vehicle safety (through, *e.g.*, the application of new crash avoidance systems). Section VI.D.2 discusses methods, data sources, and estimates involved in estimating safety impacts, comments on the same, and changes included in today's analysis. In response to the NPRM, some comments urged the agencies also to quantify different types of health impacts from changes in air pollution rather than only accounting for such impacts in aggregate estimates of the social costs of air pollution. Considering these comments, the agencies added such calculations to the model, as discussed in Section VI.D.3.

6. Calculation of Benefits and Costs

Having estimated how technologies might be applied going forward, and having estimated the range of resultant physical impacts, the CAFE Model calculates a variety of private and social benefits and costs, reporting these from the consumer, manufacturer, and social perspectives, both in undiscounted and discounted present value form (given inputs specifying the corresponding discount rate and present year). Estimates of regulatory costs are among the direct outputs of the simulation of manufacturers' potential responses to new standards. Other benefits and costs are calculated based on the above-mentioned estimates of travel demand, fuel consumption, emissions, and safety impacts. The agencies received many comments on the NPRM's calculation of benefits and costs, and Section VI.D.1 discusses these comments and presents the methods, data sources, and estimates used in calculating benefits and costs reported here.

7. Structure of Model Inputs and Outputs

All CAFE Model inputs and outputs described above are specified in Microsoft Excel format, and the user can define and edit all inputs to the system. Table VI-3 describes (non-exhaustively) which inputs are contained within each input file and Table VI-4 describes which outputs are contained in each output file. This is important for three reasons: (1) each file is discussed throughout the following sections; (2) several commenters conflated aspects of the model with its inputs; and (3) several commenters seemed confused about where to find specific information in the output files. This information was described in detail in the NPRM CAFE Model Documentation, but is reproduced here for quick reference. When specifically

---

[373] The agencies have applied the same estimates of the "on road gap" as applied for the analysis supporting the NPRM. For operation on gasoline, diesel, E85, and CNG, this gap is 20 percent; for electricity and hydrogen, 30 percent.

referencing the input or output file used for the NPRM or final rule in the following discussion, NPRM or FRM, respectively, will precede the file name.

Table VI-3 – CAFE Model Input Files

Input File	Contents
Market Data (Manufacturers Worksheet)	manufacturers included in analysis, and estimates of banked compliance credits and willingness to pay CAFE fines rather than applying technology
Market Data (Vehicles Worksheet)	description of each specific vehicle model/configuration produced in MY 2017, identifying corresponding engines and transmissions
Market Data (Engines Worksheet)	characteristics of each specific engine
Market Data (Transmissions Worksheet)	characteristics of each specific transmission
Technologies	applicability, availability, and cost of specific fuel-saving technologies included in analysis
Parameters	wide-ranging economic and other analytical inputs (e.g., fuel prices, discount rates, fatality risk rates, emission factors, emissions damage costs)
Scenarios	coefficients defining each regulatory alternative to be modeled

Table VI-4 – CAFE Model Output Files

Output File	Contents
Technology Utilization Report	rates at which specific technologies are added to and present in manufacturers' fleets
Compliance Report	required and achieved average CAFE and CO_2 levels, regulatory costs, average footprint and curb weight, new vehicle sales volumes, labor utilization, CAFE and CO_2 credit generation and use
Societal Effects Report	physical impacts (e.g., on-road fleet size and VMT, energy consumption and emissions, health and safety impacts)
Societal Costs Report	social benefits and costs
Annual Societal Effects Report	physical impacts attributable to each model year in each calendar year
Annual Societal Costs Report	social benefits and costs attributable to each model year in each calendar year
Annual Societal Effects Summary Report	physical impacts attributable to overall on-road fleet in each calendar year
Annual Societal Costs Summary Report	social benefits and costs attributable to overall on-road fleet in each calendar year
Consumer Costs Report	benefits and costs from consumer perspective
Vehicles Report	initial and final characteristics (fuel economy, CO_2 rating, footprint, weight, price, and technology content) and sales of each vehicle model/configuration in each model year

A catalog of the Argonne National Laboratory Autonomie fuel economy technology effectiveness value output files are reproduced in the following Table VI-5 as well. The left column shows the terminology used in this text to refer to the file, while the right column describes each file. NPRM or FRM, respectively, may precede the terminology in the text as appropriate.

B. What Inputs Does the Compliance Analysis Require?

1. Analysis Fleet

The starting point for the evaluation of the potential feasibility of different stringency levels for future CAFE and CO_2 standards is the analysis fleet, which is a snapshot of the recent vehicle market. The analysis fleet provides a baseline from which to project what and how additional technologies could feasibly be applied to vehicles in a cost-effective manner to raise those vehicles’ fuel economy and lower their CO_2 emission levels.[374] The fleet characterization also provides a reference point with data for other factors considered in the analysis, including environmental effects and effects estimated by the economic modules (*i.e.*, sales, scrappage, and labor utilization). When the scope of the analysis widens, another piece of data must be included for each vehicle in the analysis fleet to map a given element of the fleet appropriately onto an analysis module.

For the analysis presented in this final rule, the analysis fleet includes information about vehicles that is essential for each analysis module. The first part of projecting how additional technologies could be applied to vehicles is knowing which vehicles are produced by which manufacturers, the fuel economies of those vehicles, how many of each are sold, whether they are passenger cars or light trucks, and their footprints. This is important because it improves understanding of the overall impacts of different levels of CAFE and CO_2 standards; overall impacts that result from industry’s response to standards, and industry’s response, is made up of individual manufacturer responses to the standards in light of the overall market and their individual assessment of consumer acceptance. Establishing an accurate representation of manufacturers’ existing fleets (and the vehicle models in them) that will be subject to future

[374] The CAFE model does not generate compliance paths a manufacturer should, must, or will deploy. It is intended as a tool to demonstrate a compliance pathway a manufacturer *could* choose. It is almost certain all manufacturers will make compliance choices differing from those projected by the CAFE model.

standards helps in predicting potential individual manufacturer responses to those future standards in addition to potential changes in those standards.

Another part of projecting how additional fuel economy improving technologies could be applied to vehicles is knowing which fuel saving technologies manufacturers have equipped on which vehicles. In many cases, the agencies also collect and reference additional information on other vehicle attributes to help with this process.[375] Accounting for technologies already applied to vehicles helps avoid "double-counting" the value of those technologies, by assuming they are still available to be applied to improve fuel economy and reduce CO_2 emissions. It also promotes more realistic determinations of what additional technologies can feasibly be applied to those vehicles: if a manufacturer has already started down a technological path to fuel economy or performance improvements, the agencies do not assume it will completely abandon that path because doing so would be unrealistic and fails to represent accurately manufacturer responses to standards. Each vehicle model (and configurations of each model) in the analysis fleet, therefore, has a comprehensive list of its technologies, which is important because different configurations may have different technologies applied to them.[376] In addition, to properly account for technology costs, the agencies assign each vehicle to a technology class and an engine class. Technology classes reference each vehicle to a set of full vehicle simulations, so that the agencies may project fuel efficiency with combinations of additional fuel saving equipment and hybrid and electric vehicle battery costs.

Yet another part of projecting which vehicles might exist in future model years is developing reasonable real-world assumptions about when and how manufacturers might apply certain technologies to vehicles. The analysis fleet accounts for links between vehicles, recognizing vehicle platforms will share technologies, and the vehicles that make up that platform should receive (or not receive) additional technological improvements together. Shared engines, shared transmissions, and shared vehicle platforms for mass reduction technology are considered. In addition, each vehicle model/configuration in the analysis fleet also has information about its redesign schedule, *i.e.*, the last year it was redesigned and when the agencies expect it to be redesigned again. Redesign schedules are a key part of manufacturers' business plans, as each new product can cost more than $1B, and involve a significant portion of a manufacturer's scarce research, development, and manufacturing and equipment budgets and resources.[377] Manufacturers have repeatedly told the agencies that sustainable business plans require careful management of resources and capital spending, and that the length of time each product remains in production is crucial to recouping the upfront product development and plant/equipment costs, as well as the capital needed to fund the development and manufacturing equipment needed for future products. Because the production volume of any given vehicle

---

[375] For instance, curb weight, horsepower, drive configuration, pickup bed length, oil type, body style, aerodynamic drag coefficients, and rolling resistance coefficients, and (if applicable) battery sizes are all required to assign technology content properly.
[376] Considering each vehicle model/configuration also improves the ability to consider the differential impacts of different levels of potential standards on different manufacturers, since all vehicle model/configurations "start" at different places, in terms of technologies already used and how those technologies are used.
[377] Shea, T., Why Does It Cost So Much For Automakers To Develop New Models? Autoblog (Jul. 27, 2010), https://www.autoblog.com/2010/07/27/why-does-it-cost-so-much-for-automakers-to-develop-new-models/.

model varies within a manufacturer's product line, and varies among different manufacturers, redesign schedules typically vary for each model and manufacturer. Some (relatively few) technological improvements are small enough that they can be applied in any model year; a few other technological improvements may be applied during a refreshening (when a few additional changes are made, but well short of a full redesign), but others are major enough that they can only be cost-effectively applied at a vehicle redesign, when many other things about the vehicle are already changing. Ensuring the CAFE model makes technological improvements to vehicles only when it is feasible to do so also helps the analysis better represent manufacturer responses to different levels of standards.

Finally, the agencies restrict the applications of some technologies on some vehicles upon determining the technology is not compatible with the functional and performance requirements of the vehicle, or if the manufacturers are unlikely to apply a specific technology to a specific vehicle for reasons articulated with confidential business information that the agencies found credible.

Other data important for the analysis that are referenced to the analysis fleet include baseline economic, environmental, and safety information. Vehicle fuel tank size is required to estimate range and refueling benefit while curb weights and safety class assignments help the agencies consider how changes in vehicle mass may affect safety. The agencies identify the final assembly location for each vehicle, engine, and transmission, as well as the percent of U.S. content to support the labor impact analysis. In addition, the aforementioned accounting for first-year vehicle production volumes (*i.e.*, the number of vehicles of each new model sold in MY 2017, for this analysis) is the foundation for estimating how future vehicle sales might change in response to different potential standards.

The input file for the CAFE model characterizing the analysis fleet, referred to as the "market inputs" file or "market data" file, accordingly includes a large amount of data about vehicles, their technological characteristics, the manufacturers and fleets to which they belong, and initial prices and production volumes, which provide the starting points for projection (by the sales model) to ensuing model years. In the Draft TAR (which utilized a MY 2015 analysis fleet) and NPRM (which utilized a MY 2016 analysis fleet), the agencies needed to populate about 230,000 cells in the market data file to characterize the fleet. For this final rule (which utilized a MY 2017 analysis fleet), the agencies populated more than 400,000 cells to characterize the fleet. While the fleet is not actually much more heterogeneous in reality,[378] the agencies have provided and collected more data to justify the characterization of the analysis fleet, and to support the functionality of modules in the CAFE model.

A solid characterization of a recent model year as an analytical starting point helps realistically estimate ways manufacturers could potentially respond to different levels of standards, and the modeling strives to simulate realistically how manufacturers could progress from that starting point. While manufacturers can respond in many ways beyond those represented in the analysis (*e.g.*, applying other technologies, shifting production volumes,

[378] The expansion of cells is primarily due to (1) considering more technologies, and (2) listing trim levels separately, which often yields more precise curb weights and more accurate manufacturer suggested retail prices.

changing vehicle footprint), such that it is impossible to predict with any certainty exactly how each manufacturer will respond, it is still important to establish a solid foundation from which to estimate potential costs and benefits of potential future standards. The following sections discuss aspects of how the analysis fleet was built for this analysis, and includes discussion of the comments on fleet that the agencies received on the proposed rule.

a) Principles on Data Sources Used to Populate the Analysis Fleet

The source data for vehicles in the analysis fleet and their technologies is a central input for the analysis. The sections below discuss pros and cons of different potential sources and what the agencies used for this analysis, and responds to comments the agencies received on data sources in the proposal.

(1) Use of Confidential Business Information versus Publicly-Releasable Sources

Since 2001, CAFE analysis has used either confidential, forward-estimating product plans from manufacturers, or publicly available data on vehicles already sold as a starting point for determining what technologies can be applied to what vehicles in response to potential different levels of standards. The use of either data source requires certain tradeoffs. Confidential product plans comprehensively represent what vehicles a manufacturer expects to produce in coming years, accounting for plans to introduce new vehicles and fuel-saving technologies and, for example, plans to discontinue other vehicles and even brands. This information can be very thorough and can improve the accuracy of the analysis, but cannot be publicly released. This makes it difficult for public commenters to reproduce the analysis for themselves as they develop their comments. Some non-industry commenters have also expressed concern about manufacturers having an incentive in the submitted plans to underestimate (deliberately or not) their future fuel economy capabilities and overstate their expectations about, for example, the levels of performance of future vehicle models in order to affect the analysis. Accordingly, since 2010, EPA and NHTSA have based analysis fleets almost exclusively on information from commercial and public sources, starting with CAFE compliance data and adding information from other sources.

An analysis fleet based primarily on public sources can be released to the public, solving the issue of commenters being unable to reproduce the overall analysis. However, industry commenters have argued such an analysis fleet cannot accurately reflect manufacturers' actual plans to apply fuel-saving technologies (*e.g.*, manufacturers may apply turbocharging to improve not just fuel economy, but also to improve vehicle performance) or manufacturers' plans to change product offerings by introducing some vehicles and brands and discontinuing other vehicles and brands, precisely because that information is typically confidential business information (CBI). A fully-publicly-releasable analysis fleet holds vehicle characteristics unchanged over time and lacks some level of accuracy when projected into the future. For example, over time, manufacturers introduce new products and even entire brands. On the other hand, plans announced in press releases do not always ultimately bear out, nor do commercially available third-party forecasts. Assumptions could be made about these issues to improve the accuracy of a publicly releasable analysis fleet, but concerns include that this information would either be largely incorrect, or, if the assumptions were correct, information would be released that manufacturers would consider CBI.

Furthermore, some technologies considered in the rulemaking are difficult to observe in the analysis fleet without expensive teardown study and time-consuming benchmarking. Not giving credit for these technologies puts the analysis at significant risk of double-counting the effectiveness of these technologies, as manufacturers cannot equip technologies twice to the same vehicle for double the fuel economy benefit. As discussed in the Draft TAR, the agencies assigned little (if any) technology application in the baseline fleet for some of these technologies.[379] For the NPRM MY 2016 fleet development process, the agencies again offered the manufacturers the opportunity to volunteer CBI to the agencies to help inform the technology content of the analysis fleet, and many manufacturers did. The agencies were able to confirm that many manufacturers had already included many hard-to-observe technologies in the MY 2016 fleet (which they were not properly given credit for in the characterization of the MY 2014 and MY 2015 fleets presented in Draft TAR) so the agencies reflected this new information in the NPRM analysis and in the analysis presented today.

In addition, many manufacturers provided confidential comment on the potential applicability of fuel-saving technologies to their fleet. In particular, many manufacturers confidentially identified specific engine technologies that they will *not* use in the near term, either on specific vehicles, or at all. Reasons varied: some manufacturers cited intellectual property concerns, and others stated functional performance concerns for some engine types on some vehicles. Other manufacturers shared forward-looking product plans, and explained that it would be cost prohibitive to scrap significant investments in one technology in favor of another. This topic is discussed in more detail in Section VI.B.1.b)(6), below.

The agencies sought comment on how to address this issue going forward, recognizing both the competing interests involved and the typical timeframes for CAFE and CO_2 standards rulemakings.

Many commenters expressed concern with the agencies using any CBI as part of the rulemaking process. Some commenters expressed concern that use of CBI would make the CAFE model subject to inaccuracies because manufacturers would only provide additional information in situations in which a correction to the agencies' baseline assumptions would favor the manufacturers.[380] The agencies recognize this as a reasonable concern, but the analysis presented in the Draft TAR consistently assumed very little (if any) technology had been applied in the baseline. In addition, many manufacturers shared information on advanced technologies that were not yet in production in MY 2017, but could be used in the future; manufacturer

---

379 These technologies include low rolling resistance technology (incorrectly applied to zero baseline vehicles in Draft TAR), low-drag brakes (incorrectly applied to zero baseline vehicles in Draft TAR), electric power steering (incorrectly applied to too few vehicles in Draft TAR), accessory drive improvements (incorrectly applied to zero baseline vehicles in Draft TAR), engine friction reduction (previously named LUBEFR1, LUBEFR2, and LUBEFR3), secondary axle disconnect and transmission improvements.
380 NHTSA-2018-0067-12039, Union of Concerned Scientists.

contributions helped the agencies better model many advanced engine technologies and to include them in today's analysis, and inclusion of these technologies (and costs) in the analysis sometimes lowered the projected cost of compliance for stringent alternatives. Other commenters expressed concern that automakers would supply false or incomplete information that would unduly restrict what technologies can be deployed.[381] When possible, the agencies sought independently to verify manufacturer CBI (or claims made by other stakeholders) through lab testing and benchmarking.[382] The agencies found no evidence of misrepresentation of engineering specifications in the MY 2017 fleet in manufacturer CBI; instead, the agencies were able to verify independently many CBI submissions, and confirm the credibility of information provided from those sources.

Some commenters requested that more CBI be used in the analysis. For instance, some commenters suggested that the agencies should return to the use of product plans and announcements regarding future fleets because manufacturers had already committed investments to bring announced products to market.[383] However, if the agencies were to assume that these commitments were already in the baseline, the agencies would underestimate the cost of compliance for stringent alternatives. Moreover, while upfront investments to bring technologies to market are significant, the total marginal costs of components are typically large in comparison over the entire product life-cycle, and these costs have not yet been realized in vehicles not yet produced.

The agencies did make use of some forward-looking CBI in the analysis. The agencies received many comments from manufacturers on the technological feasibility, or functional applicability of some fuel saving technologies to certain vehicles, or certain vehicle applications, and the agencies took this information into consideration when projecting compliance pathways. These cases are discussed generally in Section VI.B.1.b)(6), below, and specifically for each technology in those technology sections. Some commenters expressed that the use of CBI for future product plans would be acceptable, but only if the agencies disclosed the CBI affecting all vehicles through MY 2025 at the time of publication.[384] Functionally, this is not possible. Manufacturer's confidential product plans cannot be made public, as prohibited under NHTSA's regulations at 49 CFR part 512, and if the information meets the requirements of section 208(c) of the Clean Air Act. If the agencies disclosed confidential information, it would not only violate the terms on which the agencies obtained the CBI, but it is unlikely that manufacturers would continue to offer CBI, which in turn would likely degrade the quality of the analysis. The agencies believe that the use of CBI in the NPRM and final rule analysis—to confirm, reference, or to otherwise modify aspects of the analysis that can be made public—threads the needle between a more accurate but less transparent analysis (using more CBI) and a less accurate but more transparent analysis (using less CBI).

[381] NHTSA-2018-0067-11741, ICCT.

[382] For instance, the agencies continue to evaluate tire rolling resistance on production vehicles via independent lab testing, and the agencies bench-marked the operating behavior and calibration of many engines and transmissions.

[383] NHTSA-2018-0067-11956, PA Department of Environmental Protection.

[384] NHTSA-2018-0067-11741.

(2) Source Data and Vintage Used in the Analysis

Based on the assumption that a publicly-available analysis fleet continued to be desirable, manufacturer compliance submissions to EPA and NHTSA were used as a starting point for the NPRM and final rule analysis fleets. Generally, manufacturer compliance submissions break down vehicle fuel economy and production volume by regulatory class, and include some very basic product information (typically including vehicle nameplate, engine displacement, basic transmission information, and drive configuration). Many different trim levels of a product are typically rolled up and reported in an aggregated fashion, and these groupings can make decomposition of different fuel-saving, road load reducing technologies extremely difficult. For instance, vehicles in different test weight classes, with different tires or aerodynamic profiles may be aggregated and reported together.[385] A second portion of the compliance submission summarizes production volume by vehicle footprints (a key compliance measure for standard setting) by nameplate, and includes some basic information about engine displacement, transmission, and drive configuration. Often these production volumes by footprint do not fit seamlessly together with the production volumes for fuel economy, so the agencies must reconcile this information.

Information from the MY 2016 fleet was chosen as the foundation for the NPRM analysis fleet because, at the time the rulemaking analysis was initiated, the 2016 fleet represented the most up-to-date information available in terms of individual vehicle models and configurations, production technology levels, and production volumes. If MY 2017 data had been used while this analysis was being developed, the agencies would have needed to use product planning information that could not be made available to the public until a later date.

The NPRM analysis fleet was initially developed with 2016 mid-model year compliance data because final compliance data was not available at that time, and the timing provided manufacturers the opportunity to review and comment on the characterization of their vehicles in the fleet. With a view toward developing an accurate characterization of the 2016 fleet to serve as an analytical starting point, corrections and updates to mid-year data (*e.g.*, to production estimates) were sought, in addition to corroboration or correction of technical information obtained from commercial and other sources (to the extent that information was not included in compliance data), although future product planning information from manufacturers (*e.g.*, future product offerings, products to be discontinued) was not requested, as most manufacturers view such information as CBI. Manufacturers offered a range of corrections to indicate engineering characteristics (*e.g.*, footprint, curb weight, transmission type) of specific vehicle model/configurations, as well as updates to fuel economy and production volume estimates in mid-year reporting. After following up on a case-by-case basis to investigate significant differences, the analysis fleet was updated.

Sales, footprint, and fuel economy values with final compliance data were also updated if that data was available. In a few cases, final production and fuel economy values were slightly different for specific MY 2016 vehicle models and configurations than were indicated in the

---

[385] Some fuel-economy compliance information for pickup trucks span multiple cab and box configurations, but manufacturers reported these disparate vehicles together.

NPRM analysis; however, other vehicle characteristics (*e.g.*, footprint, curb weight, technology content) important to the analysis were reasonably accurate. While some commenters have, in the past, raised concerns that non-final CAFE compliance data is subject to change, the potential for change is likely not significant enough to merit using final data from an earlier model year reflecting a more outdated fleet. Moreover, even ostensibly final CAFE compliance data is frequently subject to later revision (*e.g.*, if errors in fuel economy tests are discovered), and the purpose of the analysis was not to support enforcement actions but rather to provide a realistic assessment of manufacturers' potential responses to future standards.

Manufacturers integrated a significant amount of new technology in the MY 2016 fleet, and this was especially true for newly-designed vehicles launched in MY 2016. While subsequent fleets will involve even further application of technology, using available data for MY 2016 provided the most realistic detailed foundation for analysis that could be made available publicly in full detail, allowing stakeholders to reproduce the analysis presented in the proposal independently. Insofar as future product offerings are likely to be more similar to vehicles produced in 2016 than to vehicles produced in earlier model years, using available data regarding the 2016 model year provided the most realistic, publicly releasable foundation for constructing a forecast of the future vehicle market for this proposal. Many comments responding to the Draft TAR, EPA's Proposed Determination, EPA's 2017 Request for Comment, and the NPRM preceding today's notice stated that the most up-to-date analysis fleet possible should be used, because a more up-to-date analysis fleet will better capture how manufacturers apply technology and will account better for vehicle model/configuration introductions and deletions.[386,387]

On the other hand, some commenters suggested that because manufacturers continue improving vehicle performance and utility over time, an older analysis fleet should be used to estimate how the fleet could have evolved had manufacturers applied all technological potential to fuel economy rather than continuing to improve vehicle performance and utility.[388] Because manufacturers change and improve product offerings over time, conducting analysis with an older analysis fleet (or with a fleet using fuel economy levels and CO_2 emissions rates that have been adjusted to reflect an assumed return to levels of performance and utility typical of some past model year) would miss this real-world trend. While such an analysis could project what

[386] 82 FR 39551 (Aug. 21, 2017).

[387] For example, in 2016 comments to dockets EPA-HQ-OAR-2015-0827 and NHTSA-2016-0068, the Alliance of Automobile Manufacturers commented that "the Alliance supports the use of the most recent data available in establishing the baseline fleet, and therefore believes that NHTSA's selection [of, at the time, model year 2015] was more appropriate for the Draft TAR." Alliance at 82, Docket ID. EPA-HQ-OAR-2015-0827-4089. Global Automakers commented that "a one-year difference constitutes a technology change-over for up to 20% of a manufacturer's fleet. It was also generally understood by industry and the agencies that several new, and potentially significant, technologies would be implemented in MY 2015. The use of an older, outdated baseline can have significant impacts on the modeling of subsequent Reference Case and Control Case technologies." Global Automakers at A-10, Docket ID EPA-HQ-OAR-2015-0827-4009.

[388] For example, in 2016 comments to dockets EPA-HQ-OAR-2015-0827 and NHTSA-2016-0068, UCS stated "in modeling technology effectiveness and use, the agencies should use 2010 levels of performance as the baseline." UCS at 4, Docket ID. EPA-HQ-OAR-2015-0827-4016.

industry *could* do if, for example, manufacturers devoted all technological improvements toward raising fuel economy and reducing CO_2 emissions (and if consumers decided to purchase these vehicles), the agencies do not believe it would be consistent with a transparent examination of what effects different levels of standards would have on individual manufacturers and the fleet as a whole.

All else being equal, using a newer analysis fleet will produce more realistic estimates of impacts of potential new standards than using an outdated analysis fleet. However, among relatively current options, a balance must be struck between input freshness, and input completeness and accuracy.[389] During assembly of the inputs for the NPRM analysis, final compliance data was available for the MY 2015 model year but not, in a few cases, for MY 2016. However, between mid-year compliance information and manufacturers' specific updates discussed above, a robust and detailed characterization of the MY 2016 fleet was developed. While information continued to develop regarding the MY 2017 and, to a lesser extent MY 2018 and even MY 2019 fleets, this information was—even in mid-2017—too incomplete and inconsistent to be assembled with confidence into an analysis fleet for modeling supporting deliberations regarding the NPRM analysis.

Manufacturers requested that the baseline fleet supporting the final rule incorporate the MY 2018 or most recent information available.[390] Other commenters expressed desire for multiple fleets of various vintages to compare the updated model outputs with those of previous rule-makings. Specifically, some commenters requested that older fleet vintages (MY 2010, for instance) be developed in parallel with the MY 2017 fleet so that those too may be used as inputs for the model.[391]

Between the NPRM and this final rule, manufacturers submitted final compliance data for the MY 2017 fleet. When the agencies pulled together information for the fleet for the final rule, the agencies decided to use the highest-quality, most up-to-date information available. Given that pulling this information together takes some time, and given that "final" compliance submissions often lag production by a few years, the agencies decided to use 2017 model year as the base year for the analysis fleet, as the agencies stated in the NPRM.[392] While the agencies could have used preliminary 2018 data or even very early 2019 data, this information was not

---

[389] Comments provided through a recent peer review of the CAFE model recognize the competing interests behind this balance. For example, referring to NHTSA's 2016 Draft TAR analysis, one of the peer reviewers commented as follows: "The NHTSA decision to use MY 2015 data is wise. In the TAR they point out that a MY 2016 foundation would require the use of confidential data, which is less desirable. Clearly they would also have a qualitative vision of the MY 2016 landscape while employing MY 2015 as a foundation. Although MY 2015 data may still be subject to minor revision, this is unlikely to impact the predictive ability of the model… A more complex alternative approach might be to employ some 2016 changes in technology, and attempt a blend of MY 2015 and MY 2016, while relying of estimation gained from only MY 2015 for sales. This approach may add some relevancy in terms of technology, but might introduce substantial error in terms of sales."

[390] NHTSA-2018-0067-12150, Toyota North America.

[391] NHTSA-2018-0067-11741, ICCT.

[392] 83 FR 43006 ("If newer compliance data (*i.e.*, MY 2017) becomes available and can be analyzed during the pendency of this rulemaking, and if all other necessary steps can be performed, the analysis fleet will be updated, as feasible, and made publicly available.").

available in time to support the final rulemaking. Likewise, the agencies chose not to revert to a previous model year (for instance 2016 or 2012) because many manufacturers have incorporated fuel savings technologies over the last few years, realized some benefits for fuel economy, and adjusted the performance or sales mix of vehicles to remain competitive in the market. Also, using an earlier model year would provide less accurate projections because the analysis would be based on what manufacturers could have done in past model years and would have estimated the fuel economy improvements instead of using known information on the technologies that were employed and the actual fuel economy that resulted from applying those technologies.

Some additional information (about off-cycle technologies, for instance) was often not reported by manufacturers in MY 2017 formal compliance submissions in a way that provided clear information on which technologies were included on which products. As part of the formal compliance submission, some manufacturers voluntarily submitted additional information (about engine technologies, for instance). While this data was generally of very high quality, there were some mistakes or inconsistencies with publicly available information, causing the agencies to contact the manufacturers to understand and correct identified issues. In most cases, however, the formal compliance data was very limited in nature, and the agencies collected additional information necessary to characterize fully the fleet from other sources, and scrutinized additional information submitted by manufacturers carefully, independently verifying when possible.

Specifically, the agencies downloaded and reviewed numerous marketing brochures and product launch press releases to confirm information submitted by manufacturers and to fill in information necessary for the analysis fleet that was not provided in the compliance data. Product brochures often served as the basis for the curb weights used in the analysis. This publicly available manufacturer information sometimes also included aerodynamic drag coefficients, information about steering architecture, start-stop systems, pickup bed lengths, fuel tank capacities, and high-voltage battery capacities. The agencies recorded vehicle horsepower, compression ratio, fuel-type, and recommended oil weight rating from a combination of manufacturer product brochures and owner's manuals. The product brochures, as well as online references such as Autobytel, informed which combinations of fuel saving technologies were available on which trim levels, and what the manufacturer suggested retail price was for many products. Overall this information proved helpful for assigning technologies to vehicles, and for getting data (such as fuel tank size[393]) necessary for the analysis. These reference materials have been included in the rulemaking documentation.[394]

The agencies elected not to develop fleets of previous model year vintages that could be used in parallel as an input to the CAFE model. Developing a detailed characterization of the fleet of any vintage would be a huge undertaking with few benefits. As the scope has increased, and as additional modules are added, going back in time to re-characterize a previous fleet in a format that works with CAFE model updates can be time- and resource-prohibitive for the

---

393 The quality of data for today's analysis fleet is notably improved for fuel tank capacity, which factors into the calculation of refueling time benefits. In many previous analyses, fuel tank sizes were often stated as estimates or proxies, and not sourced so carefully.

394 Publicly available data used to supplement analysis fleet information is available in the docket.

agencies, even if that work is adapting a fleet that was used in previous rule-making analysis. Doing so also offers little value in determining what potential fuel saving technology can be added to a more recent fleet during the rulemaking timeframe.

The MY 2017 manufacturer-submitted data, verified and supplemented by the agencies with publicly-available information, therefore presented the fullest, most up-to-date data set that the agencies could have used to support this analysis.

b) Characterizing Vehicles and their Technology Content

The starting point for projecting what additional fuel economy improving technologies could feasibly be applied to vehicles is knowing what vehicles are produced by which manufacturers and what technologies exist on those vehicles. Rows in the market data file are the smallest portion of the fleet to which technology may be applied as part of a projected compliance pathway. For the analysis presented in this final rule, the agencies, when possible, attempted to include vehicle trim level information in discrete rows. A manufacturer, for example GM, may produce one or more vehicle makes (or brands), for example Chevrolet, Buick and others. Each vehicle make may offer one or more vehicle models, for example Malibu, Traverse and others. And each vehicle model may be available in one or more trim levels (or standard option levels), for example "RS," "Premier" and others, which have different levels of standard options, and in some cases, different engines and transmissions.

Manufacturer compliance submissions, discussed above, were used as a starting point to define working rows in the market data file; however, often the rows needed to be further disaggregated to correctly characterize vehicle information covered in the scope of the analysis, and analysis fleet. Manufacturers often grouped vehicles with multiple trim levels together because they often included the same fuel-saving technologies and may be aggregated to simplify reporting. However, the manufacturer suggested retail prices of different trim levels are certainly different, and other features relevant to the analysis are occasionally different.

As a result of further disaggregating compliance information, the number of rows in the market data file increased from 1,667 rows used in the NPRM to 2,952 rows for this final rule analysis. The agencies do not have data on sales volumes for each nameplate by trim level, and used an approach that evenly distributed volume across offered trim levels, within the defined constraints of the compliance data.[395] Evenly distributing the volume across trim levels is a simplification, but this action should (1) highlight some difficulties that could be encountered when acquiring data for a full-vehicle consumer choice model should the agencies pursue developing one in the future (discussed further, below), and (2) lower the average sales volume per row in the market data file, thereby allowing the application of very advanced electrification technologies in smaller lumps. The latter effect is responsive to comments (discussed below) that suggested electrification technologies could be more cost-effectively deployed in lower

---

[395] The sum of volumes by nameplate configuration, for fuel economy value, and for footprint value remains the same.

volumes, and that the CAFE model artificially constrains cost effective technologies that may be deployed, resulting in higher costs and large over-compliance.

(1) Assigning Vehicle Technology Classes

While each vehicle in the analysis fleet has its list of observed technologies and equipment, the ways in which manufacturers apply technologies and equipment do not always coincide perfectly with how the analysis characterizes the various technologies that improve fuel economy and reduce CO_2 emissions. To improve how the observed vehicle fleet "fits into" the analysis, each vehicle model/configuration is "mapped" to the full-vehicle simulation modeling by Argonne National Laboratory that is used to estimate the effectiveness of the fuel economy-improving/CO_2 emissions-reducing technologies considered. Argonne produces full-vehicle simulation modeling for many combinations of technologies, on many types of vehicles, but it did not simulate literally every single manufacturer's vehicle model/configuration in the analysis fleet because it would be impractical to assemble the requisite detailed information—much of which would likely only be provided on a confidential basis—specific to each vehicle model/configuration and because the scale of the simulation effort would correspondingly increase by at least two orders of magnitude. Instead, Argonne simulated 10 different vehicle types corresponding to the "technology classes" generally used in CAFE analysis over the past several rulemakings (e.g., small car, small performance car, pickup truck, etc.). Each of those 10 different vehicle types was assigned a set of "baseline characteristics" to which Argonne added combinations of fuel-saving technologies and then ran simulations to determine the fuel economy achieved when applying each combination of technologies to that vehicle type given its baseline characteristics.

Table VI-7 – Summary of Baseline Technology Class Attributes, in Argonne National Laboratory Simulations

	SmallCar	**SmallCarPerf**	**MedCar**	**MedCarPerf**	**SmallSUV**	**SmallSUVPerf**	**MedSUV**	**MedSUVPerf**	**Pickup**	**PickupHT**
Baseline Curb Weight (lbs.) at MR0	3100	3300	3800	3800	3600	4100	4100	4600	4500	5400
Target time (s) to accelerate from 0-60 miles per hour	10.0	8.0	9.0	6.0	9.0	7.0	10.0	7.0	7.0	7.0
Percent of MY 2017 Volume Mapped to Technology Class	13.3%	12.7%	4.1%	8.3%	19.4%	7.1%	3.2%	19.6%	3.5%	8.6%

In the analysis fleet, inputs assign each specific vehicle model/configuration to a technology class, and once there, map to the simulation within that technology class most closely matching the combination of observed technologies and equipment on that vehicle. This mapping to a specific simulation result most closely representing a given vehicle model/configuration's initial technology "state" enables the CAFE model to estimate the same vehicle model/configuration's fuel economy after application of some other combination of technologies, leading to an alternative technology state.

(2) Assigning Vehicle Technology Content

As explained above, the analysis fleet is defined not only by the vehicles it contains, but also by the technologies on those vehicles. Each vehicle in the analysis fleet has an associated list of observed technologies and equipment that can improve fuel economy and reduce CO_2 emissions.[396] With a portfolio of descriptive technologies arranged by manufacturer and model, the analysis fleet can be summarized and project how vehicles in that fleet may increase fuel economy over time via the application of additional technology.

In many cases, vehicle technology is clearly observable from the 2017 compliance data (*e.g.*, compliance data indicates clearly which vehicles have turbochargers and which have continuously variable transmissions), but in some cases technology levels are less observable. For the latter, like levels of mass reduction, the analysis categorized levels of technology already used in a given vehicle. Similarly, engineering judgment was used to determine if higher mass reduction levels may be used practicably and safely for a given vehicle.

Either in mid-year compliance data for MY 2016, final compliance data for MY 2017, or separately and at the agencies' invitation prior to the NPRM or in comments in responses to the NPRM, most manufacturers provided guidance on the technology already present in each of their vehicle model/configurations. This information was not as complete for all manufacturers' products as needed for the analysis, so, in some cases, information was supplemented with publicly available data, typically from manufacturer media sites. In limited cases, manufacturers did not supply information, and information from commercial and publicly available sources was used.

The agencies continued to evaluate emerging technologies in the analysis. In response to comments,[397] and given recent product launches for MY 2020, and some very recently announced future product offerings, the agencies elevated some technologies that were discussed in the NPRM to the compliance simulation. As a result, several additional engine technologies, expanded levels of mass reduction technology, and some additional combinations of engines

[396] These technologies are generally grouped into the following categories: Vehicle technologies include mass reduction, aerodynamic drag reduction, low rolling resistance tires, and others. Engine technologies include engine attributes describing fuel type, engine aspiration, valvetrain configuration, compression ratio, number of cylinders, size of displacement, and others. Transmission technologies include different transmission arrangements like manual, 6-speed automatic, 10-speed automatic, continuously variable transmission, and dual-clutch transmissions. Hybrid and electric powertrains may complement traditional engine and transmission designs or replace them entirely.

[397] NHTSA-2018-0067-11741.

with plug-in hybrid, or strong hybrid technology are available in the compliance pathways for the final rule analysis.

In addition, some redundant technologies, or technologies that were inadvertently represented on the technology tree as being available to be applied twice, have been consolidated. For instance, previous basic versions of engine friction reduction were layered on top of basic engine maps, but the efficiency in many modern engine maps already include the benefits of that engine friction reduction technology. The following Table VI-8 lists the technologies considered in the final rule analysis, with the data sources used to map those technologies to vehicles in the analysis fleet.

Table VI-8 – List of Technologies with Data Sources for Technology Assignments

Technology Name	Abbreviation	Data Source for Mapping	Tech Group
Single Overhead Cam	SOHC	Public Specifications	Basic Engines
Dual Overhead Cam	DOHC	Public Specifications	Basic Engines
Overhead Valve	OHV	Public Specification	Basic Engines
Engine Friction Reduction	EFR	Not commercialized in MY 2017	Engine Improvements
Variable Valve Timing	VVT	Public Specifications	Basic Engines
Variable Valve Lift	VVL	Public Specifications	Basic Engines
Stoichiometric Gasoline Direct Injection	SGDI	Public Specifications	Basic Engines
Cylinder Deactivation	DEAC	Public Specifications	Basic Engines
Turbocharged Engine	TURBO1	Public Specifications	Advanced Engines

Industry commenters generally stated the MY 2016 baseline technology content presented in the NPRM as an improvement over previous analyses because it more accurately accounted for technology already used in the fleet.[398,399] In contrast, some commenters expressed preference for EPA's baseline technology assignment assumptions presented in the Draft TAR for mass reduction, tire rolling resistance, and aerodynamic drag because those assumptions projected very few technology improvements were present in the baseline fleet. In assessing the comments, the agencies found that using the EPA Draft TAR approach would lead to projected compliance pathways with overestimated fuel economy improvements and underestimated costs.[400]

Many of those assumptions were neither scientifically meritorious, nor isolated examples. For instance, for the EPA Draft TAR and Proposed Determination analyses, the BMW i3, a vehicle with full carbon fiber bodysides and downsized, mass-reduced wheels and tires (some of the most advanced mass reducing technologies commercialized in the automotive industry), was assumed to have 1.0 percent mass reduction (a very minor level of mass reduction). Similarly, previous analyses assigned the Chevrolet Corvette, a performance vehicle that has long been a platform for commercializing advanced weight saving technologies,[401] with zero mass reduction. For aerodynamic drag, previous EPA analysis assumed that pickup trucks could achieve the aerodynamic drag profile typical of a sedan, with little regard for form drag constraints or frontal area (and headroom, or ground clearance) considerations. These assumptions commonly led to projections of a 20 percent improvement in mass, aerodynamic drag, and tire rolling resistance, even when a large portion of those improvements had either already been implemented, or were not technologically feasible. On the other hand, in the Draft TAR, NHTSA presented methodologies to evaluate content for mass reduction technology, aerodynamic drag improvements, and rolling resistance technologies that better accounted for the actual level of technologies in the analysis fleet. Throughout the rulemaking process, the agencies reconciled

these differences, jointly presented improved approaches in the NPRM similar to what NHTSA presented in the Draft TAR, and again used those reconciled approaches in today's analysis.[402]

Many commenters correctly observed that the analysis fleet in the NPRM recognized more technology content in the baseline than in the Draft TAR (with higher penetration rates of tire rolling resistance and aerodynamic drag improvements, for instance), but also that the fuel economy values of the fleet had not improved all that much from the previous year. Some commenters concluded that the NPRM baseline technology assignment process was arbitrary and overstated the technology content already present in the baseline fleet.[403,404] The agencies agree that there was a large increase in the amount of road load technology credited in the baseline fleet between EPA's Draft TAR and the jointly produced NPRM, and clarify that this change was largely due to a recognition of technologies that were actually present in the fleet, but not properly accounted for in previous analyses. The change in penetration rates of road load technologies (after accounting for glider share updates, which is discussed in more detail in the mass reduction technology section) between the NPRM and today's analysis is relatively small.

Many commenters noted that the different baseline road load assumptions (and other technology modeling) materially affect compliance pathways, and projected costs.[405] ICCT commented that the agencies should conduct sensitivity analyses assuming every vehicle in the analysis fleet is set to zero percent road load technology improvement, to demonstrate how the technology content of the analysis fleet affected the compliance scenarios.[406]

While the agencies have clearly described the methods by which initial road load technologies are assigned in Section VI.C.4 Mass Reduction, Section VI.C.5 Aerodynamics, and Section VI.C.6 Tire Rolling Resistance below, the agencies considered a sensitivity case that assumed no mass reduction, rolling resistance, or aerodynamic improvements had been made to the MY 2017 fleet (i.e., setting all vehicle road levels to zero - MRO, AERO and ROLL0). While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity analysis to understand any affect it may have on technology penetration along other paths (e.g. engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong hybrids and plug-in hybrids) in the baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about $300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about $200 per vehicle. Under the CO_2 program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost

[402] Because these road load technologies are no longer double counted, the projected compliance pathway in the NPRM, and in today's analysis for stringent alternatives, often requires more advanced fuel saving technologies than previously projected, including higher projected penetration rates of hybrid and electric vehicle technologies.

[404] NHTSA-2018-0067-12039, Union of Concerned Scientists.
[405] NHTSA-2018-0067-11928, Ford Motor Company.
[406] NHTSA-2018-0067-11741, ICCT.

change is also comparable, but slightly smaller ($200 per vehicle in the baseline) than the CAFE program results. Cost savings under the preferred alternative are further reduced by about $100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Some commenters preferred that the agencies develop a different methodology based on reported road load coefficients (“A,” “B” and “C” coastdown coefficients) to estimate levels of aerodynamic drag improvement and rolling resistance in the baseline fleet that did not rely on CBI.[407] The agencies considered this, but determined that using CBI to assign baseline aerodynamic drag levels and rolling resistance values was more accurate and appropriate. Estimating aerodynamic drag levels and rolling resistance levels from coastdown coefficients is not straightforward, and to do it well would require information the agencies do not have (much of which is also CBI). For instance, rotational inertias of wheel, tire, and brake packages can affect coastdown, so mass of the vehicle is not sufficient. The frontal area of the vehicles, a key component for calculating aerodynamic drag, is rarely known, and often requires manufacturer input to get an accurate value. Other important vehicle features like all-wheel-drive should also be accounted for, and the agencies would struggle to correctly identify improvements in rolling resistance, low-drag brakes, and secondary axle disconnect, because all of these technologies would present similar signature on a coast down test. All of these technologies are represented as technology pathways in today’s analysis. Manufacturers acknowledged the possibility of using road load coefficients to estimate rolling resistance and aerodynamic features, but warned that the process “required various assumptions and is not very accurate,” and stated that the use of CBI to assess aerodynamic and rolling resistance technologies is an “accurate and practical solution” to assign these difficult to observe technologies.[408]

(3) Assigning Engine Configurations

Engine technology costs can vary significantly by the configuration of the engine. For instance, adding variable valve lift to each cylinder on an engine would cost more for an engine with eight cylinders than an engine with four cylinders. Similarly, the cost of adding a turbocharger to an engine and downsizing the engine would be different going from a naturally aspirated V8 to a turbocharged V6 than going from a naturally aspirated V6 to a turbocharged I4. As discussed in detail in the engine technology section of this document, the cost files for the CAFE model account for instances such as these examples.

Information in the analysis fleet enables the CAFE model to reference the intended engine costs. The “Engine Technology Class (Observed)” lists the architecture of the observed engine. Notably, the analysis assumes that nearly all turbo charged engines take advantage of downsizing to optimize fuel efficiency, minimize the cost of turbo charging, and to maintain performance (to the extent practicable) with the naturally aspirated counterpart engine. Therefore, engines observed in the fleet that have already been down-sized must reference costs for a larger basic engine, which assumes down-sizing with the application of turbo technology.

[407] NHTSA-2018-0067-11741, ICCT.
[408] NHTSA-2018-0067-12073, Alliance of Automobile Manufacturers.

In these cases, the "Engine Technology Class" which is used to reference costs will be larger than the "Engine Technology Class (Observed)."

This is the same process agencies used in the NPRM, and it corrects a previous error in the Draft TAR analysis, which incorrectly underestimated turbocharged engine costs.[409] Some commenters expressed confusion and disagreement with this correction, with some even commenting that the analysis baselessly inflated costs of turbocharging technologies between the Draft TAR and the NPRM.[410] To be clear, this was a correction so that the costs used to calculate turbocharged engine costs accurately reflected the total costs for a turbocharged engine.

(4) Characterizing Shared Vehicle Platforms, Engines, and Transmissions

Another aspect of characterizing vehicle model/configurations in the analysis fleet is based on whether they share a "platform" with other vehicle model/configurations. A "platform" refers to engineered underpinnings shared on several differentiated products. Manufacturers share and standardize components, systems, tooling, and assembly processes within their products (and occasionally with the products of another manufacturer) to manage complexity and costs for development, manufacturing, and assembly.

The concept of platform sharing has evolved over time. Years ago, manufacturers rebadged vehicles and offered luxury options only on premium nameplates (and manufacturers shared some vehicle platforms in limited cases). Today, manufacturers share parts across highly differentiated vehicles with different body styles, sizes, and capabilities that may share the same platform. For instance, the Honda Civic and Honda CR-V share many parts and are built on the same platform. Engineers design chassis platforms with the ability to vary wheelbase, ride height, and even driveline configuration. Assembly lines can produce hatchbacks and sedans to cost-effectively utilize manufacturing capacity and respond to shifts in market demand. Engines made on the same line may power small cars or mid-size sport utility vehicles. In addition, although the agencies' analysis, like past CAFE analyses, considers vehicles produced for sale in the U.S., the agency notes these platforms are not constrained to vehicle models built for sale in the U.S.; many manufacturers have developed, and use, global platforms, and the total number of platforms is decreasing across the industry. Several automakers (for example, General Motors and Ford) either plan to, or already have, reduced their number of platforms to less than 10 and account for the overwhelming majority of their production volumes on that small number of platforms.

Vehicle model/configurations derived from the same platform are so identified in the analysis fleet. Many manufacturers' use of vehicle platforms is well documented in the public record and widely recognized among the vehicle engineering community. Engineering

[409] For instance, the Draft TAR engine costs would map an observed V6 Turbo engine to I4 Turbo engine costs, by referencing a 4C1B engine cost.

[410] NHTSA-2018-0067-11741, ICCT.

knowledge, information from trade publications, and feedback from manufacturers and suppliers was also used to assign vehicle platforms in the analysis fleet.

When the CAFE model is deciding where and how to add technology to vehicles, if one vehicle on the platform receives new technology, other vehicles on the platform also receive the technology as part of their next major redesign or refresh.[411] Similar to vehicle platforms, manufacturers create engines that share parts. For instance, manufacturers may use different piston strokes on a common engine block, or bore out common engine block castings with different diameters to create engines with an array of displacements. Head assemblies for different displacement engines may share many components and manufacturing processes across the engine family. Manufacturers may finish crankshafts with the same tools to similar tolerances. Engines on the same architecture may share pistons, connecting rods, and the same engine architecture may include both six and eight cylinder engines. One engine family may appear on many vehicles on a platform, and changes to that engine may or may not carry through to all the vehicles. Some engines are shared across a range of different vehicle platforms. Vehicle model/configurations in the analysis fleet that share engines belonging to the same platform are also identified as such.

It is important to note that manufacturers define common engines differently. Some manufacturers consider engines as "common" if the engines shared an architecture, components, or manufacturing processes. Other manufacturers take a narrower definition, and only assume "common" engines if the parts in the engine assembly are the same. In some cases, manufacturers designate each engine in each application as a unique powertrain. For example, a manufacturer may have listed two engines separately for a pair that share designs for the engine block, the crank shaft, and the head because the accessory drive components, oil pans, and engine calibrations differ between the two. In practice, many engines share parts, tooling, and assembly resources, and manufacturers often coordinate design updates between two similar engines. Engine families, designated in the analysis using "engine codes," for each manufacturer were tabulated and assigned based on data-driven criteria. If engines shared a common cylinder count and configuration, displacement, valvetrain, and fuel type, those engines may have been considered together. In addition, if the compression ratio, horsepower, and displacement of engines were only slightly different, those engines were considered the same for the purposes of redesign and sharing.

Vehicles in the analysis fleet with the same engine family will, therefore, adopt engine technology in a coordinated fashion. Specifically, if such vehicles have different design schedules (*i.e.*, refresh and redesign schedules), and a subset of vehicles using a given engine add engine technologies during of a redesign or refresh that occurs in an early model year (*e.g.*, 2018), other vehicles using the same engine "inherit" these technologies at the soonest ensuing refresh or redesign. This is consistent with a view that, over time, most manufacturers are likely to find it more practicable to shift production to a new version of an engine than to continue production of both the new engine and a "legacy" engine indefinitely. By grouping engines

---

[411] The CAFE model assigns mass reduction technology at a platform level, but many other technologies may be assigned and shared at a vehicle nameplate or vehicle model level.

together, the CAFE model controls future engine families to ensure reasonable powertrain complexity. This means, however, that for manufacturers that submitted highly atomized engine and transmission portfolios, there is a practical cap on powertrain complexity and the ability of the manufacturer to optimize the displacement of (i.e., "right size") engines perfectly for each vehicle configuration. This concept is discussed further in Section VI.B.4.a), below.

Like with engines, manufacturers often use transmissions that are the same or similar on multiple vehicles. Manufacturers may produce transmissions that have nominally different machining to castings, or manufacturers may produce transmissions that are internally identical, except for the final gear ratio. In some cases, manufacturers sub-contract with suppliers that deliver whole transmissions. In other cases, manufacturers form joint ventures to develop shared transmissions, and these transmission platforms may be offered in many vehicles across manufacturers. Manufacturers use supplier and joint-venture transmissions to a greater extent than they do with engines. To reflect this reality, shared transmissions were considered for manufacturers as appropriate. Transmission configurations are referred to in the analysis as "transmission codes." Like the inheritance approach outlined for engines, if one vehicle application of a shared transmission family upgraded the transmission, other vehicle applications also upgraded the transmission at the next refresh or redesign year. To define common transmissions, the agencies considered transmission type (manual, automatic, dual-clutch, continuously variable), number of gears, and vehicle architecture (front-wheel-drive, rear-wheel-drive, all-wheel-drive based on a front-wheel drive platform, or all-wheel-drive based on a rear-wheel-drive platform). If vehicles shared these attributes, these transmissions were grouped for the analysis. Vehicles in the analysis fleet with the same transmission configuration will adopt transmission technology together, as described above.

Having all vehicles that share a platform (or engines that are part of a family) adopt fuel economy-improving/CO_2 emissions-reducing technologies together, subject to refresh/redesign constraints, reflects the real-world considerations described above, but also overlooks some decisions manufacturers might make in the real world in response to market pull. Accordingly, even though the analysis fleet is incredibly complex, it is also over-simplified in some respects compared to the real world. For example, the CAFE model does not currently attempt to simulate the potential for a manufacturer to shift the application of technologies to improve performance rather than fuel economy. Therefore, the model's representation of the "inheritance" of technology can lead to estimates a manufacturer might eventually exceed fuel economy standards as technology continues to propagate across shared platforms and engines. While the agencies have previously seen examples of extended periods during which some manufacturers exceeded one or both CAFE and/or CO_2 standards, in plenty of other examples, manufacturers chose to introduce (or even reintroduce) technological complexity into their vehicle lineups in response to buyer preferences. Going forward, and recognizing the recent trend for consolidating platforms, it seems likely manufacturers will be more likely to choose efficiency over complexity in this regard; therefore, the potential should be lower that today's analysis turns out to be oversimplified compared to the real world.

Manufacturers described shared engines, transmissions, and vehicle platforms as "standard business practice" and they were encouraged that the NHTSA analysis in the Draft TAR, and the jointly issued NPRM placed realistic limits on the number of unique engines and transmissions in a powertrain portfolio.[412] In previous rulemakings, stakeholders pointed out that shared parts and portfolio complexity should be considered (but were not), and that the proliferation of unique technology combinations resulting from unconstrained compliance pathways would jeopardize economies of scale in the real world.[413]

HD Systems acknowledged that previous rulemakings did not appropriately consider part sharing, but contended that in today's global marketplace, manufacturers have flexibility to compete in new ways that break old part sharing rules.[414] The agencies acknowledge that some transmissions are now sourced through suppliers, and that economies of scale could, in the future be achieved at an industry level instead of a manufacturer level; however, even when manufacturers outsource a transmission, recent history suggests they apply that transmission to multiple vehicles to control assembly plant and service parts complexity, as they would if they were making the transmission themselves. Similarly, even for global platforms, or global powertrains, there is little evidence that manufacturers fragment powertrain line-ups for a vehicle, or a set of vehicles that have typically used the same engine. The agencies will continue to consider how to capture more accurately the ways vehicles share engines, transmissions, and platforms in future rulemakings, but the part-sharing and modeling approach presented in the NPRM and this final rule represents a marked improvement over previous analysis.

(5) Characterizing Production Design Cycles

Another aspect of characterizing vehicles in the analysis fleet is based on when they can next be refreshed or redesigned. Redesign schedules play an important role in determining when new technologies may be applied. Many technologies that improve fuel economy and reduce CO_2 emissions may be difficult to incorporate without a major product redesign. Therefore, each vehicle model in the analysis fleet has an associated redesign schedule, and the CAFE model uses that schedule to implement significant advances in some technologies (like major mass reduction) to redesign years, while allowing manufacturers to include minor advances (such as improved tire rolling resistance) during a vehicle "refresh," or a smaller update made to a vehicle, which can happen between redesigns. In addition to refresh and redesign schedules associated with vehicle model/configurations, vehicles that share a platform subsequently have platform-wide refresh and redesign schedules for mass reduction technologies.

To develop the refresh/redesign cycles used for the NPRM vehicles in the analysis fleet, information from commercially available sources was used to project redesign cycles through MY 2022, as was done for NHTSA's analysis for the 2016 Draft TAR.[415] Commercially

---

412 NHTSA-2018-0067-12150, Toyota North America.
413 Alliance of Automobile Manufacturers, EPA-HQ-OAR-0827 and NHTSA-2016-0068.
414 NHTSA-2018-0067-11985, HD Systems.
415 In some cases, data from commercially available sources was found to be incomplete or inconsistent with other available information. For instance, commercially available sources identified some newly imported vehicles as new platforms, but the international platform was midway through the product lifecycle. While new to the U.S. market, treating these vehicles as new entrants would have resulted in artificially short redesign cycles if carried forward, in some cases. Similarly, commercially available sources labeled some product refreshes as redesigns, and vice versa. In these limited cases, the data was revised to be consistent with other available information or typical

available sources' estimates through MY 2022 are generally supported by detailed consideration of public announcements plus related intelligence from suppliers and other sources, and recognize that uncertainty increases considerably as the forecasting horizon is extended. For MYs 2023-2035, in recognition of that uncertainty, redesign schedules were extended considering past pacing for each product, estimated schedules through MY 2022, and schedules for other products in the same technology classes. As mentioned above, potentially confidential forward-looking information was not requested from manufacturers; nevertheless, all manufacturers had an opportunity to review the estimates of product-specific redesign schedules. A few manufacturers provided related forecasts and, for the most part, that information corroborated the estimates.

Some commenters suggested supplanting these estimated redesign schedules with estimates applying faster cycles (*e.g.*, four to five years), and this approach was considered for the analysis. Some manufacturers tend to operate with faster redesign cycles and may continue to do so, and manufacturers tend to redesign some products more frequently than others. However, especially considering that information presented by manufacturers largely supports estimates discussed above, applying a "one size fits all" acceleration of redesign cycles would not improve the analysis; instead, assuming a fixed, shortened redesign schedule across the industry would likely reduce consistency with the real world, especially for light trucks, which are redesigned, on average, no less than every six years (see Table VI-9, below). Moreover, if some manufacturers accelerate redesigns in response to new standards, doing so would likely involve costs (greater levels of stranded capital, reduced opportunity to benefit from "learning"-related cost reductions) greater than reflected in other inputs to the analysis.

As discussed in the NPRM, manufacturers use diverse strategies with respect to when, and how often they update vehicle designs. While most vehicles have been redesigned sometime in the last five years, many vehicles have not. In particular, vehicles with lower annual sales volumes tend to be redesigned less frequently, perhaps giving manufacturers more time to recoup the investment needed to bring the product to market. In some cases, manufacturers continue to produce and sell vehicles designed more than a decade ago.

---

redesign and refresh schedules for CAFE modeling. In these limited cases, the forecast time between redesigns and refreshes was updated to match the observed past product timing.

Table VI-9 – Sales Distribution by Age of Vehicle Engineering Design

Most Recent Engineering Redesign Model Year of the Observed MY 2017 Vehicle	% of MY 2017 Fleet (Unit Sales) by Engineering Design Age	Portion of the Analysis Fleet Observations in MY 2017 Fleet by Engineering Design Age	Age of Vehicle Engineering Design	Portion of total New Vehicle Sales with Engineering Designs As New or Newer than "Age of Vehicle Engineering Design"
2006	1.6%	0.7%	11	99.97%
2007	1.7%	2.9%	10	98.4%
2008	1.4%	0.6%	9	96.7%
2009	4.5%	5.2%	8	95.3%
2010	6.4%	8.5%	7	90.9%
2011	7.0%	4.5%	6	84.4%
2012	3.0%	10.6%	5	77.4%
2013	18.9%	7.9%	4	74.5%
2014	15.9%	16.4%	3	55.6%

2016	14.8%	11.9%	1	27.8%
2017	13.0%	9.2%	0	13.0%

Each manufacturer may use different strategies throughout their product portfolio, and a component of each strategy may include the timing of refresh and redesign cycles. Table VI-10 summarizes the average time between redesigns, by manufacturer, by vehicle technology class. Dashes mean the manufacturer has no volume in that vehicle technology class in the MY 2017 analysis fleet. Across the industry, manufacturers average 6.6 years between product redesigns.

Trends on redesign schedules identified in the NPRM remain in place for today's analysis. Pick-up trucks have much longer redesign schedules than small cars. Some manufacturers redesign vehicles often, while other manufacturers redesign vehicles less often. Even if two manufacturers have similar redesign cadence, the model years in which the redesigns occur may still be different and dependent on where each of the manufacturer's products are in their life cycle.

Table VI-11 summarizes the average age of manufacturers' offering by vehicle technology class. A value of "0.0" means that every vehicle for a manufacturer in the vehicle technology class, represented by the MY 2017 analysis fleet was new in MY 2017. Across the industry manufacturers redesigned MY 2017 vehicles an average of 3.5 years earlier, meaning the average MY 2017 vehicle was last redesigned in approximately MY 2013, also on average near a midpoint in their product lifecycle.

Some commenters cited examples of vehicles in the NPRM analysis fleet where the redesign years were off by a year here or there in the 2017-2022 timeframe relative to the most recent public announcements, or that the extended forecasts were too rigid.[416] The CAFE model structurally requires an input for the redesign years, and the agencies worked to make these generally representative without disclosing precise CBI product plans. Many of the redesign schedules were carried over from the NPRM, with a few minor updates.

Some commenters contended that the agencies should not look at the historical data to project the timing between redesigns ("business as usual"), but should instead adopt a "policy case" with an accelerated pace of redesigns and refreshes.[417] Some commenters suggested that the agencies use a standard 5 or 6 year redesign schedule for all manufacturers and all products as a way to lower projected costs.[418] Other stakeholders commented that the entire industry

[418] NHTSA-2018-0067-11985, HD Systems.

should be modeled with the ability to redesign everything at one time in the near term because that would not presuppose precisely how manufacturers may adjust their fleet.[419]

If the agencies were to implement any such approaches, the agencies would need to more precisely account for tooling costs, research and development costs, and product lifecycle marketing costs, or risk missing "hidden costs" of a shortened cadence. To account properly for these, the CAFE model would require major changes, and would require specific inputs that are currently covered generically under the retail price equivalency (RPE) factor.[420] The agencies considered these comments, and decided the process for refresh and redesign outlined in the NPRM was a reasonable and realistic approach to characterize product changes. The agencies conducted sensitivity analysis with compressed redesign and refresh schedules, though these ignore the resulting compressed amortization schedules, missing important costs that are incorporated in the current RPE assumptions.

Some commenters claimed that the agency had extraordinarily extended redesign schedule of 17.7 years for FCA between 2021-2025, and an average redesign time of 25.8 years for Ford between 2022-2025.[421] The agencies found these claims inaccurate and without basis. Table VI-10, "Summary of Sales Weighted Average Time between Engineering Redesigns, by Manufacturer, by Vehicle Technology Class" summarizes the data used in today's analysis (which is very similar to the information used in the NPRM, with some minor adjustments and updates to the fleet), and the detailed information vehicle-by-vehicle is reported in the "market data" file. The agencies recognize that the natural sequence of redesigns for some manufacturers and some products is not ideal to meet stringent alternatives, which is part of the consideration for economic practicability and technological feasibility. Manufacturers commented supportively on the idea of vehicle specific redesign schedules, and the redesign cadence used in the NPRM, as these contribute to realistic assessments of new technology penetration within the fleet, and acknowledge the heterogeneity in the product development approaches and business practices for each manufacturer.[422] One commenter recognized that redesign and refresh schedules represented a vast improvement over phase-in caps to model the adoption of mature technologies.[423]

Other commenters argued that the structural construct of technologies only being available at redesign or at refresh (via inheritance) did not reflect real world actions and was not supported by any actual data.[424] Other commenters acknowledged the inheritance of engine and transmission technologies at refresh as an important, positive feature of the CAFE model.[425] HD Systems argued that an engine or transmission package available in other markets on a global

[420] Shorter redesign schedules are likely to put upward pressure on RPE, as the manufacturers would have less time to recoup investments.

platform could be imported to the U.S. market during refresh, and did not require a "leader" at redesign in the U.S. market to seed adoption. HDS cited a few examples where manufacturers have introduced strong hybrid powertrains on an existing vehicle a year or two after the product launch, not associated with any particular vehicle redesign or refresh.

The agencies carefully considered these comments, and observed that some relatively low volume hybrid options may appear after launch, or that some transmissions were quickly replaced shortly after a major redesign. In many of these cases, launch delays, warranty claims, or other external factors contributed to, at least in part, an atypically timed introduction of fuel saving technology to the fleet.[426] At this point, this does not appear to be a mainstream, or preferred industry practice. However, the agencies will continue to evaluate this. For future rulemaking, the agencies may consider engine refresh and redesign cycles for engines and transmissions. These may be separate from vehicle redesign and refresh schedules because the powertrain product lifecycles may be longer on average than the typical vehicle redesign schedules. This approach, if researched and implemented in future analysis, could provide some opportunity for manufacturers to introduce new powertrain technologies independent of the vehicle redesign schedules, in addition to inheriting advanced powertrain technology as refresh as already modeled in the NPRM and today's analysis.

For today's analysis, the agencies, with a few exceptions based on updated publicly available information, carried over redesign cadences for each vehicle nameplate as presented in the NPRM. The agencies do not claim that the projected redesign years will perfectly match what industry does—notably because refresh and redesign information is CBI and the agencies have applied more generalized schedules to protect the CBI. Also, what any individual manufacturer may choose to do today could be completely different than what it chooses to do tomorrow due to changing business circumstances and plans—but the agencies have worked to ensure the timing of redesigns will be roughly correct (especially in the near term), and that the time between redesigns will continue forward for each manufacturer as it has based on recent history. The agencies have also increased the frequency of refreshes in response to comments about the proliferation of some engine and transmission families through manufacturers' product portfolios.

Also for today's analysis, the agencies now explicitly model CAFE compliance pathways out through 2050. For the model to work as intended, the agencies must project refresh and redesign schedules out through 2050. The agencies recognize that the accuracy of predictions about the distant future, particularly about refresh and redesign cycles through the 2030-2050 timeframe, are likely to be poor. If historical evolution of the industry continues, many of the nameplates carried forward in the fleet are likely to be out of production, and new nameplates not considered in the analysis are sure to emerge. Still, carrying forward the MY 2017 fleet with the current refresh and redesign cadences is consistent with the current analysis, and imposing an alternative schedule on the fleet, or making up new nameplates and retiring older nameplates without a clear basis, would lack proper foundation.

---

[426] Such instances are observable in detailed CAFE and CO_2 compliance data submitted to EPA and NHTSA.

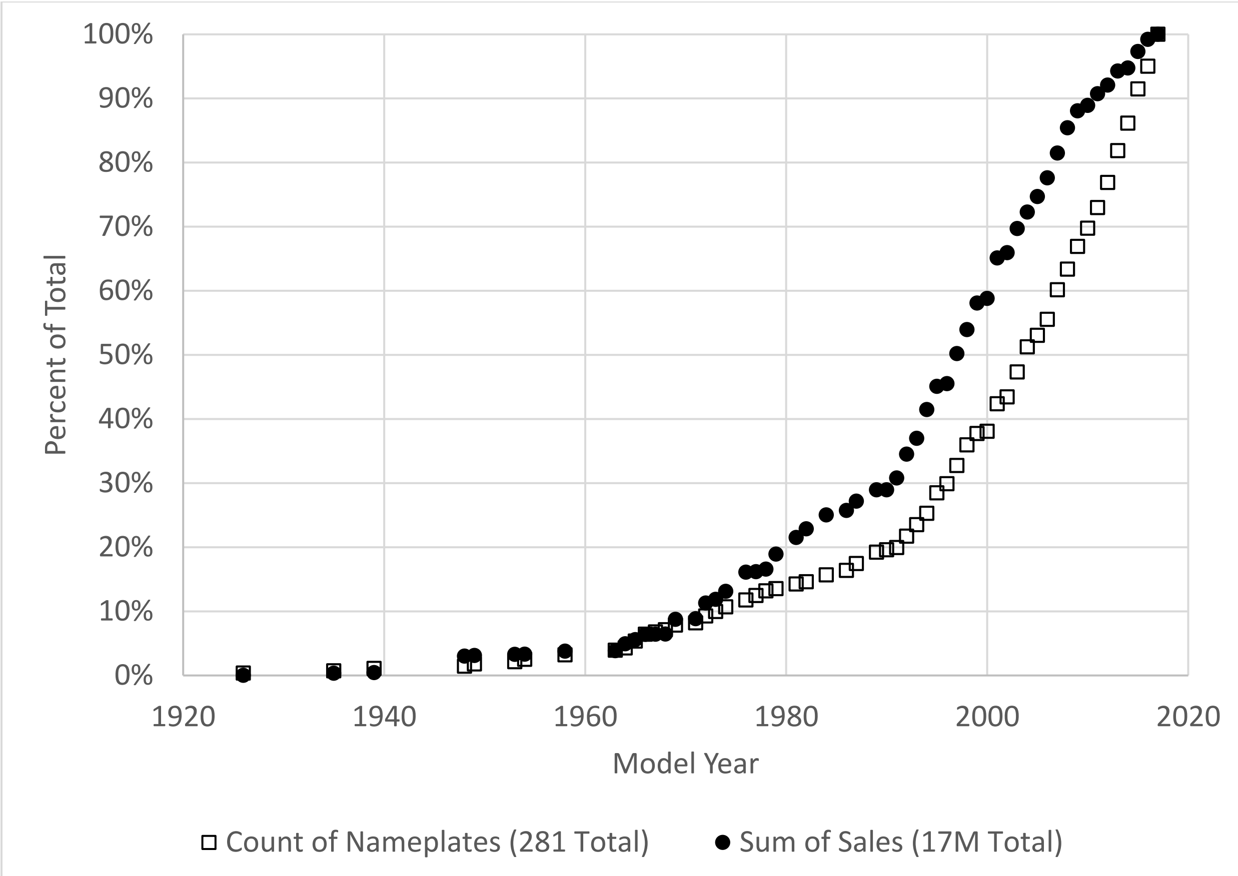

Figure VI-1 – Cumulative Portion of MY 2017 Nameplate Count and Sales by Year of Introduction to the United States Market

(6) Defining Technology Adoption Features

In some circumstances, the agencies may reference full vehicle simulation effectiveness data for technology combinations that are not able to be, or are not likely to be applied to all vehicles. In some cases, a specific technology as modeled only exists on paper, and questions remain about the technological feasibility of the efficiency characterization.[427] Or, a technology may perform admirably on the test cycle, but fail to meet all functional, or performance requirements for certain vehicles.[428] In other cases, the intellectual property landscape may make commercialization of one technology risky for a manufacturer without the consent of the

[427] High levels of aerodynamic drag reduction for some body styles, or EPA's previous, speculative characterization of "HCR2" engines, for example.

[428] Examples of applications that are unsuitable for certain technologies include low end torque requirements for HCR engines on high load vehicles, or towing and trailering applications, continuously variable transmissions in high torque applications, and low rolling resistance tires on vehicles built for precision cornering and high lateral forces, or instant acceleration from a stand still.

intellectual property owner.[429] In such cases, the agencies may not allow a technology to be applied to a certain vehicle. The agencies designate this in the "market data" file with a "SKIP" for the technology and vehicle. The logic is explained technology by technology in this document, as the logic was explained in the PRIA for this rule.

Some commenters argued that the restrictions of technologies on a case-by-case basis required case-by-case explanation (and not objective specification defined cut-offs), and that the use of CBI for performance considerations was unacceptable unless fully disclosed.[430] As discussed above, the agencies are not able to disclose CBI. Stakeholders have had plenty of opportunities to comment on the applicability of technologies, including the few that have used SKIP logic restrictions for a portion of the fleet.

Other commenters suggested an optimistic and wholly unfounded approach to manufacturer innovation, arguing that costs would continue to come down (beyond what is currently modeled with cost learning), and the list of fuel-saving technologies would continually regenerate itself (even if the technological mechanism for fuel saving technologies was not yet identified).[431] Therefore, the argument goes that people will figure out new ways to improve fuel saving technologies to increase their applicability, and the current technology characterization should be enabled for selection with no restriction—not because the commenter knows how the technology will be adapted, but that the commenter believes the technology could, eventually, within the timeline of the rulemaking, be adapted, brought to market, and be accepted by consumers. While the agencies recognize the improvements that many manufacturers have achieved in fuel saving technologies, some of which were difficult to foresee, the agencies have an obligation under the law to be judicious and specific about technological feasibility, and to avoid speculative conclusions about technologies to justify the rulemaking.

c) Other Analysis Fleet Data

(1) Safety Classes

The agencies referenced the mass-size-safety analysis to project the effects changes in weight may have on crash fatalities. That analysis, discussed in more detail in Section VI.D.2, considers how weight changes may affect safety for cars, crossover utility vehicles and sport utility vehicles, and pick-up trucks. To consider these effects, the agencies mapped each vehicle in the analysis fleet to the appropriate "Safety Class."

(2) Labor Utilization

The analysis fleet summarizes components of direct labor for each vehicle considered in the analysis. The labor is split into three components: (1) dealership hours worked on sales

[429] Variable compression ratio engines, for example.
[430] NHTSA-2018-0067-11741, ICCT.
[431] NHTSA-208-0067-12122-33, American Council for an Energy-Efficient Economy.

functions per vehicle, (2) direct assembly labor for final assembly, engine, and transmission, and (3) percent U.S. content.

In the MY 2016 fleet for the NPRM, the agencies catalogued production locations and plant employment, reviewed annual reports from the North American Dealership Association to estimate dealership employment (27.8 hours per vehicle sold), and estimated the industry average labor hours for final assembly of vehicles (30 hours per vehicle produced), engine machining and assembly (4 hours per engine produced), and transmission production (5 hours per transmission produced).

Today's analysis fleet carries over the estimated labor coefficients for sales and production, but references the most recent Part 583 American Automobile Labeling Act Report for percent U.S. content and for the location of vehicle assembly, engine assembly, and transmission assembly.[432]

(3) Production Volumes for Sales Analysis

A final important aspect of projecting what vehicles will exist in future model years and potential manufacturer responses to standards is estimating how future sales might change in response to different potential standards. If potential future standards appear likely to have major effects in terms of shifting production from cars to trucks (or vice versa), or in terms of shifting sales between manufacturers or groups of manufacturers, that is important for the agencies to consider. For previous analyses, the CAFE model used a static forecast contained in the analysis fleet input file, which specified changes in production volumes over time for each vehicle model/configuration. This approach yielded results that, in terms of production volumes, did not change between scenarios or with changes in important model inputs. For example, very stringent standards with very high technology costs would result in the same estimated production volumes as less stringent standards with very low technology costs. For this analysis, as in the proposal, the CAFE model begins with the first-year production volumes (*i.e.*, MY 2017 for today's analysis) and adjusts ensuing sales mix year by year (between cars and trucks, and between manufacturers) endogenously as part of the analysis, rather than using external forecasts of future car/truck split and future manufacturer sales volumes. This leads the model to produce different estimates of future production volumes under different standards and in response to different inputs, reflecting the expectation that regulatory standards and other external factors will, in fact, impact the market.

(4) Comments on Other Analysis Fleet Data

Some commenters suggest that the CAFE model should run as a full consumer choice model (and this idea is discussed in more detail in Section VI.D.1). While this sounds like a reasonable request on the surface, such an approach would place enormous new demands on the data characterized in the fleet (and preceding fleets, which may be needed to calibrate a model properly). For instance, some model concepts may depend on a bevy of product features, such as

---

[432] Part 583 American Automobile Labeling Act Report, available at https://www.nhtsa.gov/part-583-american-automobile-labeling-act-reports.

interior cargo room, artistic appeal of the design, and perceived quality of the vehicle. But product features alone may not be sufficient. Additional information about dealership channels, product awareness and advertising effectiveness, and financing terms also may be required. Such information could dramatically increase the scope of work needed to characterize the analysis fleet for future rulemakings. As described in Section VI.D.1.b)(2)(d) Using Vehicle Choice Models in Rulemaking Analysis. Accordingly, the agencies decided not to develop such a model for this rulemaking.

2. Treatment of Compliance Credit Provisions

Today's final rule involves a variety of provisions regarding "credits" and other compliance flexibilities. Some recently introduced regulatory provisions allow a manufacturer to earn "credits" that will be counted toward a vehicle's rated CO_2 emissions level, or toward a fleet's rated average CO_2 or CAFE level, without reference to required levels for these average levels of performance. Such flexibilities effectively modify emissions and fuel economy test procedures, or methods for calculating fleets' CAFE and average CO_2 levels. Such provisions are discussed below in Section VI.B.2. Other provisions (for CAFE, statutory provisions) allow manufacturers to earn credits by achieving CAFE or average CO_2 levels beyond required levels; these provisions may hence more appropriately be termed "compliance credits."

EPCA has long provided that, by exceeding the CAFE standard applicable to a given fleet in a given model year, a manufacturer may earn corresponding "credits" that the same manufacturer may, within the same regulatory class, apply toward compliance in a different model year. EISA amended these provisions by providing that manufacturers may, subject to specific statutory limitations, transfer compliance credits between regulatory classes, and trade compliance credits with other manufacturers. The CAA provides EPA with broad standard-setting authority for the CO_2 program, with no specific directives regarding either CO_2 standards or CO_2 compliance credits.

EPCA also specifies that NHTSA may not consider the availability of CAFE credits (for transfer, trade, or direct application) toward compliance with new standards when establishing the standards themselves.[433] Therefore, this analysis, like that presented in the NPRM, considers 2020 to be the last model year in which carried-forward or transferred credits can be applied for the CAFE program. Beginning in model year 2021, today's "standard setting" analysis for NHTSA's program is conducted assuming each fleet must comply with the CAFE standard separately in every model year.

The "unconstrained" perspective acknowledges that these flexibilities exist as part of the program, and, while not considered by NHTSA in setting standards, are nevertheless important to consider when attempting to estimate the real impact of any alternative. Under the "unconstrained" perspective, credits may be earned, transferred, and applied to deficits in the CAFE program throughout the full range of model years in the analysis. The Final Environmental Impact Analysis (FEIS) accompanying today's final rule, like the corresponding

[433] 49 U.S.C. 32902(h)(3).

Draft EIS analysis, presents results of "unconstrained" modeling. Also, because the CAA provides no direction regarding consideration of any CO_2 credit provisions, today's analysis, like the NPRM analysis, includes simulation of carried-forward and transferred CO_2 credits in all model years.

Some commenters took issue broadly with this treatment of compliance credits. Michalek and Whitefoot wrote that "we find this requirement problematic because the automakers use these flexibilities as a common means of complying with the regulation, and ignoring them will bias the cost-benefit analysis to overestimate costs."[434]

Counter to the above general claim, the CAFE model *does* provide means to simulate manufacturers' potential application of some compliance credits, and both the analysis of CO_2 standards and the NEPA analysis of CAFE standards *do* make use of this aspect of the model. As discussed above, NHTSA does not have the discretion to consider the credit program—in fact, the agency is prohibited by statute from doing so—in establishing maximum feasible standards. Further, as discussed below, the agencies also continue to find it appropriate for the analysis largely to refrain from simulating two of the mechanisms allowing the use of compliance credits.

The model's approach to simulating compliance decisions accounts for the potential to earn and use CAFE credits as provided by EPCA/EISA. The model similarly accumulates and applies CO_2 credits when simulating compliance with EPA's standards. Like past versions, the current CAFE model can be used to simulate credit carry-forward (a.k.a. banking) between model years and transfers between the passenger car and light truck fleets but not credit carry-back (a.k.a. borrowing) from future model years or trading between manufacturers.

Regarding the potential to carry back compliance credits, UCS commented that, although past versions of the CAFE model had "considered this flexibility in its approach to multiyear modeling," NHTSA had, without explanation, "abruptly discontinued support of this method of compliance," such that "manufacturers are generally incentivized to over comply, regardless of whether carrying forward a deficit to be compensated by later overcompliance would be a more cost-effective method of compliance."[435] Citing the potential that manufacturers could make use of carried back credits in the future, UCS also stated that "NHTSA's decision to constrain it in the model is unreasonable and arbitrary."[436] UCS effectively implies that the agencies should base standards on analysis that presumes manufacturers will take full theoretical advantage of provisions allowing credits to be borrowed.

The agencies have carefully considered these comments, and while EPA's decisions regarding CO_2 standards can consider the potential to carry back compliance credits from later to earlier model years, and NHTSA's "unconstrained" evaluation could also do so, past examples of failed attempts to carry back CAFE credits (e.g., a MY2014 carry back default leading to a

---

434 Michalek, J. and Whitefoot, K., NHTSA-2018-0067-11903, at 10-11.
435 UCS, NHTSA-2018-0067-12039, Technical Appendix, at 44.
436 UCS, *op. cit.*, at 77.

civil penalty payment) underscore the riskiness of such "borrowing." Recent evidence indicates manufacturers are disinclined to take such risks,[437] and both agencies find it reasonable and prudent to refrain from attempting to simulate such "borrowing" in rulemaking analysis.

Unlike past versions, the NPRM and current versions of CAFE model provide a basis to specify (in model inputs) CAFE credits available from model years earlier than those being explicitly simulated. For example, with this analysis representing model years 2017-2050 explicitly, credits earned in model year 2012 are made available for use through model year 2017 (given the current five-year limit on carry-forward of credits). The banked credits are specific to both the model year and fleet in which they were earned.

In addition to the above-mentioned comments, UCS also cited as "errors" that "the model does not accurately reflect the one-time exemption from the EPA 5-year credit life for credits earned in the MY 2010-2015 timeframe" and "NHTSA assumes that there will be absolutely no credit trading between manufacturers."

As discussed below, in the course of updating the analysis fleet from MY 2016 to MY 2017, the agencies have updated and expanded the manner in which the model accounts for credits earned prior to MY 2017, including credits earned as early as MY 2009. In order to increase the realism with which the model transitions between the early model year (MYs 2017-2020) and the later years that are the subject of this action, the agencies have accounted for the potential that some manufacturers might trade some of these pre-MY 2017 credits to other manufacturers. However, as with the NPRM, the analysis refrains from simulating the potential that manufacturers might continue to trade credits during and beyond the model years covered by today's action. The agencies remain concerned that any realistic simulation of such trading would require assumptions regarding which specific pairs of manufacturers might actually trade compliance credits, and the evidence to date makes it clear that the credit market is far from fully "open." With respect to the FCA comment cited above, the agencies also remain concerned that to set standards based on an analysis that presumes the use of program flexibilities risks making the corresponding actions mandatory. Some flexibilities—credit carry-forward (banking) and transfers between fleets in particular—involve little risk, because they are internal to a manufacturer and known in advance. As discussed above, credit carry-back involves significant risk, because it amounts to borrowing against future improvements, standards, and production volume and mix—and anticipated market demand for fuel efficient vehicles often fail to materialize. Similarly, credit trading also involves significant risk, because the ability of manufacturer A to acquire credits from manufacturer B depends not just on manufacturer B actually earning the expected amount of credit, but also on manufacturer B being willing to trade with manufacturer A, and on potential interest by other manufacturers. Manufacturers' compliance plans have already evidenced cases of compliance credit trades that were planned and subsequently aborted, reinforcing the agencies' judgment that, like credit banking, credit trading involves too much risk to be included in an analysis that informs decisions about the stringency of future standards. Nevertheless, recognizing that some manufacturers have actually

---

[437] Section IX, below, reviews data regarding manufacturers' use of CAFE compliance credit mechanism during MYs 2011-2016, and shows that the use of "carry back" credits is, relative to the use of other compliance credit mechanisms, too small to discern.

been trading credits, the agencies have, as in the NPRM, included in the sensitivity analysis a case that simulates "perfect" trading of compliance credits, focusing on CO_2 standards to illustrate the hypothetical maximum potential impact of trading. The FRIA summarizes results of this and other cases included in the sensitivity analysis.

As discussed in the CAFE model documentation, the model's default logic attempts to maximize credit carry-forward—that is, to "hold on" to credits for as long as possible. If a manufacturer needs to cover a shortfall that occurs when insufficient opportunities exist to add technology in order to achieve compliance with a standard, the model will apply credits. Otherwise the manufacturer carries forward credits until they are about to expire, at which point it will use them before adding technology that is not considered cost-effective. The model attempts to use credits that will expire within the next three years as a means to smooth out technology application over time to avoid both compliance shortfalls and high levels of over-compliance that can result in a surplus of credits. Although it remains impossible precisely to predict manufacturer's actual earning and use of compliance credits, and this aspect of the model may benefit from future refinement as manufacturers and regulators continue to gain experience with these provisions, this approach is generally consistent with manufacturers' observed practices.

NHTSA introduced the CAFE Public Information Center to provide public access to a range of information regarding the CAFE program,[438] including manufacturers' credit balances. However, there is a data lag in the information presented on the CAFE PIC that may not capture credit actions across the industry for as much as several months. Furthermore, CAFE credits that are traded between manufacturers are adjusted to preserve the gallons saved that each credit represents.[439] The adjustment occurs at the time of application rather than at the time the credits are traded. This means that a manufacturer who has acquired credits through trade, but has not yet applied them, may show a credit balance that is either considerably higher or lower than the real value of the credits when they are applied. For example, a manufacturer that buys 40 million credits from Tesla may show a credit balance in excess of 40 million. However, when those credits are applied, they may be worth only 1/10 as much—making that manufacturer's true credit balance closer to 4 million than 40 million.

For the NPRM, the agencies reviewed then-recent credit balances, estimated the potential that some manufacturers could trade credits, and developed inputs that make carried-forward credits available in each of model years 2011-2015, after subtracting credits assumed to be traded to other manufacturers, adding credits assumed to be acquired from other manufacturers through such trades, and adjusting any traded credits (up or down) to reflect their true value for the fleet and model year into which they were traded.[440] For today's analysis, an additional

[438] CAFE Public Information Center, http://www.nhtsa.gov/CAFE_PIC/CAFE_PIC_Home.htm (last visited June 22, 2018).

[439] CO_2 credits for EPA's program are denominated in metric tons of CO_2 rather than gram/mile compliance credits and require no adjustment when traded between manufacturers or fleets.

[440] The adjustments, which are based upon the CAFE standard and model year of both the party originally earning the credits and the party applying them, were implemented assuming the credits would be applied to the model year

model year's data was available in mid-2019, and the agencies updated these inputs, as summarized in Table VI-12, Table-VI-13, and Table-VI-14. While the CAFE model will transfer expiring credits into another fleet (e.g., moving expiring credits from the domestic car credit bank into the light truck fleet), some of these credits were moved into the initial banks to improve the efficiency of application and both to reflect better the projected shortfalls of each manufacturer's regulated fleets and to represent observed behavior. For context, a manufacturer that produces one million vehicles in a given fleet, and experiences a shortfall of 2 mpg, would need 20 million credits, adjusted for fuel savings, to offset the shortfall completely.

In addition to the inclusion of these existing credit banks, the CAFE model also updated its treatment of credits in the rulemaking analysis. EPCA requires that NHTSA set CAFE standards at maximum feasible levels for each model year without consideration of the program's credit mechanisms. However, as recent NHTSA CAFE/EPA tailpipe CO_2 emissions rulemakings have evaluated effects of standards over longer time periods, the early actions taken by manufacturers required more nuanced representation. Accordingly, the CAFE model now provides for a setting to establish a "last year to consider credits." This adjustment is set at the last year for which new standards are not being considered (MY 2020 in this analysis). This allows the model to replicate the practical application of existing credits toward compliance in early years but also to examine the impact of proposed standards based solely on fuel economy improvements in all years for which new standards are being considered.

Regarding the model's simulation of manufacturers' potential earning and application of compliance credits, UCS commented that the model "inexplicably lets credits expire" because "all technologies which pay for themselves within the assumed payback period are applied to all manufacturers, regardless of credit status." UCS also claimed that "NHTSA did not accurately reflect unique attributes of EPA's credit bank," that "credits are not traded between manufacturers," and that "NHTSA does not model credit carryback for compliance."[441] Relatedly, as discussed above, UCS attributes modeling outcomes to the "effective cost" metric used to select from among available fuel-saving technologies.[442] As discussed in Section VI.B.1, the agencies expect that manufacturers are likely to improve fuel economy voluntarily insofar as doing so "pays back" economically within a short period (30 months), and the agencies note that periods of regulatory stability have, in fact, been marked by CAFE levels exceeding requirements. As discussed above, the agencies have excluded simulation of credit trading (except in MYs prior to those under consideration, aside from an idealized case presented in the sensitivity analysis) and likewise excluded simulation of potential "carryback" provisions. The agencies have excluded modeling these scenarios not just because of the analytical complexities involved (and rejecting, for example, the random number generator analysis suggested by UCS), but also because the agencies agree that the actual provisions regarding trading and borrowing of compliance credits create too much risk to be used in the analysis underlying consideration of standards. However, as discussed above, the agencies have revised the "metric" used to prioritize available options to apply fuel-saving technologies. As discussed below, the agencies have revised model inputs to include the large quantity of "legacy" compliance credits EPA has made available under its CO_2 standards.

The CAFE model has also been modified to include a similar representation of existing credit banks in EPA's CO_2 program. While the life of a CO_2 credit, denominated in metric tons of CO_2, has a five-year life, matching the lifespan of CAFE credits, such credits earned in the early MY 2009-2011 years of the EPA program, may be used through MY 2021.[443] The CAFE model was not modified to allow exceptions to the life-span of compliance credits, and, to reflect

[441] UCS, NHTSA-2018-0067-12039, Technical Appendix, at 35-46.
[442] UCS, NHTSA-2018-0067-12039, Technical Appendix, at 28-30.
[443] In the 2010 rule, EPA placed limits on credits earned in MY 2009, which expired prior to this rule. However, credits generated in MYs 2010-2011 may be carried forward, or traded, and applied to deficits generated through MY 2021.

statutory requirements, treated them as if they may be carried forward for no more than five years, so the initial credit banks were modified to anticipate the years in which those credits might be needed. MY 2016 was simulated explicitly in the NPRM analysis to prohibit the inclusion of banked credits in MY 2016 (which could be carried forward from MY 2016 to MY 2021), and thus underestimated the extent to which individual manufacturers, and the industry as a whole, could rely on these early credits to comply with EPA standards between MY 2016 and MY 2021. However, as indicated in the NPRM, the final rule's model inputs updated the analysis fleet's basis to MY 2017, such that these additional banked credits *can* be included. The credit banks with which the simulations in this analysis were conducted are presented in the following tables:

While the CAFE model does not simulate the ability to trade credits between manufacturers, it does simulate the strategic accumulation and application of compliance credits, as well as the ability to transfer credits between fleets to improve the compliance position of a less efficient fleet by leveraging credits earned by a more efficient fleet. The model prefers to hold on to earned compliance credits within a given fleet, carrying them forward into the future to offset potential future deficits. This assumption is consistent with observed strategic manufacturer behavior dating back to 2009.

From 2009 to present, no manufacturer has transferred CAFE credits into a fleet to offset a deficit in the same year in which they were earned. This has occurred with credits acquired from other manufacturers via trade but not with a manufacturer's own credits. Therefore, the current representation of credit transfers between fleets—where the model prefers to transfer expiring, or soon-to-be-expiring credits rather than newly earned credits—is both appropriate and consistent with observed industry behavior.

This may not be the case for CO_2 standards, though it is difficult to be certain at this point. The CO_2 program seeded the industry with a large quantity of early compliance credits (earned in MYs 2009-2011[444]) prior to the existence formal CO_2 standards. Early credits from MYs 2010 and 2011, however, do not expire until 2021. Thus, for manufacturers looking to offset deficits, it is more sensible to exhaust credits that were generated during later model years (which are set to expire within the next five years), rather than relying on the initial bank of credits from MYs 2010 and 2011. The first model year for which earned credits outlive the initial bank is MY 2017, for which final manufacturer CO_2 performance data (and hence, banked credits) has not yet been released. However, considering that under the CO_2 program manufacturers simultaneously comply with passenger car and light truck fleets, to more accurately represent the CO_2 credit system the CAFE model allows (and encourages) intra-year transfers between regulated fleets for the purpose of simulating compliance with the CO_2 standards.

a) Off-cycle and A/C Efficiency Adjustments to CAFE and Average CO_2 Levels

In addition to more rigorous accounting of CAFE and CO_2 credits, the model now also accounts for air conditioning efficiency and off-cycle adjustments. NHTSA's program considers those adjustments in a manufacturer's compliance calculation starting in MY 2017, and the NPRM version of the model used the adjustments claimed by each manufacturer in MY 2016 as the starting point for all future years. Because air conditioning efficiency and off-cycle adjustments are not credits in NHTSA's program, but rather adjustments to compliance fuel economy (much like the Flexible Fuel Vehicle adjustments due to phase out in MY 2019), they may be included under either a "standard setting" or "unconstrained" analysis perspective.

The manner in which the CAFE model treats the EPA and CAFE A/C efficiency and off-cycle credit programs is similar, but the model also accounts for A/C leakage (which is not part of NHTSA's program). When determining the compliance status of a manufacturer's fleet (in the case of EPA's program, PC and LT are the only fleet distinctions), the CAFE model weighs future compliance actions against the presence of existing (and expiring) CO_2 credits resulting from over-compliance with earlier years' standards, A/C efficiency credits, A/C leakage credits, and off-cycle credits.

Another aspect of credit accounting, implemented in the NPRM version of the CAFE model, involved credits related to the application of off-cycle and A/C efficiency adjustments, which manufacturers earn by taking actions such as special window glazing or using reflective paints that provide fuel economy improvements in real-world operation but do not produce measurable improvements in fuel consumption on the 2-cycle test.

NHTSA's inclusion of off-cycle and A/C efficiency adjustments began in MY 2017, while EPA has collected several years' worth of submissions from manufacturers about off-cycle and A/C efficiency technology deployment. Currently, the level of deployment can vary considerably by manufacturer, with several claiming extensive Fuel Consumption Improvement Values (FCIV) for off-cycle and A/C efficiency technologies, and others almost none. The

[444] In response to public comment, EPA eliminated the possible use of credits earned in MY 2009 for future model years. However, credits earned in MY 2010 and MY 2011 remain available for use.

analysis of alternatives presented here (and in the NPRM) does not attempt to project how future off-cycle and A/C efficiency technology use will evolve or speculate about the potential proliferation of FCIV proposals submitted to the agencies. Rather, this analysis uses the off-cycle credits submitted by each manufacturer for MY 2017 compliance, and, with a few exceptions, carries these forward to future years. Several of the technologies described below are associated with A/C efficiency and off-cycle FCIVs. In particular, stop-start systems, integrated starter generators, and full hybrids are assumed to generate off-cycle adjustments when applied to vehicles to improve their fuel economy. Similarly, higher levels of aerodynamic improvements are assumed to include active grille shutters on the vehicle, which also qualify for off-cycle FCIVs.

The NPRM analysis assumed that any off-cycle FCIVs that are associated with actions outside of the technologies discussed in Section VI.C (either chosen from the pre-approved "pick list," or granted in response to individual manufacturer petitions) remained at the levels claimed by manufacturers in MY 2017. Any additional A/C efficiency and off-cycle adjustments that accrued as the result of explicit technology application calculated dynamically in each model year for each alternative. The NPRM version of the CAFE model also represented manufacturers' credits for off-cycle improvements, A/C efficiency improvements, and A/C leakage reduction in terms of values applicable across all model years.

Recognizing that application of these improvements thus far varies considerably among manufacturers, such that some manufacturers have opportunities to earn significantly more of the corresponding adjustments over time, the agencies have expanded the CAFE model's representation of these credits to provide for year-by-year specification of the amounts of each type of adjustment for each manufacturer, denominated in grams CO_2 per mile,[445] as summarized in the following table:

[445] For estimating their contribution to CAFE compliance, the grams CO_2/mile values in Table VI-1711 are converted to gallons/mile and applied to a manufacturer's 2-cycle CAFE performance. When calculating compliance with EPA's CO_2 program, there is no conversion necessary (as standards are also denominated in grams/mile).

In addition to these refinements to the estimation of the quantities of adjustments earned over time by each manufacturer, the agencies revised the CAFE model to apply estimates of the corresponding costs. For today's analysis, the agencies applied estimates developed previously by EPA, adjusting these values to 2019 dollars. The following table summarizes inputs through model year 2030:

Table VI-18 – Estimated Costs ($ per g/mi) for A/C and Off-Cycle Adjustments

Model Year	A/C Efficiency	A/C Leakage	Off-Cycle
2017	4.57	11.43	89.59
2018	4.48	11.20	87.48
2019	4.39	10.97	85.37
2020	4.30	10.76	83.79
2021	4.22	10.54	82.21
2022	4.13	10.33	81.16
2023	4.05	10.12	79.58
2024	3.97	9.92	78.52
2025	3.89	9.72	77.47
2026	3.81	9.53	76.31
2027	3.73	9.34	75.16
2028	3.66	9.15	74.04
2029	3.59	8.97	72.92
2030	3.52	8.79	71.83

The model currently accounts for any off-cycle adjustments associated with technologies that are included in the set of fuel-saving technologies explicitly simulated as part of this proposal (for example, start-stop systems that reduce fuel consumption during idle or active grille shutters that improve aerodynamic drag at highway speeds) and accumulates these adjustments up to the 10 g/mi cap. As a practical matter, most of the adjustments for which manufacturers are claiming off-cycle FCIV exist outside of the technology tree, so the cap is rarely reached during compliance simulation. The agencies have considered the potential to model their application explicitly. However, doing so would require data regarding which vehicle models already possess these improvements as well as the cost and expected value of applying them to other models in the future. Such data is currently too limited to support explicit modeling of these technologies and adjustments.

b) Alternative Fuel Vehicles

When establishing maximum feasible fuel economy standards, NHTSA is prohibited from considering the availability of alternatively fueled vehicles,[447] and credit provisions related

[447] 49 U.S.C. 32902(h).

to AFVs that significantly increase their fuel economy for CAFE compliance purposes. Under the "standard setting" perspective, these technologies (pure battery electric vehicles and fuel cell vehicles[448]) are not available in the compliance simulation to improve fuel economy. Under the "unconstrained" perspective, such as is documented in the DEIS and FEIS, the CAFE model considers these technologies in the same manner as other available technologies, and may apply them if they represent cost-effective compliance pathways. However, under both perspectives, the analysis continues to include dedicated AFVs that already exist in the MY 2017 fleet (and their projected future volumes). Also, because the CAA provides no direction regarding consideration of alternative fuels, the final rule's analysis includes simulation of the potential that some manufacturers might introduce new AFVs in response to CO_2 standards. To represent the compliance benefit from such a response fully, NHTSA modified the CAFE model to include the specific provisions related to AFVs under the CO_2 standards. In particular, the CAFE model now carries a full representation of the production multipliers related to electric vehicles, fuel cell vehicles, plug-in hybrids, and CNG vehicles, all of which vary by year through MY 2021.

EPCA also provides that CAFE levels may, subject to limitations, be adjusted upward to reflect the sale of flexible fuel vehicles (FFVs). Although these adjustments end after model year 2020, the final rule's analysis, like the NPRM's, includes estimated potential use through MY 2019, as summarized below:

Table VI-19 – Estimates of Earned FFV Credit (mpg)

Manufacturer	Passenger Cars			Light Trucks		
	2017	2018	2019	2017	2018	2019
BMW	-	-	-	-	-	-
Daimler	0.6	0.4	0.2	0.6	0.4	0.2

Volvo	-	-	-	-	-	-
VWA	-	-	-	0.6	0.4	0.2

[448] Dedicated compressed natural gas (CNG) vehicles should also be excluded in this perspective but are not considered as a compliance strategy under any perspective in this analysis.

For its part, EPA has provided that manufacturers selling sufficient numbers of PHEVs, BEVs, and FCVs may, when calculating fleet average CO_2 levels, "count" each unit of production as more than a single unit. The CAFE model accounts for these "multipliers." As for the NPRM, the final rule's analysis applies the following multipliers:

Table VI-20 – Production "Multipliers" for CNG Vehicles, PHEVs, BEVs, and FCVs

Model Year	**CNG or PHEV**	**BEV or FCV**
2017	1.60	2.00
2018	1.60	2.00
2019	1.60	2.00
2020	1.45	1.75
2021	1.30	1.50
2022	1.00	1.00

For example, under EPA's current regulation, when calculating the average CO_2 level *achieved* by its MY 2019 passenger car fleet, a manufacturer may treat each 1,000 BEVs as 2,000 BEVs. When calculating the average level *required* of this fleet, the manufacturer must use the actual production volume (in this example, 1,000 units). Similarly, the manufacturer must use the actual production volume when calculating compliance credit balances.

There were no natural gas vehicles in the baseline fleet, and the analysis did not apply natural gas technology due to cost effectiveness. The application of a 2.0 multiplier for natural gas vehicles for MYs 2022-2026 would have no impact on the analysis because given the state of natural gas vehicle refueling infrastructure, the cost to equip vehicles with natural gas tanks, the outlook for petroleum prices, and the outlook for battery prices, we have little basis to project more than an inconsequential response to this incentive in the foreseeable future.

For the final rule's analysis, the CAFE model can be exercised in a manner that simulates these current EPA requirements, or that simulates two alternative approaches. The first includes the above-mentioned multipliers in the calculation of average requirements, and the second also includes the multipliers in the calculation of credit balances. The central analysis reflects current regulations. The sensitivity analysis presented in the FRIA includes a case applying multipliers to the calculation of achieved and required average CO_2 levels, and calculation of credit balances.

c) Civil Penalties

Throughout the history of the CAFE program, some manufacturers have consistently achieved fuel economy levels below applicable standards, electing instead to pay civil penalties as specified by EPCA. As in previous versions of the CAFE model, the current version allows the user to specify inputs identifying such manufacturers and to consider their compliance decisions as if they are willing to pay civil penalties for non-compliance with the CAFE program. As with the NPRM, the civil penalty rate in the current analysis is $5.50 per 1/10 of a mile per gallon, per vehicle manufactured for sale.

NHTSA notes that treating a manufacturer as if it is willing to pay civil penalties does not necessarily mean that it is expected to pay penalties in reality. Doing so merely implies that the manufacturer will only apply fuel economy technology up to a point, and then stop, regardless of whether or not its corporate average fuel economy is above its standard. In practice, the agencies expect that many of these manufacturers will continue to be active in the credit market, using trades with other manufacturers to transfer credits into specific fleets that are challenged in any given year, rather than paying penalties to resolve CAFE deficits. The CAFE model calculates the amount of penalties paid by each manufacturer, but it does not simulate trades between manufacturers. In practice, some (possibly most) of the total estimated penalties may be a transfer from one OEM to another.

Although EPCA, as amended in 2007 by the Energy Independence and Security Act (EISA), prescribes these specific civil penalty provisions for CAFE standards, the Clean Air Act (CAA) does not contain similar provisions. Rather, the CAA's provisions regarding noncompliance prohibit sale of a new motor vehicle that is not covered by an EPA certificate of conformity, and in order to receive such a certificate the new motor vehicle must meet EPA's Section 202 regulations, including applicable emissions standards. Therefore, inputs regarding civil penalties—including inputs regarding manufacturers' potential willingness to treat civil penalty payment as an economic choice—apply only to simulation of CAFE standards. On the other hand, some of the same manufacturers recently opting to pay civil penalties instead of complying with CAFE standards have also recently led adoption of lower-GWP refrigerants, and the "A/C leakage" credits count toward compliance only with CO_2 standards, not CAFE standards. The model accounts for this difference between the programs.

When considering technology applications to improve fleet fuel economy, the model will add technology up to the point at which the effective cost of the technology (which includes technology cost, consumer fuel savings, consumer welfare changes, and the cost of penalties for non-compliance with the standard) is less costly than paying civil penalties or purchasing credits. Unlike previous versions of the model, the current implementation further acknowledges that some manufacturers experience transitions between product lines where they rely heavily on credits (either carried forward from earlier model years or acquired from other manufacturers) or simply pay penalties in one or more fleets for some number of years. The model now allows the user to specify, when appropriate for the regulatory program being simulated, on a year-by-year basis, whether each manufacturer should be considered as willing to pay penalties for non-compliance. This provides additional flexibility, particularly in the early years of the simulation. As discussed above, this assumption is best considered as a method to allow a manufacturer to under-comply with its standard in some model years—treating the civil penalty rate and payment option as a proxy for other actions it may take that are not represented in the CAFE model (e.g., purchasing credits from another manufacturer, carry-back from future model years, or negotiated settlements with NHTSA to resolve deficits).

For the NPRM, NHTSA relied on past compliance behavior and certified transactions in the credit market to designate some manufacturers as willing to pay CAFE penalties in some model years. The full set of NPRM assumptions regarding manufacturer behavior with respect to civil penalties is presented in Table VI-21, which shows all manufacturers were assumed to be willing to pay civil penalties prior to MY 2020. This was largely a reflection of either existing credit balances (which manufacturers will use to offset CAFE deficits until the credits reach their expiration dates) or inter-manufacturer trades assumed likely to happen in the near future, based on previous behavior. The manufacturers in the table whose names appear in bold all had at least one regulated fleet (of three) whose CAFE was below its standard in MY 2016. Because the NPRM analysis began with the MY 2016 fleet, and no technology could be added to vehicles that are already designed and built, all manufacturers could generate civil penalties in MY 2016. However, once a manufacturer is designated as unwilling to pay penalties, the CAFE model will attempt to add technology to the respective fleets to avoid shortfalls.

Table VI-21 – NPRM Assumptions Regarding Manufacturer Willingness to Pay Civil Penalties

Manufacturer	2017	2018	2019	2020	2021	2022	2023	2024	2025	2026
BMW	Y	Y	Y	Y	Y	Y	Y	Y	Y	Y

Volvo	Y	Y	Y	Y	Y	Y	Y	Y	Y	Y
VWA	Y	Y	Y	N	N	N	N	N	N	N

Several of the manufacturers in Table VI-21 that were presumed to be willing to pay civil penalties in the early years of the program have no history of paying civil penalties. However, several of those manufacturers have either bought or sold credits—or transferred credits from one fleet to another to offset a shortfall in the underperforming fleet. As the CAFE model does not simulate credit trades between manufacturers, providing this additional flexibility in the modeling avoids the outcome where the CAFE model applies more technology than needed in the context of the full set of compliance flexibilities at the industry level. By statute, NHTSA cannot consider credit flexibilities when setting standards, so most manufacturers (those without a history of civil penalty payment) are assumed to comply with their standards through fuel economy improvements for the model years being considered in this analysis. The notable exception to this assumption is Fiat Chrysler Automobiles (FCA), which could still satisfy the requirements of the program through a combination of credit application and civil penalties through MY 2025 before eventually complying exclusively through fuel economy improvements in MY 2026.

As mentioned above, the CAA does not provide civil penalty provisions similar to those provisions specified in EPCA/EISA, and the above-mentioned corresponding inputs apply only to simulation of compliance with CAFE standards.

Some stakeholders offering comments related to the analytical treatment of civil penalties indicated that NHTSA should tend toward assuming manufacturers will take advantage of this EPCA provision as an economically attractive alternative to compliance. Other commenters implied that NHTSA should tend toward not relying on compliance flexibilities in the analysis used to determine the maximum feasible stringency of CAFE standards. For example, New York University's Institute for Policy Integrity (IPI) offered the following comments:

> NHTSA assumes that most manufacturers will be unwilling to pay penalties based in part on the fact that most manufacturers have not paid penalties in recent years. The Proposed Rule cites the statutory prohibition on NHTSA considering credit trading as a reason to assume manufacturers without a history of paying penalties will comply through technology alone, whatever the cost. But this is an arbitrary assumption and is in no way dictated by the statute. NHTSA knows as much, since elsewhere in the proposed rollback, the agency explains "EPCA is very clear as to which flexibilities are not to be considered" and NHTSA is allowed to consider off-cycle adjustments because they are not specifically mentioned. But considering penalties are not mentioned as off-limits for NHTSA in setting the standards either. Instead, the prohibition focuses on credit trading and transferring. The penalty safety valve has existed in EPCA for decades, and Congress clearly would have known how to add penalties to the list of trading and transferring. The fact that Congress did not bar NHTSA from considering penalties as a safety valve means that NHTSA must consider manufacturer's efficient use of penalties as a cost minimizing compliance option. Besides, NHTSA does consider penalties for some of the manufacturers making its statutory justification even less rational.[449]

On the other hand, in more general comments about NHTSA's analytical treatment of program flexibilities, FCA stated that "when flexibilities are considered while setting targets, they cease to be flexibilities and become simply additional technology mandates."[450]

NHTSA agrees with IPI that EPCA does not expressly prohibit NHTSA, when conducting analysis supporting determinations of the maximum feasible stringency of future CAFE standards, from including manufacturers' potential tendency to pay civil penalties rather than complying with those standards. However, EPCA also does not *require* NHTSA to include this tendency in its analysis. NHTSA also notes, as does IPI, that EPCA *does* prohibit NHTSA from including credit trading, transferring, or the availability of credits in such analysis (although NHTSA interprets this prohibition to apply only to the model years for which standards are being set). This statutory difference is logical based on the way credits and penalties function

[450] FCA, Docket # NHTSA-2018-0067-11943, at 6.

differently under EPCA. Because credits help manufacturers achieve compliance with CAFE standards, absent the statutory prohibition, credits would be relevant to the feasibility of a standard.[451] Penalties, on the other hand, do not enable a manufacturer to comply with an applicable standard; penalties are for noncompliance.[452] When Congress added credit trading provisions to EPCA in 2007, NHTSA anticipated that competitive considerations would make manufacturers reluctant to engage in such trades. Since that time, manufacturers actually have demonstrated otherwise, although the reliance on trading—especially between specific pairs of OEMs—appears to vary widely. At this time, NHTSA considers it most likely that manufacturers will shift away from paying civil penalties and toward compliance credit trading. Consequently, for NHTSA to include civil penalty payment in its analysis would increasingly amount to using civil penalty payment as an analytical proxy for credit trading. Having further considered the question, NHTSA's current view is, therefore, that including civil penalty payment beyond MY 2020 would effectively subvert EPCA's prohibition against considering credit trading. Therefore, for today's announcement, NHTSA has modified its analysis to assume that BMW, Daimler, FCA, JLR, and Volvo would consider paying civil penalties through MY 2020, and that all manufacturers would apply as much technology as would be needed in order to avoid paying civil penalties after MY 2020.

3. Technology Effectiveness Values

The next input required to simulate manufacturers' decision-making processes for the year-by-year application of technologies to specific vehicles is estimates of how effective each technology would be at reducing fuel consumption. In the NPRM, the agencies used full-vehicle modeling and simulation to estimate the fuel economy improvements manufacturers could make to a fleet of vehicles, considering those vehicles' technical specifications and how combinations of technologies interact. Full-vehicle modeling and simulation uses computer software and physics-based models to predict how combinations of technologies perform as a full system under defined conditions.

A model is a mathematical representation of a system, and simulation is the behavior of that mathematical representation over time. In this analysis, the model is a mathematical representation of an entire vehicle,[453] including its individual components such as the engine and transmission, overall vehicle characteristics such as mass and aerodynamic drag, and the environmental conditions, such as ambient temperature and barometric pressure. The agencies simulated the model's behavior over test cycles, including the 2-cycle laboratory compliance tests (or 2-cycle tests),[454] to determine how the individual components interact. 2-cycle tests are

---

[451] *See* 49 U.S.C. 32911(b) ("Compliance is determined after considering credits available to the manufacturer . . . .").
[452] *See id.*
[453] Our full vehicle model was composed of sub-models, which is why the full vehicle model could also be referred to as a full system model, composed of sub-system models.
[454] EPA's compliance test cycles are used to measure the fuel economy of a vehicle. For readers unfamiliar with this process, it is like running a car on a treadmill following a program—or more specifically, two programs. The "programs" are the "urban cycle," or Federal Test Procedure (abbreviated as "FTP"), and the "highway cycle," or Highway Fuel Economy Test (abbreviated as "HFET"), and they have not changed substantively since 1975. Each

test cycles that are used to measure fuel economy and emissions for CAFE and CO_2 compliance, and therefore are the relevant test cycles for determining technology effectiveness when establishing standards. In the laboratory, 2-cycle testing involves sophisticated test and measurement equipment, carefully controlled environmental conditions, and precise procedures to provide the most repeatable results possible with human drivers. Measurements using these structured procedures serve as a yardstick for fuel economy and CO_2 emissions.

Full-vehicle modeling and simulation was initially developed to avoid the costs of designing and testing prototype parts for every new type of technology. For example, if a truck manufacturer has a concept for a lightweight tailgate and wants to determine the fuel economy impact for the weight reduction, the manufacturer can use physics-based computer modeling to estimate the impact. The vehicle, modeled with the proposed change, can be simulated on a defined test route and under a defined test condition, such as city or highway driving in warm ambient temperature conditions, and compared against the baseline reference vehicle. Full-vehicle modeling and simulation allows the consideration and evaluation of different designs and concepts before building a single prototype. In addition, full vehicle modeling and simulation is beneficial when considering technologies that provide small incremental improvements. These improvements are difficult to measure in laboratory tests due to variations in how vehicles are driven over the test cycle by human drivers, variations in emissions measurement equipment, and variations in environmental conditions.[455]

Full-vehicle modeling and simulation requires detailed data describing the individual technologies and performance-related characteristics. Those specifications generally come from design specifications, laboratory measurements, and other subsystem simulations or modeling. One example of data used as an input to the full vehicle simulation are engine maps for each engine technology that define how much fuel is consumed by the engine technology across its operating range.

Using full-vehicle modeling and simulation to estimate technology efficiency improvements has two primary advantages over using single or limited point estimates. An analysis using single or limited point estimates may assume that, for example, one fuel economy improving technology with an effectiveness value of 5 percent by itself and another technology with an effectiveness value of 10 percent by itself, when applied together achieve an additive improvement of 15 percent. Single point estimates generally do not provide accurate effectiveness values because they do not capture complex relationships among technologies. Technology effectiveness often differs significantly depending on the vehicle type (e.g. sedan versus pickup truck) and how the technology interacts with other technologies on the vehicle, as different technologies may provide different incremental levels of fuel economy improvement if

---

cycle is a designated speed trace (of vehicle speed versus time) that all certified vehicles must follow during testing. The FTP is meant roughly to simulate stop and go city driving, and the HFET is meant roughly to simulate steady flowing highway driving at about 50 mph. For further details on compliance testing, see the discussion in Section VI.B.3.a)(7).

[455] Difficulty with controlling for such variability is reflected, for example, in 40 CFR 1065.210, Work input and output sensors, which describes complicated instructions and recommendations to help control for variability in real world (non-simulated) test instrumentation set up.

implemented alone or in tandem with other technologies. Any oversimplification of these complex interactions leads to less accurate and often overestimated effectiveness estimates.

In addition, because manufacturers often implement several fuel-saving technologies simultaneously when redesigning a vehicle, it is difficult to isolate the effect of individual technologies using laboratory measurement of production vehicles alone. Modeling and simulation offers the opportunity to isolate the effects of individual technologies by using a single or small number of baseline vehicle configurations and incrementally adding technologies to those baseline configurations. This provides a consistent reference point for the incremental effectiveness estimates for each technology and for combinations of technologies for each vehicle type. Vehicle modeling also reduces the potential for overcounting or undercounting technology effectiveness.

An important feature of this analysis is that the *incremental* effectiveness of each technology and combinations of technologies be accurate and relative to a consistent baseline vehicle. The *absolute* fuel economy values of the full vehicle simulations are used only to determine *incremental* effectiveness and are never used directly to assign an absolute fuel economy value to any vehicle model or configuration for the rulemaking analysis.

For this analysis, absolute fuel economy levels are based on the individual fuel economy values from CAFE compliance data for each vehicle in the baseline fleet. The incremental effectiveness from the full vehicle simulations performed in Autonomie, a physics-based full-vehicle modeling and simulation software developed and maintained by the U.S. Department of Energy's Argonne National Laboratory, are applied to baseline fuel economy to determine the absolute fuel economy of applying the first technology change. For subsequent technology changes, incremental effectiveness is applied to the absolute fuel economy level of the previous technology configuration.

For example, if a Ford F150 2-wheel drive crew cab and short bed in the baseline fleet has a fuel economy value of 30 mpg for CAFE compliance, 30 mpg will be considered the reference absolute fuel economy value. A similar full vehicle model in the Autonomie simulation may begin with an average fuel economy value of 32 mpg, and with incremental addition of a specific technology X its fuel economy improves to 35 mpg, a 9.3 percent improvement. In this example, the incremental fuel economy improvement (9.3 percent) from technology X would be applied to the F150's 30 mpg absolute value.

For this analysis, the agencies determined the incremental effectiveness of technologies as applied to the 2,952 unique vehicle models in the analysis fleet. Although, as mentioned above, full-vehicle modeling and simulation reduces the work and time required to assess the impact of moving a vehicle from one technology state to another, it would be impractical—if not impossible—to build a unique vehicle model for every individual vehicle in the analysis fleet. Therefore, as explained further below, vehicle models are built in a way that maintains similar attributes to the analysis fleet vehicles, which ensures key components are reasonably represented.

We received a wide array of comments regarding the full-vehicle modeling and simulation performed for the NPRM, but there was general agreement that full-vehicle modeling and simulation was the appropriate method to determine technology effectiveness.[456] Stakeholders commented on other areas, such as full vehicle simulation tools, inputs, and assumptions, and these comments will be discussed in the following sections. For this final rule, the agencies continued to use the same full-vehicle simulation approach to estimate technology effectiveness for technology adoption in the rulemaking timeframe. The next sections will discuss the details of the explicit input specifications and assumptions used for the final rule analysis.

a) Why This Rulemaking Used Autonomie Full-Vehicle Modeling and Simulation to Determine Technology Effectiveness

The NPRM and final rule analysis use effectiveness estimates for technologies developed using Autonomie, a physics-based full-vehicle modeling and simulation software developed and maintained by the U.S. Department of Energy's Argonne National Laboratory.[457] Autonomie was designed to serve as a single tool to meet requirements of automotive engineering throughout the vehicle development process, and has been under continuous improvement by Argonne for over 20 years. Autonomie is commercially available and widely used in the automotive industry by suppliers, automakers, and academic researchers (who publish findings in peer reviewed academic journals).[458] DOE and manufacturers have used Autonomie and its ability to simulate a large number of powertrain configurations, component technologies, and vehicle-level controls over numerous drive cycles to support studies on fuel efficiency, cost-benefit analysis, and carbon dioxide emissions,[459] and other topics.

Autonomie has also been used to provide the U.S. government with data to make decisions about future research, and is used by DOE for analysis supporting budget priorities and plans for programs managed by its Vehicle Technologies Office (VTO), and to support decision making among competing vehicle technology research and development projects.[460] In addition, Autonomie is the primary vehicle simulation tool used by DOE to support its U.S. DRIVE

---

[456] *See* NHTSA-2018-0067-12039; NHTSA-2018-0067-12073. UCS and AAM both agreed that full vehicle simulation can significantly improve the estimates of technology effectiveness.

[457] More information about Autonomie is available at https://www.anl.gov/technology/project/autonomie-automotive-system-design (last accessed June 21, 2018). As mentioned in the preliminary regulatory impact analysis (PRIA) for this rule, the agencies used Autonomie version R15SP1, the same version used for the 2016 Draft TAR.

program, a government-industry partnership focused on advanced automotive and related energy infrastructure technology research and development.[461]

Autonomie is a MathWorks-based software environment and framework for automotive control-system design, simulation, and analysis.[462] It is designed for rapid and easy integration of models with varying levels of detail (low to high fidelity), abstraction (from subsystems to systems and entire architectures), and processes (e.g., calibration, validation). By building models automatically, Autonomie allows the quick simulation of many component technologies and powertrain configurations, and, in this case, to assess the energy consumption of advanced powertrain technologies. Autonomie simulates subsystems, systems, or entire vehicles; evaluates and analyzes fuel efficiency and performance; performs analyses and tests for virtual calibration, verification, and validation of hardware models and algorithms; supports system hardware and software requirements; links to optimization algorithms; and supplies libraries of models for propulsion architectures of conventional powertrains as well as hybrid and electric vehicles.

With hundreds of pre-defined powertrain configurations along with vehicle level control strategies developed from dynamometer test data, Autonomie is a highly capable tool for analyzing advantages and drawbacks of applying different technology options within each technology family, including conventional, parallel hybrid, power-split hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs), battery electric vehicles (BEV) and fuel cell vehicles (FCVs). Autonomie also allows users to evaluate the effect of component sizing on fuel consumption for different powertrain technologies as well as to define component requirements (e.g., power, energy) to maximize fuel displacement for a specific application.[463] To evaluate properly any powertrain-configuration or component-sizing influence, vehicle-level control models are critical, especially for electric drive vehicles like hybrids and plug-in hybrids. Argonne has extensive expertise in developing vehicle-level control models based on different approaches, from global optimization to instantaneous optimization, rule-based optimization, and heuristic optimization.[464]

Autonomie has been developed to consider real-world vehicle metrics like performance, hardware limitations, utility, and drivability metrics (e.g., towing capability, shift busyness, frequency of engine on/off transitions), which are important to producing realistic estimates of fuel economy and CO_2 emission rates. This increasing realism has, in turn, steadily increased confidence in the appropriateness of using Autonomie to make significant investment decisions. Autonomie has also been validated for a number of powertrain configurations and vehicle classes using Argonne's Advanced Mobility Technology Laboratory (AMTL) (formerly Advanced Powertrain Research Facility, or APRF) vehicle test data.[465]

Argonne has spent several years developing, applying, and expanding the means to use distributed computing to exercise its Autonomie full-vehicle simulation tool over the scale necessary for realistic analysis to provide data for CAFE and CO_2 standards rulemaking. The NPRM and PRIA detailed how Argonne used Autonomie to estimate the fuel economy impacts for roughly a million combinations of technologies and vehicle types.[466, 467] Argonne developed input parameters for Autonomie to represent every combination of vehicle, powertrain, and component technologies considered in this rulemaking. The sequential addition of more than 50 fuel economy-improving technologies to ten vehicle types generated more than 140,000 unique technology and vehicle combinations. Running the Autonomie powertrain sizing algorithms to determine the appropriate amount of engine downsizing needed to maintain overall vehicle performance when vehicle mass reduction is applied and for certain engine technology changes (discussed further, below) increased the total number of simulations to more than one million. The result of these simulations is a useful dataset identifying the impacts of combinations of vehicle technologies on energy consumption—a dataset that can be referenced as an input to the CAFE model for assessing regulatory compliance alternatives.

[466] As part of the Argonne simulation effort, individual technology combinations simulated in Autonomie were paired with Argonne's BatPAC model to estimate the battery cost associated with each technology combination based on characteristics of the simulated vehicle and its level of electrification. Information regarding Argonne's BatPAC model is available at http://www.cse.anl.gov/batpac/.

[467] Additionally, the impact of engine technologies on fuel consumption, torque, and other metrics was characterized using GT POWER simulation modeling in combination with other engine modeling that was conducted by IAV Automotive Engineering, Inc. (IAV). The engine characterization "maps" resulting from this analysis were used as inputs for the Autonomie full-vehicle simulation modeling. Information regarding GT Power is available at https://www.gtisoft.com/gt-suite-applications/propulsion-systems/gt-power-engine-simulation-software.

The following sections discuss the full-vehicle modeling and simulation inputs and data assumptions, and comments received on the NPRM analysis. The discussion is necessarily technical, but also important to understand the agencies' decisions to modify (or not) the Autonomie analysis for the final rule.

(1) Full-Vehicle Modeling, Simulation Inputs and Data Assumptions

The agencies provided extensive documentation that quantitatively and qualitatively described the over 50 technologies considered as inputs to the Autonomie modeling.[468, 469] These inputs consisted of engine technologies, transmission technologies, powertrain electrification, light-weighting, aerodynamic improvements, and tire rolling resistance improvements.[470] The PRIA provided an overview of the sub-models for each technology, including the internal combustion engine model, automatic transmission model, and others.[471] The Argonne NPRM model documentation expanded on these sub-models in detail to show the interaction of each sub-model input and output.[472] For example, as shown in Figure VI-2, the input for Autonomie's driver model (i.e., the model used to approximate the driving behavior of a real driver) is vehicle speed, and outputs are accelerator pedal, brake pedal, and torque demand.

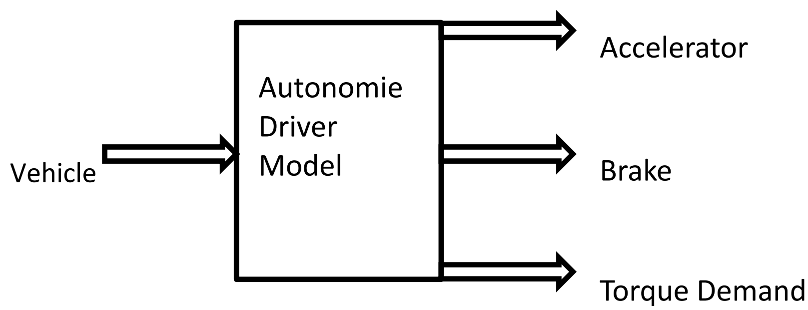

Figure VI-2 – Autonomie Driver Sub-Model inputs and outputs

Effectiveness inputs for the NPRM and the final rule analysis were specifically developed to consider many real world and compliance test cycle constraints, to the extent a computer model could capture them. Examples include the advanced engine knock model discussed

below, in addition to other constraints like allowing cylinder deactivation to occur in ways that would not negatively impact noise-vibration-harshness (NVH), and similarly optimizing the number of engine on/off events (e.g., from start/stop 12V micro hybrid systems) to balance between effectiveness and NVH.

One major input used in the effectiveness modeling that the agencies provided key specifications for in the PRIA are engine fuel maps that define how an engine equipped with specific technologies operates over a variety of engine load (torque) and engine speed conditions. The engine maps used as inputs to the Autonomie modeling portion of the analysis were developed by starting with a base map and then modifying that base map, incrementally, to model the addition of engine technologies. These engine maps, developed using the GT-Power modeling tool by IAV, were based off real-world engine designs. Simulated operation of these engines included the application of an IAV knock model, also developed from real-world engine data.[473, 474] Using this process, which incorporated real-world data, ensured that real-world constraints were considered for each vehicle type. Although the same type of engine map is used for all technology classes, the effectiveness varies based on the characteristics of each vehicle type. For example, a compact car with a turbocharged engine will have different fuel economy and performance values than a pickup truck with the same engine technology type. The engine map specifications are discussed further in Section VI.C.1 in the preamble and Section VI of FRIA.

The agencies also provided key details about input assumptions for various vehicle specifications like transmission gear ratios, tire size, final drive ratios, and individual component weights.[475] Each of these assumptions, to some extent, varied between the ten technology classes to capture appropriately real-world vehicle specifications like wheel mass or fuel tank mass. These specific input assumptions were developed based on the latest test data and current market fleet information.[476] The agencies relied on default assumptions developed by the Autonomie team, based on test data and technical publication review, for other model inputs required by Autonomie, such as throttle time response and shifting strategies for different transmission technologies. The Autonomie modeling tool did not simulate vehicle attributes determined to have minimal impacts, like whether a vehicle had a sun roof or hood scoops, as those attributes would have trivial impact in the overall analysis.

Because the agencies model ten different vehicle types to represent the 2,952 vehicles in the baseline fleet, improper assumptions about an advanced technology could lead to errors in estimating effectiveness. Autonomie is a sophisticated full-vehicle modeling tool that requires

---

[473] Engine knock in spark ignition engines occurs when combustion of some of the air/fuel mixture in the cylinder does not result from propagation of the flame front ignited by the spark plug, but one or more pockets of air/fuel mixture explodes outside of the envelope of the normal combustion front.

[475] ANL Autonomie Model Assumptions Summary. Aug 21, 2018, NHTSA-2018-0067-0005. ANL – Summary of Main Component Performance and Assumptions NPRM. Aug 21, 2018, NHTSA-2018-0067-0003.
[476] See further details in Section VI.B.1 Analysis Fleet.

extensive technology characteristics based on both physical and intangible data, like proprietary software. With a few technologies, the agencies did not have publicly available data, but had received confidential business information confirming such technologies potential availability in the market during the rulemaking time frame. For such technologies, including advanced cylinder deactivation, the agencies adopted a method in the CAFE model to represent the effectiveness of the technology, and did not explicitly simulate the technologies in the Autonomie model. For this limited set of technologies, the agencies determined that effectiveness could reasonably be represented as a fixed value.[477] Effectiveness values for technologies not explicitly simulated in Autonomie are discussed further in the individual technology sections of this FRIA.

The agencies sought comments on all effectiveness inputs and input assumptions, including the specific data used to characterize the technologies, such as data to build the technology input, data representing operating range of technologies, and data for variation among technology inputs. The agencies also sought comment on the effectiveness values used for technologies not explicitly defined in Autonomie.

Meszler Engineering Services, commenting on behalf of the Natural Resources Defense Council, and ICCT questioned the accuracy of the effectiveness estimates in the Argonne database, and as an example Meszler analyzed the fuel economy impacts of a 10-speed automatic transmission relative to a baseline 8-speed automatic transmission, concluding that the widely ranging effectiveness estimates were unexpected. ICCT questioned the accuracy of the IAV engine maps that serve as an input to the Autonomie effectiveness modeling, and asked whether those could "reasonably stand as a foundation for automotive developments and technology combinations" discussed elsewhere in their comments. ICCT also questioned whether Autonomie realistically and validly modeled synergies between technologies, using the effectiveness values from CEGR and transmissions as an example. Meszler stated that the agencies have an obligation to validate the Autonomie estimates before using them to support the NPRM or any other rulemaking. The agencies also received comments on the specific effectiveness estimates generated by Autonomie; however, those comments will be discussed in each individual technology section, below.

Despite these criticisms, Meszler stated that the critiques of the Autonomie technology database were not meant to imply that the Autonomie vehicle simulation model used to develop the database was fundamentally flawed, or that the model could not be used to derive accurate fuel economy impact estimates. Meszler noted that, as with any model, estimates derived with Autonomie are only valid for a given set of modeling parameters and if those parameters are well defined, the estimates should be accurate and reliable. Conversely, if those parameters are not well defined, the estimates would be inaccurate and unreliable. Meszler stated that the agencies

---

[477] For final rule, 9 out of 50 plus technologies use fixed offset effectiveness values. The total effectiveness of these technologies cannot be captured on the 2-cycle test or, like ADEAC, they are a new technology where robust data that could be used as an input to the technology effectiveness modeling does not yet exist. Specifically, these nine technologies are LDB, SAX, EPS, IACC, EFR, ADEAC, DSLI, DSLIAD and TURBOAD.

must make the full set of modeling assumptions used for the Autonomie database available for review and comment.

We agree with Meszler that, in general, when inputs to a model are inaccurate, output effectiveness results may be too high or too low. The technology effectiveness estimates from modeling results often vary with the type of vehicle and the other technologies that are on that vehicle.[478] The Autonomie output database consists of permutations of over 50 technologies for each of the ten technology classes simulated by the CAFE model. A wide range of effectiveness is expected when going from a baseline technology to an advanced technology across different technology classes because there are significant differences in how much power is required from the powertrain during 2-cycle testing across the ten vehicle types. This impacts powertrain operating conditions (e.g., engine speed and load) during 2-cycle testing. Fuel economy improving technologies have different effectiveness at each of those operating conditions so vehicles that have higher average power demands will have different effectiveness than vehicles with lower average power demands. Further, the differences in effectiveness at higher power and lower power vary by technology so the overall relationship is complex. Large-scale full-vehicle modeling and simulation account for these interactions and complexities.

Before conducting any full-vehicle modeling and simulation, the agencies spent a considerable amount of time and effort developing the specific inputs used for the Autonomie analysis. The agencies believe that these technology inputs provide reasonable estimates for the light-duty vehicle technologies the agencies expect to be available in the market in the rulemaking timeframe. As discussed earlier, these inputs vary in effectiveness due to how different vehicles, like compact cars and pickup trucks, operate on the 2-cycle test and in the real world. Some technologies, such as 10-speed automatic transmissions (AT10) relative to 8-speed automatic transmissions (AT8), can and should have different effectiveness results in the analysis between two different technology classes.[479] These unique synergistic effects can only be taken into account through conducting full-vehicle modeling and simulation, which the agencies did here.

With regards to Meszler's comment that the agencies have an obligation to validate the Autonomie estimates before using them to support the NPRM or any other rulemaking, the agencies would like to point Meszler to the description of the Argonne Autonomie team's robust process for vehicle model validation that was contained in the PRIA.[480] To summarize, the

---

[478] The PRIA Chapter 6.2.2.1, Table 6-2 and Table 6-3 defined the characteristics of the reference technology classes that representative of the analysis fleet.

[479] Separately, the agencies modified specific transmission modeling parameters for the final rule after additional review, including a thorough review of public comments, and this review is discussed in detail in Section VI.C.2.

NPRM and final rule analysis leveraged extensive vehicle test data collected by Argonne National Laboratory.[481] Over the past 20 years, the Argonne team has developed specific instrumentation lists and test procedures for collecting sufficient information to develop and validate full vehicle models. In addition, the agencies described the Argonne team's efforts to validate specific component models as well, such as the advanced automatic transmission and dual clutch transmission models.[482]

The agencies also described the process for validating inputs used to develop the IAV engine maps,[483, 484] another input to the Autonomie simulations. As discussed in the PRIA, IAV's engine model development relied on a collection of sub-models that controlled independent combustion characteristics such as heat release, combustion knock, friction, heat flow, and other combustion optimization tools. These sub-models and other computational fluid dynamics models were utilized to convert test data for use in the IAV engine map development. Specific combustion parameters, like from test data for the coefficient of variation for the indicated mean effective pressure (COV of IMEP), which is a common variable for combustion stability in a spark ignited engine, was used to assure final engine models were reasonable. The assumptions and inputs used in the modeling and validation of engine model results leveraged IAV's global engine database, which included benchmarking data, engine test data, single cylinder test data and prior modeling studies, and also technical publications and information presented at conferences. The agencies referenced in the PRIA that engine maps were validated with engine dynamometer test data to the maximum extent possible.[485] Because the NPRM and the final rule analysis considered some technologies not yet in production, the agencies relied on technical publications and engine modeling by IAV to develop and corroborate inputs and input assumptions where engine dynamometer test data was not available.

In addition, as described earlier in this section, the full set of NPRM modeling assumptions used for the Autonomie database were available for review and comment in the

docket for this rulemaking.[486] The full set of modeling assumptions used for the final rule are also available in the docket.[487]

Both ICCT and Meszler also commented on the availability of technologies within the Autonomie database, with Meszler stating that with limited exceptions, technologies were not included in the NPRM CAFE model if they were not included in the simulation modeling that underlay the Argonne database, and accordingly if a combination of technologies was not modeled during the development of the Argonne database, that package (or combination) of technologies was not available for adoption in the CAFE model. Meszler stated that these constraints limited the slate of technologies available to respond to fuel economy standards, and independently expanding the model to include additional technologies or technology combinations is not trivial.

ICCT gave specific examples of key efficiency technologies that it stated Autonomie did not include, like advanced DEAC, VCR, Miller Cycle, e-boost, and HCCI. ICCT argued that this was especially problematic as the agencies appeared to have available engine maps from IAV on advanced DEAC, VCR, Miller Cycle, E-boost (and from advanced DEAC, VCR, Miller Cycle, E-boost, HCCI from EPA) that Argonne or the agencies have been unable to or opted not to include in their modeling. ICCT stated that the agencies must disclose how Autonomie had been updated to incorporate "cutting edge" 2020-2025 automotive technologies to ensure they reflect available improvements.[488]

The agencies have updated the final rule analysis to include additional technologies. In the NPRM, the agencies presented the engine maps for all of the technologies that ICCT listed, except HCCI, and sought comment on the engine maps, technical assumptions and the potential use of the technologies for the final rule analysis. Based on the available technical information and the ICCT and Meszler comments, for the final rule analysis, VCR, Miller Cycle (VTG), and e-boost (VTGe with 48V BISG) technologies have been added and included in the Autonomie modeling and simulations, and advanced DEAC technology has been added using fixed point effectiveness estimates in the CAFE model analysis. The agencies disagree with ICCT's assessment of HCCI and do not believe it will be available for wide-scale application in the rulemaking timeframe, and therefore have not included it as a technology. HCCI technology has been in the research phase for several decades, and the only production applications to date use a

Preliminary Regulatory Impact Analysis (July 2018). Posted July 2018 and updated August 23 and October 16, 2018.

[487] The CAFE Model is available at https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system with documentation and all inputs and outputs supporting today's notice.

[488] ICCT also made the same request of EPA's ALPHA model, and the agencies' response to that comment is discussed in Section VI.C.1 Engine Paths, below.

highly-limited version that restricts HCCI combustion to a very narrow range of engine operating conditions.[489, 490, 491] Additional discussion of how Autonomie-modeled and non-modeled technologies are incorporated into the CAFE Model is located in Section VI.B.3.c), below.

ICCT and Meszler also commented that the agencies overly limited the availability of several technologies in the NPRM analysis. In response, the agencies reconsidered the restrictions that were applied in the NPRM analysis, and agree with the commenters for several technologies and technology classes. Many technologies identified by the commenters are now in production for the MY2017 as well as MY2018 and MY2019. The agencies also think that the baseline fleet compliance data reflects adoption of many of these technologies. For the final rule analysis, the agencies have expanded the availability of several technologies. In the CAFE model, the agencies are now allowing parallel hybrids (SHEVP2) to be adopted with high compression Atkinson mode engines (HCR0 and HCR1). In addition, as mentioned above, the Autonomie full-vehicle modeling included Variable Compression Ratio engine (VCR), Miller Cycle Engine (VTG), E-boost (VTGe) technologies, and cylinder deactivation technologies (DEAC) to be applied to turbocharged engines (TURBO1). As these changes relate to the technology effectiveness modeling, the CAFE model analysis now includes effectiveness estimates based on full vehicle simulations for all of these technology combinations.

We disagree with comments stating the agencies should allow every technology to be available to every vehicle class.[492] Discussed earlier in this section, Autonomie models key aspects of vehicle operation that are most relevant to assessing fuel economy, vehicle performance and certain aspects of drivability (like EPA 2-cycle tests, EPA US06 cycle tests, gradability, low speed acceleration time from 0-to-60 mph, passing acceleration time from 50 to 80 mph, and number of transmission shifts). However, there are other critical aspects of vehicle functionality and operation that the agencies considered beyond those criteria, that cannot necessarily be reflected in the Autonomie modeling. For example, a pickup truck can be modeled with a continuously variable transmission (CVT) and show improvements on the 2-cycle tests. However, pickup trucks are designed to provide high load towing utility.[493] CVTs lack the torque levels needed to provide that towing utility, and would fail mechanically if subject to high load towing.[494] The agencies provided discussions of some of these technical considerations in the PRIA, and explained why the agencies had limited technologies for certain

vehicle classes, such as limiting CVTs on pickups as in the example above. These and other limitations are discussed further in the individual technology sections.

The agencies also received a variety of comments that conflated aspects of the Autonomie models with technology inputs and input assumptions. For example, commenters expressed concern about the transmission gear set and final drive values used for the NPRM analysis, or more specifically, that the gear ratios were held constant across applications.[495] In this case, both the inputs (gear set and final drive ratio) and input assumption (ratios held constant) were discussed by the commenters. Because these comments are actually about technology inputs to the Autonomie model, for these and similar cases, the agencies are addressing the comments in the individual technology sections which discuss the technology inputs and input assumptions that impact the effectiveness values for those technologies.

For the NPRM analysis, the agencies prioritized using inputs that were based on data for identifiable technology configurations and that reflected practical real world constraints. The agencies provided detailed information on the NPRM analysis inputs and input assumptions in the NPRM Preamble, PRIA and Argonne model documentation for engine technologies, transmission technologies, powertrain electrification, light-weighting, aerodynamic improvements, tire rolling resistance improvements, and other vehicle technologies. Comments and the agencies' assessment of comments for each technology are discussed in the individual technology sections below. Through careful consideration of the comments, the agencies have updated analytical inputs associated with several technologies, and as discussed above, have included several advanced technologies for which technical information was included in the NPRM. However, for most technologies, the agencies have determined that the technology inputs and input assumptions that were used in the NPRM analysis remain reasonable and the best available for the final rule analysis.

(2) How The Agencies Defined Different Vehicle Types in Autonomie

As described in the NPRM, Argonne produced full-vehicle models and ran simulations for many combinations of technologies, on many types of vehicles, but it did not simulate literally every single vehicle model/configuration in the analysis fleet because it would be impractical to assemble the requisite detailed information—much of which would likely only be provided on a confidential basis—specific to each vehicle model/configuration and because the scale of the simulation effort would correspondingly increase by orders of magnitude. Instead, Argonne simulated 10 different vehicle types, corresponding to the five "technology classes" generally used in CAFE analysis over the past several rulemakings, each with two performance levels and corresponding vehicle technical specifications (e.g., small car, small performance car, pickup truck, performance pickup truck, etc.).

Technology classes are a means of specifying common technology input assumptions for vehicles that share similar characteristics. Because each vehicle technology class has unique

---

[495] NHTSA-2018-0067-11873. Comments from Roush Industries, Attachment 1, at p. 14-15. NHTSA-2018-0067-11873. Comments from CARB, at p.110.

characteristics, the effectiveness of technologies and combinations of technologies is different for each technology class. Conducting Autonomie simulations uniquely for each technology class provides a specific set of simulations and effectiveness data for each technology class. Like the Draft TAR analysis, there are separate technology classes for compact cars, midsize cars, small SUVs, large SUVs, and pickup trucks. However, new for the NPRM analysis and carried into this final rule analysis, each of those vehicle types has been split into "low" (or "standard") performance and a "high" performance versions, which represent two classes with similar body styles but different levels of performance attributes (for a total of 10 technology classes). The separate technology classes for high performance and low performance vehicles better account for performance diversity across the fleet.

NHTSA directed Argonne to develop a vehicle assumptions database to capture vehicle attributes that would comprise the full vehicle models. For each vehicle technology class, representative vehicle attributes and characteristics were identified from publicly available information and automotive benchmarking databases like A2Mac1,[496] Argonne's Downloadable Dynamometer Database (D^3),[497] and EPA compliance and fuel economy data,[498] EPA's guidance on the cold start penalty on 2-cycle tests.[499] The resulting vehicle assumptions database consists of over 100 different attributes like vehicle frontal area, drag coefficient, fuel tank weight, transmission housing weight, transmission clutch weight, hybrid vehicle component weights, and weights for components that comprise engines and electric machines, tire rolling resistance, transmission gear ratios and final drive ratio. Each of the 10 different vehicle types was assigned a set of these baseline attributes and characteristics, to which combinations of fuel-saving technologies were added as inputs for the Autonomie simulations. For example, the characteristics of the MY 2016 Honda Fit were considered along with a wide range of other compact cars to identify representative characteristics for the Autonomie simulations for the base compact car technology class. The simulations determined the fuel economy achieved when applying each combination of technologies to that vehicle type, given its baseline characteristics.

For each vehicle technology class and for each vehicle attribute, Argonne estimated the attribute value using statistical distribution analysis of publicly available data and data obtained from the A2Mac1 benchmarking database.[500] Some vehicle attributes were also based on test data and vehicle benchmarking, like the cold-start penalty for the FTP test cycle and vehicle electrical accessories load. The analysis of vehicle attributes used in the NPRM was discussed in

These components are weighed and documented for key specifications which is then available to their subscribers.

the Argonne model documentation,[501] and values for each vehicle technology class were provided with the NPRM for public review.[502]

The agencies did not believe it was appropriate to assign one single engine mass for each vehicle technology class in the NPRM analysis. To account for the difference in weight for different engine types, Argonne performed a regression analysis of engine peak power versus weight, based on attribute data taken from the A2Mac1 benchmarking database. For example, to account for weight of different engine sizes like 4-cylinder versus 8-cylinder, Argonne developed a relationship curve between peak power and engine weight based on the A2Mac1 benchmarking data. For the NPRM analysis, this relationship was used to estimate mass for all engine types regardless of technology type (e.g., variable valve lift and direct injection). Secondary weight reduction associated with changes in engine technology was applied by using this linear relationship between engine power and engine weight from the A2Mac1 benchmarking database. When a vehicle in the analysis fleet with an 8-cylinder engine adopted a more fuel efficient 6-cylinder engine, the total vehicle weight would reflect the updated engine weight with two less cylinders based on the peak power versus engine weight relationship. The impact of engine mass reduction on effectiveness is accounted for directly in the Autonomie simulation data through the application of the above relationship. Engine mass reduction through downsizing is, therefore, appropriately not included as part of vehicle mass reduction technology that is discussed in Section VI.C.4 because doing so would result in double counting the impacts. As discussed further below, for the final rule the agencies improved upon the precision of engine weights by creating two curves to separately represent naturally aspirated engine designs and turbocharged engine designs.

In addition, certain attributes were held at constant levels within each technology class to maintain vehicle functionality, performance and utility including noise, vibration, and harshness (NVH), safety, performance and other utilities important for customer satisfaction. For example, in addition to the vehicle performance constraints discussed in Section VI.B.3.a)(6), the analysis does not allow the frontal area of the vehicle to change, in order to maintain utility like ground clearance, head-room space, and cargo space, and a cold-start penalty is used to account for fuel economy degradation for heater performance and emissions system catalyst light-off.[503] This allows us to capture the discrete improvement in technology effectiveness while maintaining vehicle attributes that are important vehicle utility, consumer acceptance and compliance with criteria emission standards, and considering these constraints similar to how manufacturers do in the real world.

The agencies sought comment on the analytical approach used to determine vehicle attributes and characteristics for the Autonomie modeling. In response, the agencies received a wide variety of comments on vehicle attributes ranging from discussions of performance increase

---

[501] NHTSA-2018-0067-0007, at 131. Islam, E., S, Moawad, A., Kim, N, Rousseau, A., "A Detailed Vehicle Simulation Process To Support CAFE Standards 04262018 – Report" ANL Autonomie Documentation. Aug 21, 2018.

[502] NHTSA-2018-0067-0003. ANL Autonomie Summary of Main Component Assumptions. Aug 21, 2018.

[503] The catalyst light-off is the temperature necessary to initiate the catalytic reaction and this energy is generated from engine.

from technology adoption (e.g. if a vehicle adopting an electrified powertrain improved its time to accelerate from 0-60 mph), to comments on vehicle attributes *not* modeled in Autonomie, like heated seats and cargo space.

Toyota and the Alliance commented that the inclusion of performance vehicle classes addressed the market reality that some consumers will purchase vehicles for their performance attributes and will accept the corresponding reduction in fuel economy. Furthermore, Toyota commented that some gain in performance is more realistic, and that "dedicating all powertrain improvements to fuel efficiency is inconsistent with market reality." Toyota "supports the agencies' inclusion of performance classes in compliance modeling where a subset of certain models is defined to have higher performance and a commensurate reduction in fuel efficiency."[504] Also, in support of the addition of performance vehicle classes, the Alliance commented that "vehicle categories have been increased to 10 to better recognize the range of 0–60 performance characteristics within each of the 5 previous categories, in recognition of the fact that many vehicles in the baseline fleet significantly exceeded the previously assumed 0–60 performance metrics. This provides better resolution of the baseline fleet and more accurate estimates of the benefits of technology."[505]

UCS commented that the CAFE model incorporates technology improvements to each vehicle by applying the effectiveness improvement of the average vehicle in the technology class, leading to discrete "stepped" effectiveness levels for technologies across the different vehicle types. UCS stated that in contrast, the OMEGA model takes into account a vehicle's performance characteristics through response-surface modeling based on relative deviation from the class average modeled in ALPHA.[506]

Although differences between the ALPHA and Autonomie models are discussed in more detail below, for the NPRM vehicle simulation analysis the agencies expanded the number of vehicle classes from the five classes used in the Draft TAR to ten classes, to represent better the diversity of vehicle characteristics across the fleet. Each of these ten vehicle technology classes are empirically built from benchmarking data and other information from various sources, amounting to hundreds of vehicle characteristics data points to develop each vehicle class. The agencies expand on these vehicle classes and characteristics in Section VI.B.3.a)(2) Vehicle Types in Autonomie and Section VI.B.3.a)(3) How Vehicle Models are Built in Autonomie and Optimized for Simulation. The agencies believe that the real-world data used to define vehicle characteristics for each of the ten vehicle classes, in addition to the ten vehicle technology classes themselves, ensures the analysis reasonably accounts for the diversity in vehicle characteristics across the fleet.

The agencies believe that UCS's characterization of how technology improvements are applied in the analysis is a misleading oversimplification. While the analysis approach in the final rule uses a representative effectiveness value, the value is not linked solely to the vehicle

---

[506] NHTSA-2018-0067-12039, at p.24.

technology class, as the UCS implies. The entire technology combination, or technology key, which includes the vehicle technology class, is used to determine the value for the platform being considered. Within each vehicle class, the interactions between the added technology and the full vehicle system (including other technologies and substantial road load characteristics) are considered in the effectiveness values calculated for each technology during compliance modeling. As discussed under each of the technology pathways sections, the effectiveness for most technologies is reported as a range rather than a single value. The range exists because the effectiveness for each technology is adjusted based on the technologies it is coupled with and the major road load characteristics of the full vehicle system. This approach, in combination with using the baseline vehicle's initial performance values as a starting point for performance improvement, results in a widely variable level of improvement for the system, dependent on individual vehicle platform characteristics. As a result, the application of a response-surface approach would likely result in minimal improvement in accuracy for the Autonomie and CAFE model analysis approach.

For the final rule analysis, the agencies used the same process to obtain the vehicle attributes and characteristics for the vehicle technology classes. Data was acquired from publicly available sources, Argonne D^3, EPA compliance and fuel economy data, and A2mac1 benchmarking data. Accordingly, the attributes and characteristics of the modeled vehicles reflect actual vehicles that meet customer expectations and automakers' capabilities to manufacture the vehicles. In addition, for the final rule, the agencies improved the NPRM analysis by updating some of the attribute values to account for changes in the fleet. For example, the agencies have updated vehicle electrical accessory load on the test cycle to reflect higher electrical loads associated with contemporary vehicle features.

(3) How This Rulemaking Builds Vehicle Models for Autonomie and Optimize Them for Simulation

Before any simulation is initiated in Autonomie, Argonne must "build" a vehicle by assigning reference technologies and initial attributes to the components of the vehicle model representing each technology class.[507] The reference technologies are baseline technologies that represent the first step on each technology pathway used in the analysis. For example, a compact car is built by assigning it a baseline engine, a baseline 6-speed automatic transmission (AT6), a baseline level of aerodynamic improvement (AERO0), a baseline level of rolling resistance improvement (ROLL0), a baseline level of mass reduction technology (MR0), and corresponding attributes from the Argonne vehicle assumptions database like individual component weights.[508] A baseline vehicle will have a unique starting point for the simulation and a unique set of assigned inputs and attributes, based on its technology class.

The next step in the process is to run a powertrain sizing algorithm that ensures the built vehicle meets or exceeds defined performance metrics, including low-speed acceleration (i.e.,

[507] For the NPRM analysis, Chapter 8 Vehicle-Sizing Process in the ANL Model Documentation had discussed this process in detail. Further discussion of this process is located in Chapter 8 of the ANL Model Documentation for this final rule.
[508] *See* Section VI.A.7.

time required to accelerate from 0-60 mph), high-speed passing acceleration (time required to accelerate from 50-80 mph), gradeability (e.g. the ability of the vehicle to maintain constant 65 miles per hour speed on a six percent upgrade), and towing capacity. Together, these performance criteria are widely used by industry as metrics to quantify vehicle performance attributes that consumers observe and that are important for vehicle utility and customer satisfaction.

In the compact car example used above, the agencies assigned an initial specific engine design and engine power, transmission, AERO, ROLL, and MR technologies, and other attributes like vehicle weight. If the built vehicle does not meet all the performance criteria in the first iteration, then the engine power is increased to meet the performance requirement. This increase in power is from higher engine displacement, which could involve an increase in number of cylinders, leading to an increase in the engine weight. The iterative process continues to check whether the compact car with updated engine power, and corresponding updated engine weight, meets its defined performance metrics. The loop stops once all the metrics are met, and at this point, a compact car technology class vehicle model becomes ready for simulation. For further discussion of the vehicle performance metrics, see Section VI.B.3.a).

Autonomie then adopts a single fuel saving technology to the baseline vehicle model, keeping everything else the same except for that one technology and the attributes associated with it. For example, the model would apply an 8-speed automatic transmission in place of the baseline 6-speed automatic transmission, which would lead to either an increase or decrease in the total weight of the vehicle based on the technology class assumptions. At this point, Autonomie confirms whether performance metrics are met for this new vehicle model through the previously discussed sizing algorithm. Once a technology has been assigned to the vehicle model and the resulting vehicle meets its performance metrics, those vehicle models will be used as inputs to the full vehicle simulations. So, in the example of the 6-speed to 8-speed automatic transmission technology update, the agencies now have the initial ten vehicle models (one for each technology class), plus the ten new vehicle models with the updated 8-speed automatic transmission, which adds up to 20 different vehicle models for simulation. This permutation process is conducted for each of the over 50 technologies considered, and for all ten technology classes, which results in more than one million optimized vehicle models.
Figure VI-3 shows the process for building vehicles in Autonomie for simulation.

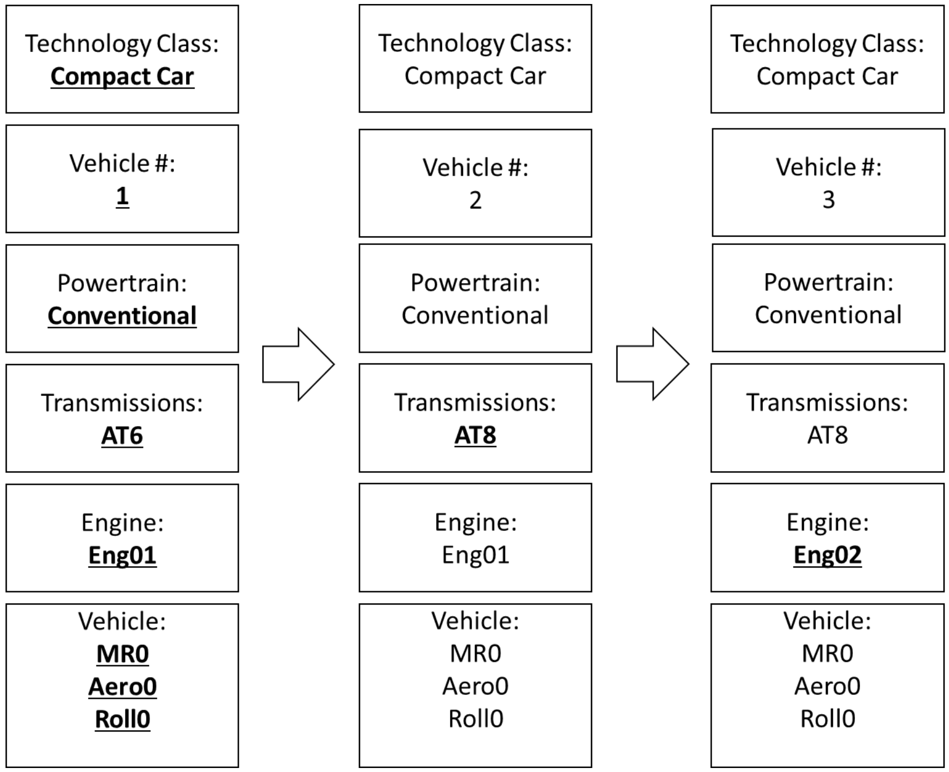

Figure VI-3 – Autonomie Technology Adoption Process for Vehicle building with compact car technology class as an example

Some of the technologies require extra steps for optimization before the vehicle models are built for simulation; for example, the sizing and optimization process is more complex for the electrified vehicles (i.e., HEVs, PHEVs) compared to vehicles with internal combustion engines, as discussed further, below. Throughout the vehicle building process, the following items are considered for optimization:

- Vehicle weight is decreased or increased in response to switching from one type of technology to another for the technologies for which the agencies consider weight, such as different engine and transmission types;
- Vehicle performance is decreased or increased in response to the addition of mass reduction technologies when switching from one vehicle model to another vehicle model for the same engine;
- Vehicle performance is decreased or increased in response to the addition of a new technology when switching from one vehicle model to another vehicle model for the same hybrid electric machine; and
- Electric vehicle battery size is decreased or increased in response to the addition of mass, aero and/or tire rolling resistance technologies when switching from one vehicle model to another vehicle model.

Every time a vehicle adopts a new technology, the vehicle weight is updated to reflect the new component weight. For some technologies, the direct weight change is easy to assess. For example, in the NPRM the agencies designated weights for transmissions so, when a vehicle is updated to a higher geared transmission, the weight of the original transmission is replaced with the corresponding transmission weight (e.g., the weight of a vehicle moving from a 5-speed automatic transmission to an 8-speed automatic transmission will be updated based on the 8-speed transmission weight).

For other technologies, like engine technologies, assessing the updated vehicle weight is much more complex. Discussed earlier, modeling a change in engine technology involves both the new technology adoption and a change in power (because the reduction in vehicle weight leads to lower engine loads, and a resized engine). When a new engine technology is adopted on a vehicle the agencies account for the associated weight change to the vehicle based on the earlier discussed regression analysis of weight versus power. For the NPRM engine weight regression analysis, the agencies considered 19 different engine technologies that consisted of unique components to achieve fuel economy improvements. This regression analysis is technology agnostic by taking the approach of using engine peak power versus engine weight because it removed biases to any specific engine technology in the analysis. Although the agencies do not estimate the specific weight for each individual engine technology, such as VVT and SGDI, this process provides a reasonable estimate of the weight differences among engine technologies.

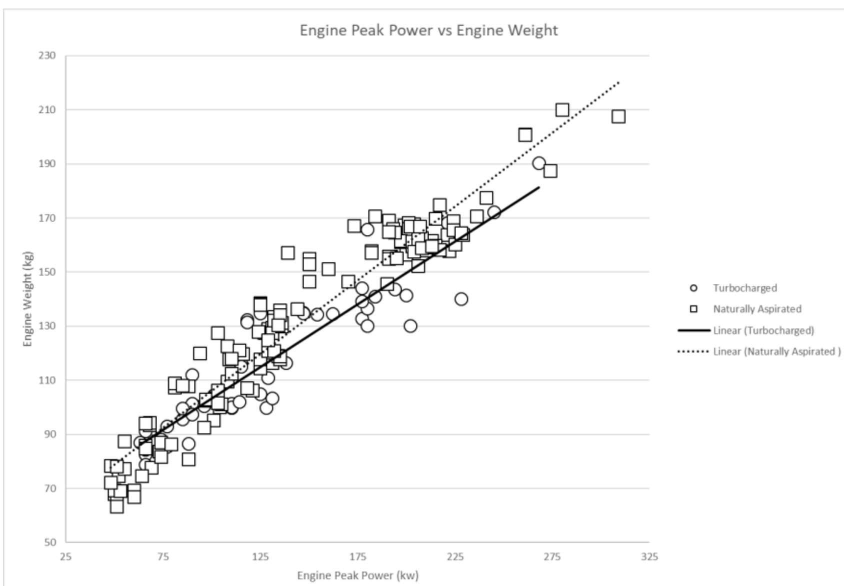

Figure VI-4 – Engine weight determination as function of power and type of air induction (naturality aspirated vs turbocharged)

For the final rule analysis, the agencies used the same process to assign initial weights to the original 19 engines, plus the added engines. However, the agencies improved upon precision of the weights by creating two separate curves separately to represent naturally aspirated engine designs and turbocharged engine designs.[509] This update resulted in two benefits. First, small

[509] ANL Model Documentation for the final rule analysis, Chapter 5.2.9 Engine Weight Determination.

naturally aspirated 4-cylinder engines that adopted turbocharging technology reflected the increased weight of associated components like ducting, clamps, the turbocharger itself, a charged air cooler, wiring, fasteners, and a modified exhaust manifold. Second, larger cylinder count engines like naturally aspirated 8-cylinder and 6-cylinder engines that adopted turbocharging and downsized technologies would have lower weight due to having fewer engine cylinders. For example, a naturally aspirated 8-cylinder engine that adopts turbocharging technology when downsized to a 6-cylinder turbocharged engine appropriately reflects the added weight of turbocharging components, and the lower weight of fewer cylinders.

As with conventional vehicle models, electrified vehicle models were built from the ground up. For the NPRM analysis, Argonne used data from the A2mac1 database and vehicle test data to define different attributes like weights and power. Argonne used one electric motor specific power for each type of hybrid and electric vehicle.[510] For MY2017, the U.S. market has an expanded number of available hybrid and electric vehicle models. To capture appropriately the improvements for electrified vehicles for the final rule analysis, the agencies applied the same regression analysis process that considers electric motor weight versus electric motor power for vehicle models that have adopted electric motors. Benchmarking data for hybrid and electric vehicles from the A2Mac1 database was analyzed to develop a regression curve of electric motor peak power versus electric motor weight.[511]

(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation

The agencies maintain performance neutrality of the full vehicle simulation analysis by resizing engines, electric machines, and hybrid electric vehicle battery packs at specific incremental technology steps. To address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.[512] Manufacturers have repeatedly told the agencies that the high costs for redesign and the increased manufacturing complexity that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination of technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. The agencies reiterated in the NPRM that the analysis should not include engine resizing with the application of every technology or for combinations of technologies that drive small performance changes so that the analysis better reflects what is feasible for manufacturers.[513]

[512] *See* 83 FR 43027 (Aug. 24, 2018).

[513] For instance, a vehicle would not get a modestly bigger engine if the vehicle comes with floor mats, nor would the vehicle get a modestly smaller engine without floor mats. This example demonstrates small levels of mass reduction. If manufacturers resized engines for small changes, manufacturers would have dramatically more part complexity, potentially losing economies of scale.

When a powertrain does need to be resized, Autonomie attempts to mimic manufacturers' development approaches to the extent possible. Discussed earlier, the Autonomie vehicle building process is initiated by building a baseline vehicle model with a baseline engine, transmission, and other baseline vehicle technologies. This baseline vehicle model (for each technology class) is sized to meet a specific set of performance criteria, including acceleration and gradeability.

The modeling also accounts for the industry practice of platform, engine, and transmission sharing to manage component complexity and the associated costs.[514] At a vehicle refresh cycle, a vehicle may inherit an already resized powertrain from another vehicle within the same engine-sharing platform that adopted the powertrain in an earlier model year. In the Autonomie modeling, when a new vehicle adopts fuel saving technologies that are inherited, the engine is not resized (the properties from the baseline reference vehicle are used directly and unchanged) and there may be a small change in vehicle performance. For example, in Figure VI-3, Vehicle 2 inherits Eng01 from Vehicle 1 while updating the transmission. Inheritance of the engine with new transmission may change performance. This example illustrates how manufacturers generally manage manufacturing complexity for engines, transmissions, and electrification technologies.

Autonomie implements different powertrain sizing algorithms depending on the type of powertrain being considered because different types of powertrains contain different components that must be optimized.[515] For example, the conventional powertrain resizing considers the reference power of the conventional engine (e.g., Eng01, a basic VVT engine, is rated at 108 kilowatts and this is the starting reference power for all technology classes) against the power-split hybrid (SHEVPS) resizing algorithm that must separately optimize engine power, battery size (energy and power), and electric motor power. An engine's reference power rating can either increase or decrease depending on the architecture, vehicle technology class, and whether it includes other advanced technologies.

Performance requirements also differ depending on the type of powertrain because vehicles with different powertrain types may need to meet different criteria. For example, a plug-in hybrid electric vehicle (PHEV) powertrain that is capable of traveling a certain number of miles on its battery energy alone (referred to as all-electric range, or AER, or as performing in electric-only mode) is also sized to ensure that it can meet the performance requirements of a US06 cycle in electric-only mode.

The powertrain sizing algorithm is an iterative process that attempts to optimize individual powertrain components at each step. For example, the sizing algorithm for conventional powertrains estimates required power to meet gradeability and acceleration performance and compares it to the reference engine power for the technology class. If the

[514] Ford EcoBoost Engines are shared across ten different models in MY2019. https://www.ford.com/powertrains/ecoboost/. Last accessed Nov. 05, 2019.
[515] ANL Model Documentation for the final rule Analysis, Chapter 8.3.1 Conventional-Vehicle Sizing Algorithm; Chapter 8.3.2 Split-HEV Sizing Algorithm; 8.3.4 Blended PHEV sizing Algorithm; 8.3.5 Voltec PHEV (Extended Range) Vehicle Sizing Algorithm; Chapter 8.3.6 BEV Sizing Algorithm.

power required to meet gradeability and acceleration performance exceeds the reference engine power, the engine power is updated to the new value. Similarly, if the reference engine power exceeds the gradeability and acceleration performance power, it will be decreased to the lower power rating. As the change in power requires a change design of the engine, like increasing displacement (e.g., going from a 5.2-liter to 5.6-liter engine, or vice versa) or increasing cylinder count (e.g., going from an I4 to a V6 or vice versa), the engine weight will also change. The new engine power is used to update the weight of the engine.

Next, the conventional powertrain sizing algorithm enters an acceleration algorithm loop to verify low-speed acceleration performance (time it takes to go from 0 mph to 60 mph). In this step, Autonomie adjusts engine power to maintain a performance attribute for the given technology class and updates engine weight accordingly. Once the performance criteria are met, Autonomie ends the low-speed acceleration performance algorithm loop and enters a high-speed acceleration (time it takes to go from 50 mph to 80 mph) algorithm loop. Again, Autonomie might need to adjust engine power to maintain a performance attribute for the given technology, and it exits this loop once the performance criteria have been met. At this point, the sizing algorithm is complete for the conventional powertrain based on the designation for engine type, transmissions type, aero type, mass reduction technology and low rolling resistance technology.

Figure VI-5 below shows the sizing algorithm for conventional powertrains.

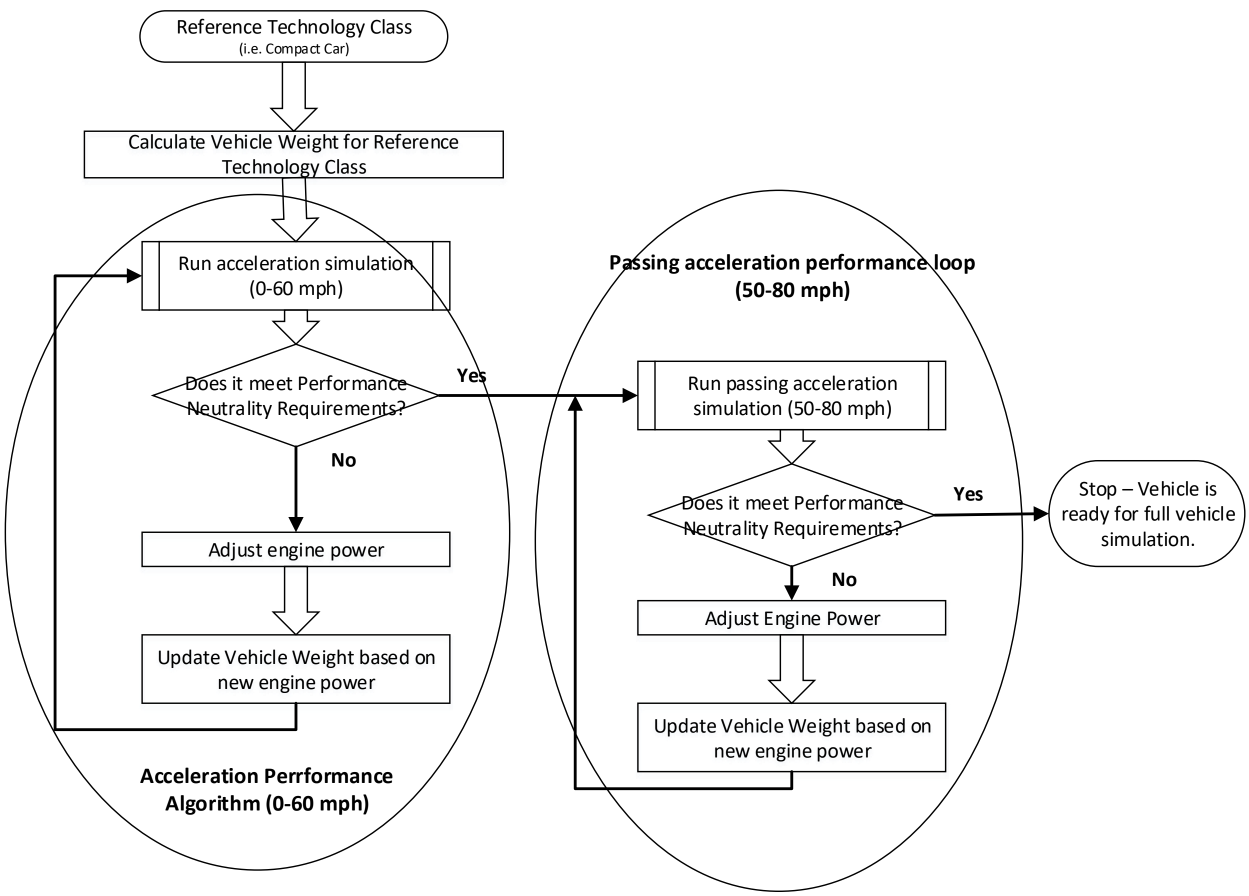

Figure VI-5 – Conventional powertrain sizing algorithm

Depending on the type of powertrain considered, the sizing algorithms may also size to meet different performance criteria in different order. The powertrain sizing algorithms for electrified vehicles are considerably more complex, and are discussed in further detail in Section VI.C.3, below.

(a) Engine Displacement & Determining the Number of Engine Cylinders

The NPRM and this final rule analysis limited engine displacement and downsizing in full vehicle simulation results to mimic powertrain portfolio complexity of full line vehicle manufacturers. Analytical and empirical data were used to develop engine displacement and downsizing assumptions. For each vehicle class, each engine has eight power values, with four dedicated for conventional vehicles and four for pre-transmission HEVs. Analytically, the engine power was defined using performance tests such as acceleration and gradeability, which represent max rate engine power. Empirically, the analysis defined all number of cylinders as a function of engine displacement based on the data from light duty vehicle population.

The flowchart below shows the method to calculate the engine displacement and number of cylinders. Figure VI-6 shows the relationship of number of engine cylinders with respect to engine displacement from the existing vehicles in the U.S. market. Sizing of the engine is only dependent on four levels of mass reduction; MR0 to MR2 received one power level, while MR3, MR4, and MR5 each receive one power level. Once these engine power levels are defined, they are not changed due to change in transmission, aero, or tire technologies.

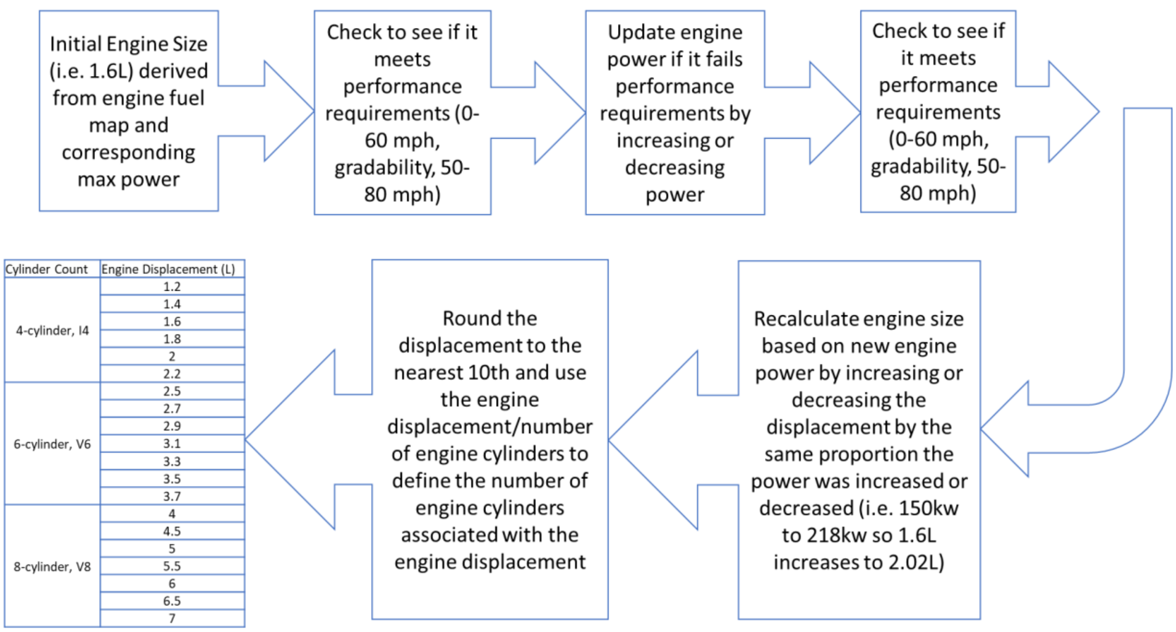

Figure VI-6 – Engine Displacement / Number of Engine Cylinder Relationship

Using the relationship, certain thresholds are created to define the number (and type) of engine cylinders with respect to engine displacement. The thresholds are defined in table below:

Table VI-22 - Engine Displacement vs. Number of Engine Cylinders Threshold

(Type and) Number of engine cylinders	Engine displacement (L)
4-cylinder inline (I4)	1.2 1.4 1.6 1.8 2.0 2.2
6 cylinder (V6)	2.5 2.7 2.9 3.1 3.3 3.5 3.7
8 cylinder (V8)	4.0 4.5 5.0 5.5 6.0 6.5 7.0

(5) How The Agencies Considered Maintaining Vehicle Attributes

For this rulemaking analysis, consistent with past CAFE and CO_2 rulemakings, the agencies have analyzed technology pathways manufacturers could use for compliance that attempt to maintain vehicle attributes, utility, and performance. Using this approach allows the agencies to assess costs and benefits of potential standards under a scenario where consumers continue to get the similar vehicle attributes and features, other than changes in fuel economy. The purpose of constraining vehicle attributes is to simplify the analysis and reduce variance in other attributes that consumers value across the analyzed regulatory alternatives. This allows for a more streamlined accounting of costs and benefits by not requiring the values of other vehicle attributes that trade off with fuel economy.

Several examples of vehicle attributes, utility and performance that could be impacted by adoption of fuel economy improving technology include the following.

Table VI-23 – Vehicle Attributes that Could be Impacted by Fuel Economy Improving Technologies

Vehicle Attribute	Impacted by Fuel Economy Improving Technologies
Interior volume	Electrification, aerodynamics
Cargo/trunk space	Electrification, aerodynamics
Heater/defroster performance	Engine, transmission, start-stop
Air conditioning system performance	Air conditioning system, start-stop
Drivability	Engine, transmission
Idle quality	Engine, transmission
Noise	Engine, transmission, mass reduction
Vibration	Engine, transmission, mass reduction
Harshness	Engine, transmission, mass reduction, tires
Ride quality	Mass reduction, tires
Handling	Mass reduction, tires
Braking	Brake drag, tires
Steering feel	Electric power steering, tires
Turning circle	Footprint
0 - 60 mph acceleration	Engine, transmission, electrification, mass reduction, aero, tires
Passing acceleration	Engine, transmission, electrification, mass reduction, aero, tires
Gradeability	Engine, transmission, electrification, mass reduction, aero, tires
Towing capacity	Engine, transmission, electrification, mass reduction, aero
Launch acceleration feel	Engine, transmission, electrification, mass reduction
Styling	Aero, engine, transmission, electrification
Driving range	Electrification, fuel economy/tank size (mass)
Refueling time	Fuel economy/tank size

Consequences for the agencies not fully considering or accounting for potential changes in vehicle attributes, utility, and performance are degradation in vehicle attributes, utility, and performance that lead to consumer acceptance issues without accounting for the corresponding costs and/or not accounting for the costs of technology designs that maintain vehicle attributes, utility, and performance. The agencies incorporated changes in the NPRM analysis and that are carried into this final rule that address deficiencies in past analyses, including the Draft TAR and Proposed Determination analyses. These changes were discussed in the NPRM and are repeated in the discussion of individual technologies in this FRIA. The following are several examples of technologies that did not maintain vehicle attributes, utility, and performance in the Draft TAR and Proposed Determination analyses.

For the EPA Draft TAR and Proposed Determination analyses, HCR engine and downsized and turbocharged engine technologies effectiveness was estimated using Tier 2 certification fuel, which has a higher octane rating compared to regular octane fuel.[516, 517] This does not maintain functionality because consumers would incur higher costs for using premium fuel in order to achieve the modeled fuel economy improvements, compared to baseline engines that were replaced, which operated on lower cost regular octane fuel. By not maintaining the fuel octane functionality and vehicle attributes, the EPA Draft TAR and Proposed Determination analyses applied higher effectiveness for these technologies than could be achieved had regular octane fuel been assumed for the HCR and downsized turbocharged engines. The Draft TAR and Proposed Determination analyses also did not account for the higher costs that would be incurred by consumers to pay for high octane fuel. These issues were addressed in the NPRM and this final rule analysis, and account for some of the effectiveness and cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.[518]

Another example is mass reduction technology. As background, the agencies characterize mass reduction as either primary mass reduction or secondary mass reduction. Primary mass reduction involves reducing mass of components that can be done independently of the mass of other components. For example, the mass of a hood (e.g., replacing a steel hood with an aluminum hood) or reducing the mass of a seat are examples of primary mass reduction because each can be implemented independently. When there is a significant level of primary mass reduction, other components that are designed based on the mass of primary components, may be redesigned and have lower mass. An example of secondary mass reduction is the brake system. If the mass of primary components is reduced sufficiently, the resulting lighter weight vehicle could maintain braking performance and attributes, and safety with a lighter weight brake system. Mass reduction in the brake system is secondary mass reduction because it requires primary mass reduction before it can be incorporated. For the EPA Draft TAR and Proposed Determination analyses, secondary mass reduction was applied exclusively based on cost, with no regard to whether sufficient primary mass reduction was applied concurrently. The analyses did not account for the degraded functionality of the secondary components and systems and also understated the costs for lower levels of mass reduction.[519] These issues were addressed in the NPRM and this final rule analysis, and account for some of the cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.

The agencies note that for some technologies it is not reasonable or practicable to match exactly the baseline vehicle's attributes, utility, and performance. For example, when engines are resized to maintain acceleration performance, if the agencies applied a criterion that allowed no shift in performance whatsoever, there would be an extreme proliferation of unique engine displacements. Manufacturers have repeatedly and consistently told the agencies that the high costs for redesign and the increased manufacturing complexity that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the

---

[516] Tier 2 fuel has an octane rating of 93. Typical regular grade fuel has an octane rating of 87 ((R+M)/2 octane.
[517] EPA Proposed Determination at 2-209 to 2-212.
[518] For more details, *see* Section VI.C.1 Engine Paths.
[519] For more details, *see* Section VI.C.4 Mass Reduction.

extreme manufacturing complexity that would be required to do so.[520] For the NPRM and final rule analyses, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign to address product complexity and economies of scale considerations. The EPA Draft TAR and Proposed Determination analyses adjusted the effectiveness of every technology combination assuming performance could be held constant for every combination, and the analysis did not recognize or account for the extreme complexity nor the associated costs for that impractical assumption. The NPRM and final rule analyses account for these real-world practicalities and constraints, and doing so explains some of the effectiveness and cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.

The subsections for individual technologies discuss the technology assumptions and constraints that were considered to maintain vehicle attributes, utility, and performance as closely as possible. The agencies believe that any minimal remaining differences, which may directionally either improve or degrade vehicle attributes, utility and performance are small enough to have *de minimis* impact on the analysis.

(6) How The Agencies Considered Performance Neutrality

The CAFE model examines technologies that can improve fuel economy and reduce CO_2 emissions. An improvement in efficiency can be realized by improving the powertrain that propels the vehicle (e.g., replacing a 6-cylinder engine with a smaller, turbocharged 4-cylinder engine), or by reducing the vehicle's loads or burdens (e.g., lowering aerodynamic drag, reducing vehicle mass and/or rolling resistance). Either way, these changes reduce energy consumption and create a range of choices for automobile manufacturers. At the two ends of the range, the manufacturer can choose either:

A) *To design a vehicle that does same the amount of work as before but uses less fuel.*

For example, a redesigned pickup truck would receive a turbocharged V6 engine in place of the outgoing V8. The pickup would offer no additional towing capacity, acceleration, larger wheels and tires, expanded infotainment packages, or customer convenience features, but would achieve a higher fuel economy rating (and correspondingly lower CO_2 emissions).

B) *To design a vehicle that does more work and uses the same amount of fuel as before.*

For example, a redesigned pickup truck would receive a turbocharged V6 engine in place of the outgoing V8, but with engine efficiency improvements that allow the same amount of fuel to do more work. The pickup would offer improved towing capacity, improved acceleration, larger wheels and tires, an expanded (heavier) infotainment

[520] For more details, *see* Section VI.B.3.a)(6) Performance Neutrality.

package, and more convenience features, while maintaining (not improving) the fuel economy rating of the previous year's model.

In other words, automakers weigh the trade-offs between vehicle performance/utility and fuel economy, and they choose a blend of these attributes to balance meeting fuel economy and emissions standards and suiting the demands of their customers.

Historically, vehicle performance has improved over the years. The average horsepower is the highest that it has ever been; all vehicle types have improved horsepower by at least 49 percent compared to the 1975 model year, and pickup trucks have improved by 141 percent.[521] Since 1978, the 0-60 acceleration time of vehicles has improved by 39-47 percent depending on vehicle type.[522] Also, to gain consumer acceptance of downsized turbocharged engines, manufacturers have stated they often offer an *increase* in performance.[523] Fuel economy has also improved, but the horsepower and acceleration trends show that not 100 percent of technological improvements have been applied to fuel savings. While future trends are uncertain, the past trends suggest vehicle performance is unlikely to *decrease*, as it seems reasonable to assume that customers will at a minimum demand vehicles that offer the same utility as today's fleet.

For this rulemaking analysis, consistent with past CAFE and CO_2 rulemakings, the agencies have analyzed technology pathways manufacturers could use for compliance that attempt to maintain vehicle attributes, utility and performance. NHTSA's analysis in the Draft TAR used the same approach for performance neutrality as was used for the NPRM and is being carried into this final rule. This approach is described throughout this section and further in FRIA Section VI. For the Draft TAR and Proposed Determination, the EPA analyses used an approach that maintained 0-60 mph acceleration time for every technology package. However, that approach did not account for the added development, manufacturing, assembly and service parts complexity and associated costs that would be incurred by manufacturers to produce the substantial number of engine variants that would be required to achieve those CO_2 improvements.[524] Using the NPRM approach, which is carried into this final rule, allows the agencies to assess costs and benefits of potential standards under a scenario where consumers continue to get the same vehicle attributes and features, other than changes in fuel economy (approaching the scenario in example "A" above). This approach also eliminates the need to assess the value of changes in vehicle attributes and features. As discussed later in this section, while some small level of performance increase is unavoidable when conducting this type of analysis, the added technology results almost exclusively in improved fuel economy. This allows the cost of these technologies to reflect almost entirely the cost of compliance with standards with nearly neutral vehicle performance.

523 Alliance of Automobile Manufacturers, Attachment "Comment," Docket No. EPA-HQ-OAR-2015-0827-4089, at p. 122.

524 Each variant would require a unique engine displacement, requiring unique internal engine components, such as crankshaft, connecting rods and others.

The CAFE model maintains the initial performance and utility levels of the analysis vehicle fleet, while considering real world constraints faced by manufacturers.

To maintain performance neutrality when applying fuel economy technologies, it is first necessary to characterize the performance levels of each of the nearly 3000 vehicle models in the MY 2017 baseline fleet. As discussed in Section VI.B.1.b) Assigning Vehicle Technology Classes, above, each individual vehicle model in the analysis fleet was assigned to one of ten vehicle "technology classes"— the class that is most similar to the vehicle model. The technology classes include five standard class vehicles (compact car, midsize car, small SUV, midsize SUV, pickup) plus five "performance" versions of these same body styles.[525] Each vehicle class has a unique set of attributes and characteristics, including vehicle performance metrics, that describe the typical characteristics of the vehicles in that class.

The analysis used four criteria to characterize vehicle performance attributes and utility:

- Low-speed acceleration (time required to accelerate from 0-60 mph)
- High-speed acceleration (time required to accelerate from 50-80 mph)
- Gradeability (the ability of the vehicle to maintain constant 65 miles per hour speed on a six percent upgrade)
- Towing capacity

Low-speed and high-speed acceleration target times are typical of current production vehicles and range from 6 to 10 seconds depending on the vehicle class; for example, the midsize SUV performance class has a low- and high-speed acceleration target of 7 seconds.[526] The gradeability criterion requires that the vehicle, given its attributes of weight, engine power, and transmission gearing, be capable of maintaining a minimum of 65 mph while going up a six percent grade. The towing criterion, which is applicable only to the pickup truck and performance pickup truck vehicle technology classes, is the same as the gradeability requirement but adds an additional payload/towing mass (3,000 lbs. for pickups, or 4,350 lbs. for performance pickups) to the vehicle, essentially making the vehicle heavier.

In addition, to maintain the capabilities of certain electrified vehicles in the 2017 baseline fleet, the analysis required that those vehicles be capable of achieving the accelerations and speeds of certain standard driving cycles. The agencies use the US06 "aggressive driving" cycle and the UDDS "city driving" cycle to ensure that core capabilities of BEVs and PHEVs, such as driving certain speeds and/or distances in electric-only mode, are maintained. In addition to the four criteria discussed above, the following performance criteria are applied to these electrified vehicles:

---

[525] Separate technology classes were created for high performance and low performance vehicles to better account for performance diversity across the fleet.

[526] Note, for all vehicle classes, the low and high-speed acceleration targets use the same value. *See* section VI.B.1.b)(1) Assigning Vehicle Technology Classes for a list of low-speed acceleration target by vehicle technology class.

- Battery electric vehicles (BEV) are sized to be capable of completing the US06 "aggressive driving" cycle.
- Plug-in hybrid vehicles with 50 mile all-electric range (PHEV50) are sized to be capable of completing the US06 "aggressive driving" cycle in electric-only mode.
- Plug-in hybrid vehicles with 20 mile all-electric range (PHEV20) are sized to be capable of completing the UDDS "city driving" cycle in electric-only (charge depleting) mode.[527]

Together, these performance criteria are widely used by industry as metrics to quantify vehicle performance attributes that consumers observe and that are important for vehicle utility and customer satisfaction.[528]

When certain fuel-saving technologies are applied that affect vehicle performance to a significant extent, such as replacing a pickup truck's V8 engine with a turbocharged V6 engine, iterative resizing of the vehicle powertrain (engine, electric motors, and/or battery) is performed in the Autonomie simulation such that the above performance criteria is maintained. For example, if the aforementioned engine replacement caused an improvement in acceleration, the engine may be iteratively resized until vehicle acceleration performance is shifted back to the initial target time for that vehicle technology class. For the low and high-speed acceleration criteria, engine resizing iterations continued until the acceleration time was within plus or minus 0.2 seconds of the target time,[529, 530] which is judged to balance reasonably the precision of engine resizing with the number of simulation iterations needed to achieve performance within the 0.2 second window, and the associated computer resources and time required to perform the iterative simulations. Engine resizing is explained further in Section VI.B.3.a)(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation and the Argonne Model Documentation for the final rule analysis.

The Autonomie simulation resizes until the least capable of the performance criteria is met, to ensure the pathways do not degrade any of the vehicle performance metrics. It is possible that as one criterion target is reached after the application of a specific technology or

---

[527] PHEV20's are blended-type plug-in hybrid vehicles, which are capable of completing the UDDS cycle in charge depleting mode without assistance from the engine. However, under higher loads, this charge depleting mode may use supplemental power from the engine.
[528] Conlon, B., Blohm, T., Harpster, M., Holmes, A. et al., "The Next Generation "Voltec" Extended Range EV Propulsion System," SAE Int. J. Alt. Power. 4(2):2015, doi:10.4271/2015-01-1152. Kapadia, J., Kok, D., Jennings, M., Kuang, M., et al., "Powersplit or Parallel - Selecting the Right Hybrid Architecture," SAE Int. J. Alt. Power. 6(1):2017, doi:10.4271/2017-01-1154. Islam, E., A. Moawad, N. Kim, and A. Rousseau, 2018a, An Extensive Study on Vehicle Sizing, Energy Consumption and Cost of Advance Vehicle Technologies, Report No. ANL/ESD-17/17, Argonne National Laboratory, Lemont, Ill., Oct 2018.
[529] For example, if a vehicle has a target 0-60 acceleration time of 6 seconds, a time within 5.8-6.2 seconds was accepted.
[530] With the exception of a few performance electrified vehicle types which, based on observations in the marketplace, use different criteria to maintain vehicle performance without battery assist. Performance PHEV20, and Performance PHEV50 resize to the performance of a conventional six-speed automatic (CONV 6AU). Performance SHEVP2, engines/electric-motors were resized if the 0-60 acceleration time was worse than the target, but not resized if the acceleration time was better than the target time.

technology package, other criteria may be better than their target values. For example, if the engine size is decreased until the low speed acceleration target is just met, it is possible that the resulting engine size would cause high speed acceleration performance to be better than its target.[531] Or, a PHEV50 may have an electric motor and battery appropriately sized to operate in all electric mode through the repeated accelerations and high speeds in the US06 driving cycle, but the resulting motor and battery size enables the PHEV50 slightly to over-perform in 0-60 acceleration, which utilizes the power of both the electric motor and combustion engine.

To address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.[532] Manufacturers have repeatedly and consistently told the agencies that the high costs for redesign and the increased manufacturing complexity that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. Engine displacements are further described in Section VI.C.1 Engine Paths.

To address this issue, and consistent with past rulemakings, the NPRM simulation allowed engine resizing when mass reductions of 7.1 percent, 10.7 percent, 14.2 percent (and 20 percent for the final rule analysis) were applied to the vehicle curb weight,[533] and when one powertrain architecture was replaced with another architecture during a redesign cycle.[534] At its refresh cycle, a vehicle may also inherit an already resized powertrain from another vehicle within the same engine-sharing platform. The analysis did not re-size the engine in response to adding technologies that have smaller effects on vehicle performance. For instance, if a vehicle's curb weight is reduced by 3.6 percent (MR1), causing the 0-60 mile per hour time to improve slightly, the analysis would not resize the engine. The criteria for resizing used for the analysis better reflects what is feasible for manufacturers to do.[535]

Automotive manufacturers have commented that the CAFE model's consideration of the constraints faced in relation to vehicle performance and economies of scale are realistic.

---

[531] The Autonomie simulation databases include all of the estimated performance metrics for each combination of technology as modeled.
[532] *See* 83 FR 43027 (Aug. 24, 2018).
[533] These correspond, respectively, to reductions of 10%, 15%, 20%, and 28.2% of the vehicle glider mass. For more detail on glider mass calculation, *see* section VI.C.4 Mass Reduction.
[534] Some engine and accessory technologies may be added to an engine without an engine architecture change. For instance, manufacturers may adapt, but not replace engine architectures to include cylinder deactivation, variable valve lift, belt-integrated starter generators, and other basic technologies. However, switching from a naturally aspirated engine to a turbo-downsized engine is an engine architecture change typically associated with a major redesign and radical change in engine displacement.
[535] For instance, a vehicle would not get a modestly bigger engine if the vehicle comes with floor mats, nor would the vehicle get a modestly smaller engine without floor mats. This example demonstrates small levels of mass reduction. If manufacturers resized engines for small changes, manufacturers would have dramatically more part complexity, potentially losing economies of scale.

Industry associations and individual manufacturers widely supported the use of the performance metrics used in the NPRM analysis, the use of standard and higher performance technology classes, and the representation in the analysis of the real-world manufacturing complexity constraints and criteria for powertrain redesign.

The Alliance of Automobile Manufacturers (Alliance), Ford, and Toyota stated that the inclusion of additional performance metrics such as gradeability are appropriate. Specifically in support of the gradeability performance criteria, the Alliance commented that "performance metrics related to vehicle operation in top gear are just as critical to customer acceptance as are performance metrics such as 0-60 mph times that focus on performance in low-gear ranges."[536] The Alliance also commented specifically on the relationship between gradeability and downsized engines, stating that as "engine downsizing levels increase, top-gear gradeability becomes more and more important," and further that the consideration of gradeability "helps prevent the inclusion of small displacement engines that are not commercially viable and that would artificially inflate fuel savings."[537]

Ford and Toyota similarly commented in support of the CAFE model's consideration of multiple performance criteria. Ford stated that this model "takes a more realistic approach to performance modeling" and "better replicates OEM attribute-balancing practices." Ford stated furthermore that "OEMs must ensure that each individual performance measure—and not an overall average—meets its customer's requirements," and that, in contrast, previous analyses did "not align with product planning realities."[538] Toyota commented in support of including gradeability as a performance metric "to avoid underpowered engines and overestimated fuel savings."[539]

Toyota and the Alliance commented that the inclusion of performance vehicle classes addressed the market reality that some consumers will purchase vehicles for their performance attributes and will accept the corresponding reduction in fuel economy. Furthermore, Toyota commented that most consumers consider more than just fuel economy when purchasing a vehicle, and that "dedicating all powertrain improvements to fuel efficiency is inconsistent with market reality." Toyota "supports the agencies' inclusion of performance classes in compliance modeling where a subset of certain models is defined to have higher performance and a commensurate reduction in fuel efficiency."[540] Also in support of the addition of performance vehicle classes, the Alliance commented that "vehicle categories have been increased to 10 to better recognize the range of 0–60 performance characteristics within each of the 5 previous categories, in recognition of the fact that many vehicles in the baseline fleet significantly

---

[537] Alliance of Automobile Manufacturers, Attachment "Full Comment Set," Docket No. NHTSA-2018-0067-12073, at 135.
[538] Ford, Attachment 1, Docket No. NHTSA-2018-0067-11928, at 8.
[539] Toyota, Attachment 1, Docket No. NHTSA-2018-0067-12098, at 6.
[540] Toyota, Attachment 1, Docket No. NHTSA-2018-0067-12098, at 6.

exceeded the previously assumed 0–60 performance metrics. This provides better resolution of the baseline fleet and more accurate estimates of the benefits of technology."[541]

Toyota also commented in support of various real-world manufacturing complexity constraints employed in the analysis for powertrain redesigns. Toyota commented that model parameters such as redesign cycles and engine sharing across vehicle models place a more realistic limit on the number of engines and transmissions that a manufacturer is capable of introducing. Toyota also commented in support of the constraints that the CAFE model placed on engine resizing, stating that "there are now more realistic limits placed on the number of engines and transmissions in a powertrain portfolio which better recognizes [how] manufacturers must manage limited engineering resources and control supplier, production, and service costs. Technology sharing and inheritance between vehicle models tends to limit the rate of improvement in a manufacturer's fleet." Toyota pointed out that this is in contrast to previous analyses in which resizing was too unconstrained, which created an "unmanageable number of engine configurations within a vehicle platform" and spawned cases where "engine downsizing and power reduction sometimes exceeded limits beyond basic acceleration requirements needed for vehicle safety and customer satisfaction."[542]

The above comments from the Alliance, Ford, and Toyota support the methodologies the agencies employed to conduct a performance neutral analysis. These methodologies helped to ensure that multiple performance criteria, including gradeability, are all individually accounted for and maintained when a vehicle powertrain is resized, and that real-world manufacturing complexity constraints are factored in to the agencies' analysis of feasible pathways manufacturers could take to achieve compliance with CAFE standards. The agencies continue to believe this is a reasonable approach for the aforementioned reasons.

Environmental advocacy groups and CARB criticized the CAFE model's engine resizing constraints and how they affected the acceleration performance criteria.

CARB, The International Council on Clean Transportation (ICCT), the Union of Concerned Scientists (UCS), and the American Council for an Energy-Efficient Economy (ACEEE) commented that the CAFE model was not performance neutral, allowing an improvement in performance which reduced the effectiveness of applied fuel-saving technologies and/or increased the cost of compliance. Specifically, ACEEE stated that there appeared to be a shortfall in the fuel economy effectiveness of technology packages, potentially resulting from the effectiveness being "consumed" by additional vehicle performance rather than improvement of fuel economy. Several of these same commenters conducted analyses attempting to quantify the magnitude of these changes in vehicle performance for various vehicle technology classes.

[542] Toyota, Attachment 1, Docket No. NHTSA-2018-0067-12098, at 6.

CARB commented on the performance shift of several vehicle types. Analyzing the 0-60 acceleration for the medium car non-performance technology class and looking at all cases with resized engines, CARB claimed that "effectively half of the simulations resulted in improved performance."[543] Focusing on electrified vehicles in that same technology class, CARB stated that "the data from the Argonne simulations shows that 76 of the 88 strong electrified packages (including P2HPV, SHEVPS, BEV, FCEV, PHEV), where Argonne purposely resized the system to maintain performance neutrality, resulted in notably faster 0 to 60 mph acceleration times and passing times." Specifically regarding parallel hybrid electric vehicles (SHEVP2), CARB stated that all modeled packages resulted in improved performance.[544] UCS commented that the NPRM analysis allowed too much change in vehicle performance, stating that "while some performance creep may be reasonable" many performance values show "an overlap between performance and non-performance vehicles" within the compact car technology class.[545]

The agencies carefully considered these comments. For the NPRM analysis, the SHEVP2 engines/electric-motors were resized if the 0-60 acceleration time was worse than the target, but not resized if the acceleration time was better than the target. This approach maintained vehicle performance with a depleted battery (without electric assist) in order to maintain fully the performance and utility characteristics under all conditions, and improved performance when electric assist was available (when the battery is not depleted), such as during the 0-60 mph acceleration. The agencies found that this resulted in some parallel hybrid vehicles having improved 0-60 acceleration times. This approach was initially chosen for the NPRM because the resulting level of improved performance was consistent with observations of how industry had applied SHEVP2 technology. However, in assessing the CARB comment, the agencies balanced the NPRM approach for SHEVP2 performance with the agencies' criteria of maintaining vehicle functionality and performance when technology is applied. Both could not be fully achieved under all conditions for the case of the SHEVP2.

The agencies concluded it is reasonable to maintain performance including electric assist when SHEVP2 technology is applied to a standard (non-performance) vehicle, and therefore the analysis for the final rule allows upsizing *and* downsizing of the parallel hybrid powertrain (SHEVP2) using the 0.2 seconds window around the target.[546] For performance vehicles, the agencies concluded that it remains reasonable to maintain vehicle performance with a depleted battery (without electric assist) in order to maintain fully the performance characteristics under all conditions, and continued to use the NPRM methodology.

---

543 California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 180. Note that the target acceleration time for medium car non-performance is in fact 9.0 seconds, as indicated in ANL documentation, but was incorrectly reported as 9.4s in NPRM table II-7 in the NPRM.
544 California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 186.
545 Union of Concerned Scientists, Attachment 2, Docket No. NHTSA-2018-0067- 12039, at 24.
546 To represent marketplace trends better, the performance class of SHEVP2's allow acceleration time below 0.2 seconds less than the target, and PHEV20's and PHEV50's inherit combustion engine size from the conventional powertrain they are replacing. Further discussion of resizing targets can be found in Chapter 8 of the ANL Model Documentation for the final rule analysis.

The refinement for the standard performance SHEVP2 resolved the electrified packages issue identified by CARB, and also addressed most of the change in performance in the overall fleet, including with compact cars as mentioned by UCS. As explained further below, the agencies assessed performance among the alternatives for the final rule analysis. That assessment showed that, with the final rule refinements, 245 out of 255 total resized vehicles (96 percent of vehicles) in the medium non-performance class (same class focused on by CARB), had 0-60 mph acceleration times within the plus-or-minus 0.2 second window (8.8 to 9.2 seconds).[547] The only vehicles outside the window were certain strong electrified vehicles which exceeded 0-60 the acceleration target as a result of achieving other performance criteria, such as the US06 driving cycles in all-electric-mode.[548]

The assessment also showed that for the small car class (mentioned by UCS) the acceleration times of performance and non-performance vehicles do not go beyond each other's targets. For example, the vehicle in the small car class with the very best 0-60 mph time and a conventional powertrain achieves an 8.38 second 0-60 mph time, which is slower than the performance small car baseline of 8 seconds. This vehicle had multiple incremental technologies applied, including for example aerodynamic improvements, and has not reached the threshold for engine resizing.[549] After engine resizing, the "fastest" conventional small car has a 0-60 mph time of 9.9 seconds, only 0.1 seconds from the target of 10 seconds.[550]

CARB also commented on the improvement of "passing times," or 50-80 mph high-speed acceleration times. As stated above, an improvement in one or more of the performance criteria is an expected outcome when using the rulemaking analysis methodology that resizes powertrains such that there is no degradation in any of the performance metrics. Consistent with past rulemakings, the agencies do not believe it is appropriate for the rulemaking analysis to show pathways that degrade vehicle performance or utility for one or more of the performance criteria, as doing so would adversely impact functional capability of the vehicle and could lead to customer dissatisfaction. The agencies agree there is very small increase in passing performance for some technology combinations, and believe this is an appropriate outcome. High-speed acceleration is rarely the least-capable performance criteria.

CARB, ICCT, UCS, and H-D Systems (HDS), in an attempt to identify a potential cause for changes in performance, commented that the CAFE model should have placed fewer constraints on engine resizing. CARB and ICCT commented that engine resizing should have been allowed even at low levels of mass reduction. Comments from CARB, UCS, HDS, and ICCT stated that engine resizing should also have been allowed for other incremental technologies, and within their comments they conducted performance analysis of non-resized cases.

---

[547] This includes 135 strong electrified vehicles.
[548] As noted earlier, electrified vehicles had to be capable of successfully completing UDDS or US06 driving cycles in all-electric mode, and in some cases the resulting motor size produced improved acceleration times.
[549] Discussion of engine resizing can be found in Section VI.B.3.a)(5).
[550] *See* NPRM Autonomie simulation database for Small cars, Docket ID NHTSA-2018-0067-1855.

CARB claimed that requiring a minimum of 7.1 percent curb weight reduction before engine resizing is a constraint that "limits the optimization of the technologies being applied."[551] UCS stated that "a significant share of the benefit of a few percent reduction in mass has gone towards improved performance rather than improved fuel economy, leaving a substantial benefit of mass reduction underutilized and/or uncounted."[552] ICCT also commented that "when vehicle lightweighting is deployed at up to a 7 percent mass reduction, the engine is not resized even though less power would be needed for the lighter vehicle, meaning any such vehicles inherently are higher performance."[553]

UCS and HDS commented on the lack of resizing for technologies other than mass reduction, with HDS stating that "the Agencies incorrectly limited the efficacy of technologies that reduce tractive load because their modeling does not re-optimize engine performance after applying these technologies."[554] CARB also commented that the lack of resizing when a BISG or CISG system is added "results in a less than optimized system that does not take full advantage of the mild hybrid system." Similarly, ICCT noted a case in which a Dodge RAM "did not apply engine downsizing with the BISG system on that truck, so there are also significant performance benefits that should be accounted for, meaning that for constant-performance the fuel consumption reduction would be even greater."[555]

CARB further commented on the performance improvement in cases without engine resizing by stating that "94 percent of the packages modeled result in improved performance," and that for these non-resized cases that were actually adopted by a vehicle in the simulation, "fewer than 20 percent maintained baseline performance with gains of 2 percent or less in acceleration time."[556] Referring specifically to non-resized electrified vehicles, CARB also stated that "44,878 of the 53,818 packages, or greater than 83 percent, result in improved performance."[557] CARB also commented that engine sharing across different vehicles within a platform, which in some cases may constrain resizing for a member of that platform, should not dictate that these engines must remain identical in all aspects, and that "this overly restrictive sharing of identical engines newly imposed in the CAFE Model is not consistent with today's industry practices and results in less optimal engine sizing and causes a systematic overestimation of technology costs to meet the existing standards."[558]

The agencies note broadly, in response to these comments, that when conducting an analysis which balances performance neutrality against the realities faced by manufacturers, such

---

[558] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 185.

as manufacturing complexity, economies of scale, and maintaining the full range of performance criteria, it is inevitable to observe at least some minor shift in vehicle performance. For example, if a new transmission is applied to a vehicle, the greater number of gear ratios helps the engine run in its most efficient range which improves fuel economy, but also helps the engine to run in the optimal "power band" which improves performance. Thus, the technology can provide both improved fuel economy and performance. Another example is applying a small amount of mass reduction that improves both fuel economy and performance by a small amount. Resizing the engine to maintain performance in these examples would require a unique engine displacement that is only slightly different than the baseline engine. While engine resizing in these incremental cases could have some small benefit to fuel economy, the gains may not justify the costs of producing unique niche engines for each combination of technologies. If manufacturers were to produce marginally downsized engines to complement every small increment of mass reduction or technology, the resulting large number of engine variants that would need to be manufactured would cause a substantial increase in manufacturing complexity, and require significant changes to manufacturing and assembly plants and equipment.[559] The high costs would be economically infeasible.

Also, as noted in the NPRM, the 2015 NAS report stated that "[f]or small (under 5 percent [of curb weight]) changes in mass, resizing the engine may not be justified, but as the reduction in mass increases (greater than 10 percent [of curb weight]), it becomes more important for certain vehicles to resize the engine and seek secondary mass reduction opportunities."[560] In consideration of both the NAS report and comments received from manufacturers, the agencies determined it would be reasonable to allow allows engine resizing upon adoption of 7.1 percent, 10.7 percent, 14.2 percent, and 20 percent curb weight reduction, but not at 3.6 percent and 5.3 percent.[561] Resizing is also allowed upon changes in powertrain type or the inheritance of a powertrain from another vehicle in the same platform. The increments of these higher levels of mass reduction, or complete powertrain changes, more appropriately match the typical engine displacement increments that are available in a manufacturer's engine portfolio.

The agencies point to the comments from manufacturers, discussed further above, which support the agencies' assertion that the CAFE model's resizing constraints are appropriate. As discussed previously, Toyota commented that this approach better considers the constraints of engineering resources and manufacturing costs and results in a more realistic number of engines and transmissions.[562] The Alliance also commented on the benefit of constraining engine

---

[559] For example, each unique engine would require unique internal components such as crankshafts, pistons, and connecting rods, as well as unique engine calibrations for each displacement. Assembly plants would need to stock and feed additional unique engines to the stations where engines are dressed and inserted into vehicles.
[560] National Research Council. 2011. Assessment of Fuel Economy Technologies for Light-Duty Vehicles. Washington, DC – The National Academies Press. *http://nap.edu/12924*.
[561] These curb weight reductions equate to the following levels of mass reduction as defined in the analysis: MR3, MR4, MR5 and MR6, but not MR1 and MR2; additional discussion of engine resizing for mass reduction can be found in Section VI.B.3.a)(6) Autonomie Sizes Powertrains for Full Vehicle Simulation.
[562] Toyota, Attachment 1, Docket No. NHTSA-2018-0067-12098, at 6.

resizing, stating that "the platform and engine sharing methodology in the model better replicates reality by making available to each manufacturer only a finite number of engine displacements, helping to prevent unrealistically 'over-optimized' engine sizing."[563]

Another comment from CARB stated that engine resizing "was only simulated for cases where those levels of mass reduction were applied, *in the absence of virtually all other technology or efficiency improvements*."[564] The agencies do not agree that resizing should be simulated in all cases which involve small incremental technologies. In the final rule analysis, vehicles can have engines resized at four (out of six) levels of mass reduction technology, during a vehicle redesign cycle which changes powertrain architecture, and by inheritance during a vehicle refresh cycle. As discussed previously, the application of small incremental technologies such as reductions in aerodynamic drag or rolling resistance does not justify the high cost and complexity of producing additional varieties of engine sizes. Accordingly, for each curb weight reduction level of 7.1 percent or above and for each vehicle technology class, Autonomie sized a baseline engine by running a simulation of a vehicle without incremental technologies applied; then, those baseline engines were inherited by all other simulations using the same levels of curb weight reduction, which also added any variety of incremental technologies.[565] For further clarification, in any case in which a vehicle adopts a 7.1 percent or more curb weight reduction, no matter what other technologies were already present or are added to the vehicle in conjunction with the mass reduction, that vehicle will receive an engine which has been appropriately sized for the newly applied mass reduction level.[566] This can be observed in the Autonomie simulation databases by tracking the "EngineMaxPower" column (not the "VehicleSized" column).

Finally, ICCT claimed that the agencies did not sufficiently report performance-related vehicle information. ICCT commented that the output files did not show data on "engine displacement, the maximum power of each engine, the maximum torque of each engine, the initial and final curb weight of each vehicle (in absolute terms), and estimated 0-60 mph acceleration." ICCT claimed that because this data was not found, the agencies are "showing that they have not even attempted to analyze accurately the future year fleet for their performance" and that "the agencies are intentionally burying a critical assumption, whereby their future fleet has not been appropriately downsized, and it therefore has greatly increased utility and performance characteristics."[567]

[563] Alliance of Automobile Manufacturers, Attachment "Full Comment Set," Docket No. NHTSA-2018-0067-12073, at 140.
[564] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 178.
[565] In the Autonomie simulation database files, the simulations which establish baseline sized engines are marked "yes" in the "VehicleSized" column, and the subsequent simulations which use this engine and add other incremental technologies are marked "inherited." For a list of Autonomie simulation database files, *see* Table VI-5 Autonomie Simulation Database Output Files in Section VI.A.7 Structure of Model Inputs and Outputs.
[566] For example, if a vehicle possesses MR2, AERO1, and ROLL1 and subsequently adopts MR3, AERO1, ROLL2, the vehicle will adopt the lower engine power level associated with MR3. As a counter example, if a vehicle possesses MR3, ROLL1, and AERO1 and subsequently adopts MR3, ROLL1, AERO2, the engine will not be resized and it will retain the power level associated with MR3.
[567] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-74.

In fact, for the NPRM, and again for this final rule, the agencies did analyze vehicle performance and have made the data available to the public. An indication of the actual engine displacement change is available by noting the displacements used in Autonomie simulation database for each of the technology states. The displacements reported in Autonomie are used by the full-vehicle-simulation within the Autonomie model, and while they do not directly represent each specific vehicle's actual engine sizes, they do fully reflect the relative change in engine size that is applied to each vehicle. It is the relative change in engine size that is relevant for the analysis. Similarly, the vehicle power and torque used by the full vehicle simulations are reported in the Autonomie simulation databases; their values and relative change across an engine resizing event can be observed. Initial and final curb weights for the analysis fleet are reported in Vehicles Report output file column titled "CW Initial" and "CW," respectively. The time required for 0-60mph acceleration is reported in the Autonomie simulation database files. A detailed description of the engine resizing methodology is available in the Argonne Model Documentation, which explains how vehicle characteristics are used to calculate powertrain size.[568] These data and information that are available in the Autonomie and CAFE model documentation provide the information needed to analyze performance, and in fact, this is evidenced by the statements of numerous commenters discussed in this section. The agencies have conducted their own performance analysis, which is discussed further below, using the same data documentation mentioned here.

Updates to the CAFE model have minimized performance shift over the simulated model years, and have eliminated performance differences between simulated standards.

The Autonomie simulation updates, discussed previously, were included in the final rule analysis, and have resulted in average performance that is similar across the regulatory alternatives. Because the regulatory analysis compares differences in impacts among the alternatives, the agencies believe that having consistent performance across the alternatives is an important aspect of performance neutrality. If the vehicle fleet had performance gains which varied significantly depending on the alternative, performance differences would impact the comparability of the simulations.

Using the NPRM CAFE model data, the agencies analyzed the sales-weighted average 0-60 mph acceleration performance of the entire simulated vehicle fleet for MYs 2016 and 2029. The analysis compared performance under the Augural standards to the performance under the NPRM Preferred Alternative, which reflects no change in standards in MYs 2021-2026. Two inputs were required for this performance analysis. The first was the CAFE model's NPRM Vehicles Report, which lists the MY 2016 sales volumes and the resulting "tech key" for every vehicle in the analysis fleet for every simulated model year. The tech key is a string of characters which summarizes the fuel consumption reducing technologies applied to that vehicle, as deemed necessary by the CAFE model simulations of different proposed standards. The second input was the full set of NPRM Autonomie Simulation Databases, which includes the 0-60 and 50-80 mph acceleration times related to every tech key. Using a spreadsheet program, each vehicle in the NPRM Vehicles Report was matched, via tech key, with the appropriate

[568] *See* Chapter 8 of the ANL Model documentation for the final rule analysis.

acceleration time in the NPRM Autonomie Simulation Databases. This process effectively assigned a 0-60 mph time to every vehicle in the fleet for four scenarios: 1) MY 2016 under augural standards, 2) MY 2016 under the preferred alternative, 3) MY 2029 under augural standards, and 4) MY 2029 under the preferred alternative. Using the MY 2016 sales volumes as weights, the weighted average 0-60 mph acceleration time was calculated for the analysis fleet in each of the four above scenarios. This analysis identified that the analysis fleet under Augural standards in MY 2029 had a 4.7 percent better 0-60 mph acceleration time than under the NPRM preferred alternative, confirming the observations of the various commenters. The same performance analysis was later repeated to observe the effects of refinements incorporated into the final rule analysis. Using the same methodology, the final rule performance analysis used the FRM Vehicles Report and the FRM Autonomie Simulation Databases. With the refinements that were incorporated for the final rule, this updated performance analysis showed that the Augural standards had a negligible 0.1 percent difference in 0-60 mph acceleration time compared to the NPRM preferred alternative. Figure VI-7 shows the results of the updated performance analysis, including final rule refinements, comparing 0-60 mph acceleration time under Augural and NPRM Preferred Alternative. As indicated by the position of the open circle data point labeled "2029 Avg (Sales-Weighted) 0-60 Time, Entire Fleet", the resulting 0-60 acceleration time is around 7.6 seconds for both of the two standards being compared.

The updates applied to the final rule Autonomie simulations also resulted in further minimizing the performance change across model years. As the agencies attempted to minimize this performance shift occurring "over time," it was also acknowledged that a small increase would be expected and would be reasonable. This increase is attributed to the analysis recognizing the practical constraints on the number of unique engine displacements manufacturers can implement, and therefore not resizing powertrains for every individual technology and every combination of technologies when the performance impacts are small. Perfectly equal performance with 0 percent change would not be achievable while accounting for these real world resizing constraints. The performance analysis in the 2011 NAS report shared a similar view on performance changes, stating that "truly equal performance involves nearly equal values… within 5 percent."[569] In response to comments, using NPRM CAFE model data, the agencies analyzed the sales-weighted average 0-60 performance of the entire simulated vehicle fleet, and identified that the performance increase from MYs 2016 and 2029 was 7.5 percent under Augural Standards and 3.1 percent under the NPRM preferred alternative standards. The agencies conducted a similar analysis using final rule data and found the performance increase over time from MYs 2017 to 2029 was 3.9 percent for Augural Standards and 4.0 percent for the NPRM preferred alternative standards. The agencies determined this change in performance is reasonable and note it is within the 5 percent bound in discussed by NAS in its 2011 report.

Figure VI-7 shows the results of the performance analysis using final rule data, comparing 0-60 mph acceleration time under Augural and the 0%/yr NPRM Preferred Alternative. The two open circles represent the 2017 and 2029 sales-volume-weighted average

---

[569] National Research Council. 2011. Assessment of Fuel Economy Technologies for Light-Duty Vehicles. Washington, DC – The National Academies Press, at 62. *http://nap.edu/12924*.

0-60 time for the entire analysis fleet. The filled circles represent individual vehicles' 0-60 times, and the relative sizes of those circles are proportional to the vehicles' sales volume.

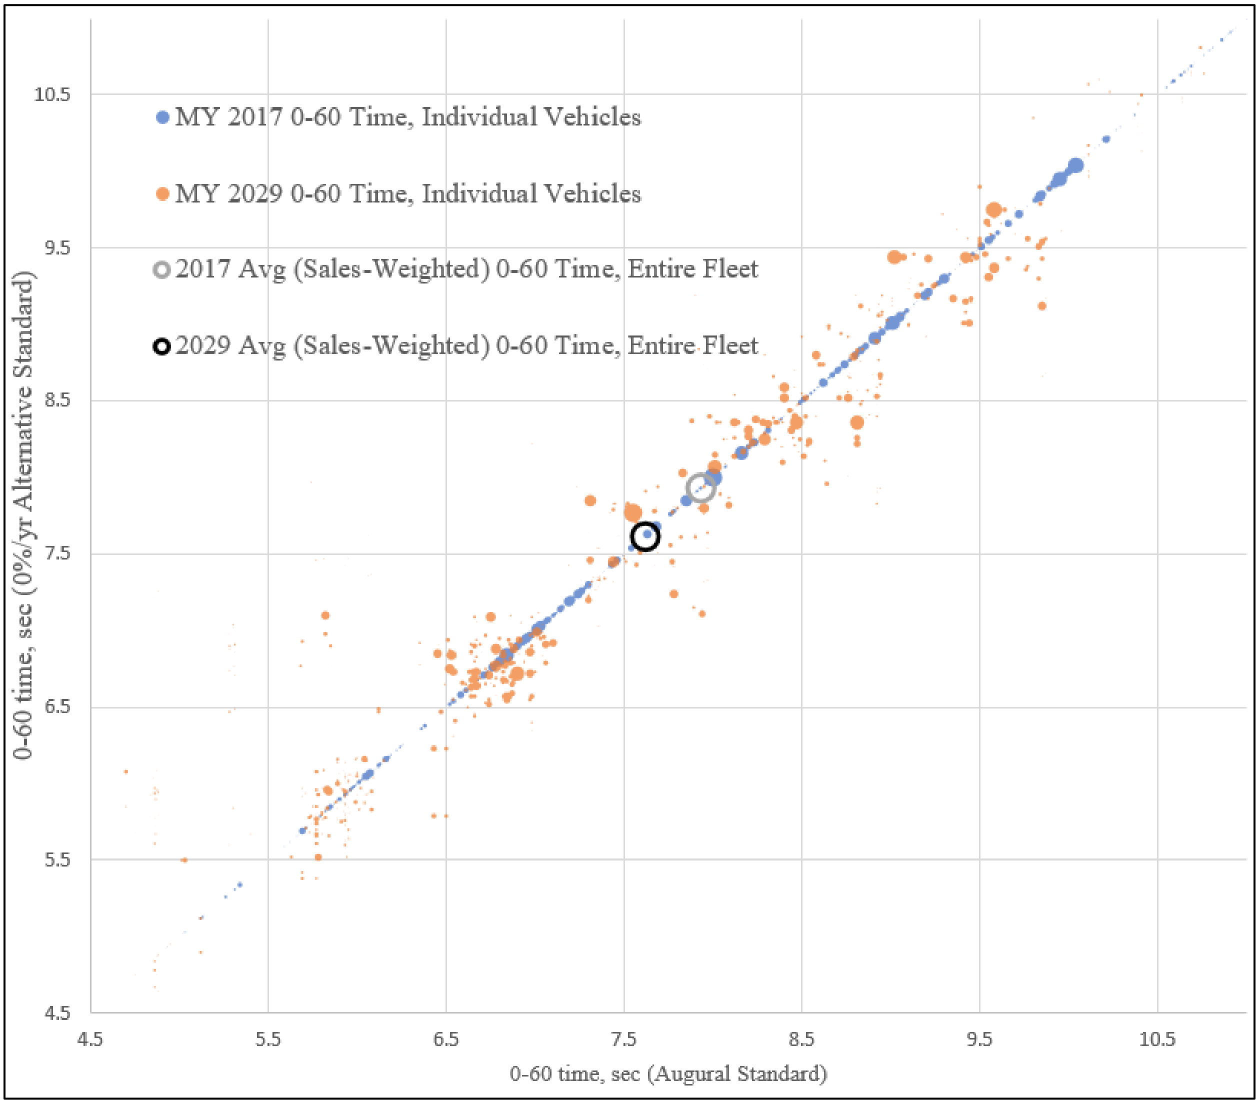

Figure VI-7 – 0-60 mph Acceleration Times for Final Rule Analysis Fleet, 0%/yr NPRM Preferred Alternative Standard and Augural Standard

This assessment shows that for the final rule analysis, performance is neutral across regulatory alternatives and across the simulated model years allowing for fair, direct comparison among the alternatives.

(7) How The Agencies Simulated Vehicle Models on Test Cycles

After vehicle models are built for every combination of technologies and vehicle classes represented in the analysis, Autonomie simulates their performance on test cycles to calculate the effectiveness improvement of the fuel-economy-improving technologies that have been added to the vehicle. Discussed earlier, the agencies minimize the impact of potential variation in determining effectiveness by using a series of tests and procedures specified by federal law and regulations under controlled conditions.

Autonomie simulates vehicles in a very similar process as the test procedures and energy consumption calculations that manufacturers must use for CAFE and CO_2 compliance.[570,571,572] Argonne simulated each vehicle model on several test procedures to evaluate effectiveness. For vehicles with conventional powertrains and micro hybrids, Autonomie simulates the vehicles on EPA 2-cycle test procedures and guidelines.[573] For mild and full hybrid electric vehicles and FCVs, Autonomie simulates the vehicles using the same EPA 2-cycle test procedure and guidelines, and the drive cycles are repeated until the initial and final state of charge are within a SAE J1711 tolerance. For PHEVs, Autonomie simulates vehicles in similar procedures and guidelines as SAE J1711.[574] For BEVs Autonomie simulates vehicles in similar procedures and guidelines as SAE J1634.[575]

b)   Selection of One Full-vehicle Modeling and Simulation Tool

The NPRM described tools that the agencies previously used to estimate technology effectiveness. For the analysis supporting the 2012 final rule for MYs 2017 and beyond, the agencies used technology effectiveness estimates from EPA's lumped parameter model (LPM). The LPM was calibrated using data from vehicle simulation work performed by Ricardo Engineering.[576] The agencies also used full vehicle simulation modeling data from Autonomie vehicle simulations performed by Argonne for mild hybrid and advanced transmission effectiveness estimates.[577,578]

For the 2016 Draft TAR analysis, EPA and NHTSA used two different full system simulation programs for complementary but separate analyses. NHTSA used Argonne's Autonomie tool, described in detail above, with engine map inputs developed by IAV using GT-

Power in 2014, and updated in 2016.[579,580,581] Argonne, in coordination with NHTSA, developed a methodology for large scale simulation using Autonomie and distributed computing, thus overcoming one of the challenges to full vehicle simulation that the NAS committee outlined in its 2015 report and implementing a recommendation that the agencies use full-vehicle simulation to improve the analysis method of estimating technology effectiveness.[582] EPA used a limited number of full-vehicle simulations performed using its ALPHA model, an EPA-developed full-vehicle simulation model,[583] to calibrate the LPM, used to estimate technology effectiveness. EPA also used the same modeling approach for its Proposed Determination analysis.[584]

In the subsequent August 2017 Request for Comment on Reconsideration of the Final Determination of the Mid-Term Evaluation of Greenhouse Gas Emissions Standards for MY 2022-2025 Light-Duty Vehicles, the agencies requested comments on whether EPA should use alternative methodologies and modeling, including the Autonomie full-vehicle simulation tool and DOT's CAFE model, for the analysis that would accompany its revised Final Determination.[585] As discussed in the NPRM, stakeholders questioned the efficacy of the combined outputs and assumptions of the LPM and ALPHA,[586] especially as the tools were used to evaluate increasingly heterogeneous combinations of technologies in the vehicle fleet.[587]

More specifically, the Auto Alliance noted that their previous comments to the midterm evaluation, in addition to comments from individual manufacturers, highlighted multiple

586 83 FR 43022 ("At NHTSA-2016-0068-0082, p. 49, FCA provided the following comments, "FCA believes EPA is overestimating the benefits of technology. As the LPM is calibrated to those projections, so too is the LPM too optimistic." FCA also shared the chart, 'LPM vs. Actual for 8 Speed Transmissions.'").
587 83 FR 43022 (referencing Automotive News "CAFE math gets trickier as industry innovates" (Kulisch), March 26, 2018.).

concerns with EPA's ALPHA model that were unresolved, but addressed in Autonomie.[588] First, the Alliance expressed concern over ALPHA modeling errors related to road load reductions, stating that an error derived from how mass and coast-down coefficients were updated when mass, tire and aero improvements were made resulted in benefits overstated by 3 percent to 11 percent for all vehicle types. Next, the Alliance repeated its concern that EPA should consider top-gear gradeability as one of its performance metrics to maintain functionality, noting that EPA had acknowledged the industry's comments in the Proposed Determination, "but generally dismissed the auto industry concerns." Additional analysis by EPA in its Response to Comments document did not allay the Alliance's concerns,[589] as the Alliance concluded that "[c]onsistent with the National Academy of Sciences recommendation from 2011, EPA should monitor gradeability to ensure minimum performance."

Furthermore, the Alliance stated that ALPHA vehicle technology walks provided in response to manufacturer comments on the Proposed Determination did not correctly predict cumulative effectiveness when compared to technologies in real world applications. The Alliance stated that many of the individual technologies and assumptions used by ALPHA overestimated technology effectiveness and were derived from questionable sources. As an example, the Alliance referenced an engine map used by EPA to represent the Honda L15B7 engine, where the engine map data was collected by "(1) taking a picture of an SAE document containing an image of the engine map, and then (2) 'digitizing' the image by 'tracing image contours'" (citing EPA's ALPHA documentation). The Alliance could not definitively state whether the "digitization" process, lack of detail in the source image, or another factor were the reasons that some regions of overestimated efficiency were observed in the engine map, but concluded that "the use of this map should be discontinued within ALPHA," and "any analysis conducted with it is highly questionable." Based on these concerns and others, the Alliance recommended that Autonomie be used to inform the downstream cost optimization models (i.e., the CAFE model and/or OMEGA).

Global Automakers argued that NHTSA's CAFE model, which incorporates data from Autonomie simulations, provided a more transparent and discrete step through each of the modeling scenarios.[590] Global pointed out that the LPM is "of particular concern due to its simplified technology projection processes," and it "propagates fundamentally flawed content into the ALPHA and OMEGA models and therefore cannot accurately assess the efficacy of fuel economy technologies." Global did note that EPA "plans to abandon its reliance on LPM in favor of another modeling approach," referring to the RSE,[591] but stated that "EPA must provide

[589] The Alliance noted that in higher-gear-count transmissions, like 8-speed automatics, modeled by ALPHA with an expanded ratio spread to achieve fuel economy, are concerning for gradeability. Additionally, infinite engine downsizing along with expanded ratio spread transmission, in real world gradeability may cause further deteriorate as modeled in ALPHA, which leads to inflated effectiveness values for powertrains that would not meet customer demands.
[590] EPA-HQ-OAR-2015-0827-9728, at 14.
[591] *See* Moskalik, A., Bolon, K., Newman, K., and Cherry, J. "Representing GHG Reduction Technologies in the Future Fleet with Full Vehicle Simulation," SAE Technical Paper 2018-01-1273, 2018, doi:10.4271/2018-01-1273. Since 2018, EPA has employed vehicle-class-specific response surface equations automatically generated from a

stakeholders with adequate time to evaluate the updated modeling approach, ensure it is analytically robust, and provide meaningful feedback." Global Automakers concluded that EPA's engine mapping and tear-down analyses have played an important role in generating publicly-available information, and stated that the data should be integrated into the Autonomie model.

On the other hand, other stakeholders commented that EPA's ALPHA modeling should continue to be used, for procedural reasons like, "[i]t would appear arbitrary for EPA now, after five years of modeling based on ALPHA, to declare it can no longer use its internally developed modeling tools and must rely solely on the Autonomie model," and "[t]he ALPHA model is inextricably built into the regulatory and technical process. It will require years of new analysis to replace the many ALPHA and OMEGA modeling inputs and outputs that permeate the entire rulemaking process, should EPA suddenly decide to change its models."[592] Commenters also cited technical reasons to use ALPHA, like EPA's progress benchmarking and validating the ALPHA model to over fifteen various MY 2013-2015 vehicles,[593] and that technologies like the "Atkinson 2" engine technology were not considered in NHTSA's compliance modeling.[594] Commenters also cited that ALPHA was created to be publicly available, open-sourced, and peer-reviewed, "to allow for transparency to both automakers and public stakeholders, without hidden and proprietary aspects that are present in commercial modeling products."[595]

The agencies described in the NPRM that after having reviewed comments about whether EPA should use alternative methodologies and modeling, and after having considered the matter fully, the agencies determined it was reasonable and appropriate to use Autonomie for full-vehicle simulation.[596] The agencies stated that nothing in Section 202(a) of the Clean Air Act (CAA) mandated that EPA use any specific model or set of models for analysis of potential CO_2 standards for light duty vehicles. The agencies also distinguished the models and the inputs used to populate them; specifically, comments presented as criticisms of the models, such as "Atkinson 2" engine technology not considered in the compliance modeling, actually concerned model inputs.[597]

With regards to modeling technology effectiveness, the agencies concluded that, although the CAFE model requires no specific approach to developing effectiveness inputs, the National Academy of Sciences recommended, and stakeholders have commented, that full-vehicle simulation provides the best balance between realism and practicality. As stated above, Argonne has spent several years developing, applying, and expanding means to use distributed computing to exercise its Autonomie full-vehicle simulation tool at the scale necessary for realistic analysis

of technologies that could be used to comply with CAFE and CO_2 standards, and this scalability and related flexibility (in terms of expanding the set of technologies to be simulated) makes Autonomie well-suited for developing inputs to the CAFE model.

In response to the NPRM, the Auto Alliance commented that NHTSA's modeling and analysis tools are superior to EPA's, noting that NHTSA's tools have had a significant lead in their development.[598] The Alliance pointed out that Autonomie was developed from the beginning to address the complex task of combining two power sources in a hybrid powertrain, while EPA's ALPHA model had not been validated or used to simulate hybrid powertrains. While both models are physics-based forward looking vehicle simulators, the Alliance commented that Autonomie is fully documented with available training, while ALPHA "has not been documented with any instructions making it difficult for users outside of EPA to run and interpret the model." The Alliance also mentioned specific improvements in the Autonomie simulations since the Draft TAR, including expanded performance classes to better consider vehicle performance characteristics, the inclusion of gradeability as a performance metric, as recommended by the NAS, the inclusion of new fuel economy technologies, and the removal of unproven technologies.

The Alliance, Global Automakers, and other automakers writing separately all stated that the agencies should use one simulation and modeling tool for analysis.[599, 600] The Alliance stated that since both the Autonomie and ALPHA modeling systems answer essentially the same questions, using both systems leads to inconsistencies and conflicts, and is inefficient and counterproductive.

The agencies agree with the Alliance that the fully developed and validated Autonomie model fulfills the agencies' analytical needs for full-vehicle modeling and simulation. The agencies also agree that it is counterintuitive to have two separate models conducting the same work.

Some commenters stated that broadly, EPA was required to conduct its own technical analysis and rely on its own models to do so.[601] Those comments are addressed in Section IV.

Regarding the merits of EPA's models, and based on previous inputs and assumptions used to populate those models, ICCT commented that "[b]ased on the ICCT's global analysis of vehicle regulations, the EPA's physics-based ALPHA modeling offers the most sophisticated and thorough modeling of the applicable technologies that has ever been conducted." ICCT listed several reasons for this, including that the EPA modeling is based on systematic modeling of technologies and their synergies; it was built and improved upon by extensive modeling by

and with Ricardo (an engineering consulting firm); it incorporated National Academies input at multiple stages; it has included many peer reviews at many stages of the modeling and the associated technical reports published by engineers in many technical journal articles and conference proceedings; and EPA's Draft TAR analysis, which used ALPHA, used state-of-the-art engine maps based on benchmarked high-efficiency engines. ICCT concluded that "[d]espite these rigorous advances in vehicle simulation modeling, it appears that the agencies have inexplicably abandoned this approach, expressly disregarding the EPA benchmarked engines, ALPHA modeling, and all its enhancements since the last rulemaking."

The hallmarks ICCT lists regarding the ALPHA modeling are equally applicable to Autonomie.[602] Autonomie is also based on systematic modeling of technologies and their synergies when combined as packages. The U.S. Department of Energy created Autonomie, and over the past two decades, helped to develop and mature the processes and inputs used to represent real-world vehicles using continuous feedback from the tool's worldwide user base of vehicle manufacturers, suppliers, government agencies, and other organizations. Moreover, using Autonomie brings the agencies closer to the NAS Committee's stated goal of "full system simulation modeling for every important technology pathway and for every vehicle class."[603] While the NAS Committee originally thought that full vehicle simulation modeling would not be feasible for the thousands of vehicles in the analysis fleets because the technologies present on the vehicles might differ from the configurations used in the simulation modeling,[604] Argonne has developed a process to simulate explicitly every important technology pathway for every vehicle class. Moreover, although separate from the Autonomie model itself, the Autonomie modeling for this rulemaking incorporated other NAS committee recommendations regarding full vehicle simulation inputs and input assumptions, including using engine-model-generated maps derived from a validated baseline map in which all parameters except the new technology of interest are held constant.[605]

As discussed further below and in VI.C.1 Engine Paths, this is one reason why the IAV maps were used instead of the EPA maps, and the agencies instead referenced EPA's engine maps to corroborate the Autonomie effectiveness results. The IAV maps are engine-model-generated maps derived from a validated baseline map in which all parameters except the new technology of interest are held constant. While EPA's engine maps benchmarking specific vehicles' engines incorporate multiple technologies, for example including improvements in engine friction and reduction in accessory parasitic loads, comparisons presented in Section VI.C.1 showed that engine maps developed by IAV, while not exactly the same, are representative of EPA's engine benchmarking data.

In addition, both ALPHA and Autonomie have been used to support analyses that have been published in technical journal articles and conference proceedings, but those analyses differ fundamentally because of the nature of the tools. ALPHA was developed as a tool to be used by

605 NAS Recommendation 2.1.

EPA's in-house experts.[606] As EPA stated in the ALPHA model peer review,[607] "ALPHA is not intended to be a commercial product or supported for wide external usage as a development tool."[608] Accordingly, EPA experts have published several peer-reviewed journal articles using ALPHA and have presented the results of those papers at conference proceedings.[609]

To explore ICCT's comments on the importance of peer review further, it is important to take the actual substantive content of the ALPHA peer review into account.[610] One reviewer raised significant questions over the availability of ALPHA documentation, stating "[t]here is an overall lack of detail on key technical features that are new in the model," and "[w]e were not able to find any information on how the model handles component weight changes." Reviewers also raised questions related to model readiness, stating "[a]ccording to the documentation review, ALPHA's stop/start modeling appears to be very simplistic." Moreover, when running ALPHA simulations, the reviewer noted the results "strongly suggest that the model has errors in the underlying equations or coding with respect to all of the load reductions." Also, one reviewer said the following of ALPHA: "A specific simulation runtime is significantly high, more than 10 mins. without providing any indication to the user progress made so far. A fairly more complicated model such as Autonomie available even with enhanced capabilities is significantly faster today."[611]

The peer reviewer's assessment of Autonomie as a more complicated model with enhanced capabilities is not surprising, given Autonomie's history of development. Autonomie is a commercial tool with more than 275 worldwide organizational users, including vehicle manufacturers, suppliers, government agencies, and nonprofit organizations having licensed and used Autonomie. Both Autonomie's creators and user base unaffiliated with Argonne have published over 100 papers, including peer-reviewed papers in journals, related to Autonomie validation and other studies.[612,613] One could even argue that the tool has been continuously peer reviewed by these thousands of experts over the past two decades.

---

[606] ALPHA Peer Review, at 4-1.
[607] ICCT's comments intimate that ALPHA has been peer reviewed at many stages of the modeling; although EPA has published several peer-reviewed technical papers, the ALPHA model itself has been subject to one peer review. *See* Peer Review of ALPHA Full Vehicle Simulation Model, available at https://nepis.epa.gov/Exe/ZyPdf.cgi?Dockey=P100PUKT.pdf.

[612] At least 15 peer-reviewed papers authored by ANL experts have been referenced throughout this Section, and others can be found at SAE International's website, https://www.sae.org/, using the search bar for "Autonomie."
[613] *See, e.g.*, Haupt, T., Henley, G., Card, A., Mazzola, M. et al., "Near Automatic Translation of Autonomie-Based Power Train Architectures for Multi-Physics Simulations Using High Performance Computing," SAE Int. J. Commer. Veh. 10(2):483-488, 2017, https://doi.org/10.4271/2017-01-0267; Samadani, E., Lo, J., Fowler, M.,

In fact, in responding to a peer review comment on the ALPHA model's underlying equations and coding with respect to road load reductions, EPA noted that Autonomie had been used as a reference system simulation tool to validate ALPHA model results.[614]

Outside of formal peer-reviewed studies, Autonomie has been used by organizations like ICCT to support policy documents, position briefs, and white papers assessing the potential of future efficiency technologies to meet potential regulatory requirements,[615] just as the agencies did in this rulemaking.

Similarly to ICCT, UCS stated that in contrast to Autonomie, ALPHA had been thoroughly peer-reviewed and is constantly being updated to reflect the latest technology developments based on work performed by the National Vehicle and Fuel Emissions Laboratory.[616] UCS also stated that because EPA has direct control over the model and its interface to OMEGA, EPA can better ensure that the inputs into OMEGA reflect the most up-to-date data, unlike the Autonomie work, which effectively has to be "locked in" before it can be deployed in the CAFE model. UCS also stated that ALPHA is based on the GEM model (used to simulate compliance with heavy-duty vehicle regulations) which was been updated with feedback from heavy-duty vehicle manufacturers and suppliers, and in fact, "NHTSA has such confidence in the GEM model that they accept its simulation-based results as compliance with the heavy-duty fuel economy regulations."

Again, the agencies believe that it is important to note that Autonomie not only meets, but also exceeds, UCS' listed metrics. Autonomie's models, sub-models, and controls are constantly being updated to reflect the latest technology developments based on work performed by Argonne National Laboratory's Advanced Mobility Technology Laboratory (AMTL) (formerly Advanced Powertrain Research Facility, or ARPF).[617,618] The Autonomie validation

has included nine validation studies with accompanying reports for software, six validation studies and reports for powertrains, nine validation studies and reports for advanced components, ten validation studies and reports for advanced controls, and overall model validation using test data from over 50 vehicles.[619]

In fact, using Autonomie, which has validated data based on test data from over 50 vehicles, alleviates other stakeholder concerns about the level of model validation in past analyses. For example, Global Automakers expressed concerns about whether the effectiveness values used in past EPA analysis, generated from ALPHA full-vehicle model simulations, were properly validated, stating that "[a]lthough EPA claims that the LPM was calibrated based on thorough testing and modeling with the ALPHA model, the materials provided with the Proposed and Final Determination only cover 18 percent of the projected vehicle fleet with regards to specific combinations of powertrain technology presented by EPA in the MY 2025 OMEGA pathway. It is unclear how EPA calibrated the LPM for the remaining 82 percent of the projected vehicles. EPA's failure to publicly share the data for such a large percentage of vehicles raises questions about the quality of data."[620] While simple modeled parameters like single dimensional linear systems, such as engine dynamometer torque measurements can be validated through other models,[621] full vehicle systems are complex multi-dimensional non-linear systems that need to be developed with multiple data sets, and validated with other fully independent data sets. Autonomie's models and sub-models have undergone extensive validation that has proven the models' agreement with empirical data and the principles of physics.

In addition, the agencies disagree with UCS' comment that EPA's direct control over its effectiveness modeling and interface to OMEGA results in a more up-to-date analysis. Argonne's participation in developing inputs for the rulemaking analysis allowed the agencies access to vehicle benchmarking data from more vehicles than if the agencies were limited by their own resources, and access to the Argonne staff's extensive experience based on direct coordination with vehicle manufacturers, suppliers, and researchers that all actively use Autonomie for their own work. In addition to Autonomie's continuous updates to incorporate the latest fuel-economy-improving technologies, discussed throughout this section, the data

[619]Rousseau, A. Moawad, A. Kim, Namdoo. "*Vehicle System Simulation to Support NHTSA CAFE standards for the Draft Tar*." https://www.nhtsa.gov/sites/nhtsa.dot.gov/files/anl-nhtsa-workshop-vehicle-system-simulation.pdf Last accessed Nov 20, 2019.

[620] Docket ID EPA-HQ-OAR-2015-0827-9728 . Global later repeated that "only 18% of all vehicle data used as inputs to the ALPHA modeling was made available in the EPA's public sources. Additional data had to be specifically requested subsequent to the publication of the Draft TAR and Proposed Determination. This lack of publicly available data highlights transparency concerns, which Global Automakers has raised on several previous occasions."

[621] Section 89.307 Dynamometer calibration.

supplied to and generated by Autonomie for use in the CAFE model was continuously updated during the analysis process. This is just one part of the iterative quality assurance (QA) and quality check (QC) process that the agencies developed when Argonne's large-scale simulation modeling based in Autonomie was first used for the Draft TAR.

In addition to Argonne's team constantly updating Autonomie, Argonne's use of high performance computing (HPC) allowed for constant update of the analysis during the rulemaking process. Argonne's HPC platform allows a full set of simulations—over 750,000 modeled vehicles that incorporate over 50 different fuel-economy-improving technologies—to be simulated in one week. Subsets of the simulations can be re-run should issues come up during QA/QC in a day or less. Tools like the internet and high performance computers have allowed the agencies to evaluate technology effectiveness with up-to-date inputs without the proximity of the computers and the people running them working as a detriment the analysis.

Finally, GEM, ALPHA, and Autonomie were all developed in the MATLAB computational environment as forward-looking physics-based vehicle models. Just as ALPHA has roots in GEM, created in 2010 to accompany the agencies' heavy-duty vehicle CO_2 emissions and fuel consumption standards, Autonomie has its origins in the software PSAT, developed over 20 years ago. While this information is useful, as implied by UCS' comment, the origin of the software was less important than the capabilities the software could provide for today's analysis. NHTSA's acceptance of GEM results for compliance with heavy-duty fuel economy regulations had no bearing on the decision to use Autonomie to assess the effectiveness of light-duty fuel economy and CO_2 improving technologies. GEM was developed to serve as the compliance model for heavy-duty vehicles,[622] and GEM serves that limited scope very well.

UCS did comment that full vehicle simulation could significantly improve the estimates of technology effectiveness, but thought it critical that the process be as open and transparent as possible. UCS pointed to ALPHA results published in peer-reviewed journals as an example of how transparency has provided the ALPHA modeling effort with significant and valuable feedback, and contrasted what they characterized as Autonomie's "black box" approach, which they stated "does not lend itself to similar dialog, nor does it make it easy to assess the validity of the results." Specifically, UCS stated that it is "impossible to verify, replicate, or alter the work done by Autonomie due to the expensive nature of the tools used and lack of open source or peer-reviewed output." In contrast, UCS stated that EPA's ALPHA model has been thoroughly peer reviewed, and is readily "downloadable, editable, and accessible to anyone with a MATLAB license."

The agencies responses on the merits of how ALPHA and Autonomie were peer-reviewed are discussed above. Regarding UCS' comment that it is impossible to verify, replicate, or alter the work done by Autonomie, the agencies disagree. All inputs, assumptions, model documentation—including of component models and individual control algorithms—and

---

outputs for the NPRM Autonomie modeling were submitted to the docket for review.[623] Commenters were able to provide a robust analysis of Autonomie's technology effectiveness inputs, input assumptions, and outputs, as shown by their comments on specific vehicle technology effectiveness assumptions, discussed throughout this section and in the individual technology sections below.

The agencies also disagree with UCS' assessment of Autonomie as "expensive." While Autonomie is a commercial product, the biggest financial barrier to entry for both ALPHA and Autonomie is the same: a MathWorks license.[624,625] Regardless, Argonne has made the version of Autonomie used for this final rule analysis available upon request, including the individual runs used to generate each technology effectiveness estimate.[626]

Next, ICCT supplanted its statement that the agencies "inexplicably" abandoned ALPHA, commenting that the agencies' explanation and justification for relying on Autonomie rather than ALPHA failed to discuss ALPHA in detail, and the agencies did not compare and contrast the two models. ICCT continued, "the EPA cannot select its modeling tool arbitrarily, yet it appeared that the EPA has whimsically shifted from an extremely well-vetted, up-to-date, industry-grade modeling tool to a less-vetted, academic-grade framework with outdated inputs without even attempt to scrutinize the change." ICCT also stated that the agencies are legally obligated to acknowledge and explain when they change position, and "cannot simply ignore that

EPA previously concluded that the ALPHA modeling accurately projected real-world effects of technologies and technology packages."

The agencies disagree that a more in-depth discussion of ALPHA was required in the NPRM. In acknowledging the transition to using Autonomie for effectiveness modeling and the CAFE model for analysis of regulatory alternatives,[627] the agencies described several analytical needs that using a single analysis from the CAFE model—with inputs from the Autonomie tool—addressed. These included that Autonomie produced realistic estimates of fuel economy levels and CO_2 emission rates through consideration of real-world constraints, such as the estimation and consideration of performance, utility, and drivability metrics (e.g., towing capability, shift busyness, frequency of engine on/off transitions).[628] That EPA previously concluded the ALPHA modeling accurately projected real-world effects of technologies and technology packages has no bearing on Autonomie's ability to fulfill the analytical needs that the agencies articulated in the NPRM, including that Autonomie also accurately projects real-world effects of technologies and technology packages.

The agencies also disagree with ICCT's characterization of ALPHA as "an extremely well-vetted, up-to-date, industry-grade modeling tool" and Autonomie as a "less-vetted, academic-grade framework with outdated inputs." Again, Autonomie has been used by government agencies, vehicle manufacturers (and by agencies and manufacturers together in the collaborative government-industry partnership U.S. DRIVE program), suppliers, and other organizations because of its ability to simulate many powertrain configurations, component technologies, and vehicle-level controls over numerous drive cycles. Characterizing ALPHA as an "industry-grade modeling tool" contravenes EPA's own description of its tool—an in-house vehicle simulation model used by EPA, not intended to be a commercial product.[629]

That characterization also contravenes documentation from the automotive industry indicating that manufacturers consider ALPHA to generate overly optimistic effectiveness

[627] 83 FR 43000 (Aug. 24, 2018).
[628] 83 FR 43001 (Aug. 24, 2018).
[629] *See, e.g.,* Overview of ALPHA Model, https://www.epa.gov/regulations-emissions-vehicles-and-engines/advanced-light-duty-powertrain-and-hybrid-analysis-alpha; ALPHA Effectiveness Modeling: Current and Future Light-Duty Vehicle & Powertrain Technologies (Jan. 20, 2016), available at https://www.epa.gov/sites/production/files/2016-10/documents/alpha-model-sae-govt-ind-mtg-2016-01-20.pdf ("ALPHA is not a commercial product (e.g. there are no user manuals, tech support hotlines, graphical user interfaces, or full libraries of components)."). *See also* Peer Review of ALPHA Full Vehicle Simulation Model, *available at* https://nepis.epa.gov/Exe/ZyPdf.cgi?Dockey=P100PUKT.pdf. While ALPHA peer reviewers found the model to be a "fairly simple transparent model . . . [t]he model execution requires an expert MatLab/Simulink user since no user-friendly interface currently exists." Indeed, EPA noted in response to this comment that "[a]s with any internal tool, EPA does not have the need for a "user-friendly interface" like one that would normally accompany a commercial product which is available for purchase and fully supported for wide external usage."

values, to be unrepresentative of real-world constraints, and a difficult tool to use.[630,631] The Alliance commented to the MTE reconsideration that "[p]revious comments from the Alliance and individual manufacturers to the MTE docket have highlighted multiple concerns with EPA's ALPHA model. Many of these concerns remain unresolved."[632] Furthermore, the Alliance commented that ALPHA "has not been documented with any instructions making it difficult for users outside of EPA to run and interpret the model."[633] Global Automakers further stated that the "lack of publicly available data [related to inputs used in the ALPHA modeling] highlights transparency concerns, which Global Automakers has raised on several previous occasions."[634] In fact, both the Alliance of Automobile Manufacturers and Global Automakers, the two trade organizations that represent the automotive industry, concluded that Autonomie should be used to generate effectiveness inputs for the CAFE model.[635]

In addition, Autonomie contains up-to-date sub-models to represent the latest electrification and advanced transmission and advanced engine technologies. As summarized by the Alliance, "Autonomie was developed from the start to address the complex task of combining 2 power sources in a hybrid powertrain."[636] Autonomie has continuously improved over the years by adopting new technologies into its modeling framework. Even a small sampling of SAE papers shows how Autonomie has been validated to simulate the latest fuel-economy-improving technologies like hybrid vehicles and PHEVs.[637]

Moreover, Autonomie effectively considers other real-world constraints faced by the automotive industry. Vehicle manufacturers and suppliers spend significant time and effort to ensure technologies are incorporated into vehicles in ways that will balance consumer acceptance

for attributes such as driving quality,[638] noise-vibration-harshness (NVH), and meeting other regulatory mandates, like EPA's and CARB's On-Board Diagnostics (OBD) requirements,[639] and EPA's and CARB's criteria exhaust emissions standards.[640] The implementation of new fuel economy improving technologies have at times raised consumer acceptance issues.[641] As discussed earlier, there are diminishing returns for modeling every vehicle attribute and tradeoff, as each takes time and incurs cost; however, Autonomie sub-models are designed to account for a number of the key attributes and tradeoffs, so the resulting effectiveness estimates reflect these real world constraints.

Furthermore, aside from the fact that Autonomie represents the structural state-of-the-art in full-vehicle modeling and simulation, Autonomie can be populated with any inputs that could be populated in the ALPHA model.[642] The agencies chose to use specific inputs for this rulemaking because, as discussed further in Sections VI.C below, they best represent the technologies that manufacturers could incorporate in the rulemaking timeframe, in a way that balanced important concerns like consumer acceptance. Some other examples of how Autonomie inputs have been updated with the latest vehicle technology data specifically for this analysis include test data incorporated from both Argonne and NHTSA-sponsored vehicle benchmarking, including an updated automatic transmission skip-shifting feature,[643] additional application of cylinder deactivation for turbocharged downsized engines, and as discussed above, new modeling and simulation that includes variable compression ratio and Miller Cycle engines.

Finally, ICCT commented that the agencies must conduct a systematic comparison of the Autonomie modeling system and ALPHA modeling in several respects, including the differences in technical inputs and resulting efficiency estimates, to explain how the choice of model altered the regulatory technology penetration and compliance cost estimations, and the differences in modeling methodologies, including regarding the relative level of experience of the teams conducting the effectiveness modeling, to demonstrate that the choice to use Autonomie was not "due to convenience and easier access by the NHTSA research team, rather than for any technical improvement." ICCT stated that without performing this comparison, "it otherwise appears that the agencies switched from a better-vetted model and system of inputs with more recent input data to a less-vetted model and system of inputs as a way to bury many dozens of

---

638 An example of a design requirement is accommodating the "lag" in torque delivery due to the spooling of a turbine in a turbocharged downsized engine. This affects real-world vehicle performance, as well as the vehicle's ability to shift during normal driving and test cycles.

639 EPA adopted and incorporated by reference current OBD regulations by the California ARB, effective for MY 2017, that cover all vehicles except those in the heavier fraction of the heavy-duty vehicle class.

640 Tier 3 emission standards for light-duty vehicles were proposed in March 2013 78 FR 29815 (May 21, 2013) and signed into law on March 3, 2014 79 FR 23413 (June 27, 2014). The Tier 3 standards—closely aligned with California LEV III standards—are phased-in over the period from MY2017 through MY2025. The regulation also tightens sulfur limits for gasoline.

641 Atiyeh, C. *"What you need to know about Ford's PowerShift Transmission Problems"* Car and Driver. July 11, 2019. https://www.caranddriver.com/news/a27438193/ford-powershift-transmission-problems/.

642 For example, Autonomie used the HCR1 and HCR2 engine maps used as inputs to ALHPA in the Draft TAR and Proposed Determination.

643 NHTSA Benchmarking, "Laboratory Testing of a 2017 Ford F-150 3.5 V6 EcoBoost with a 10-speed transmission." DOT HS 812 520.

changes without transparency or expert assessment (as illustrated in the above errors and invalidated data on individual technologies)." Each issue is discussed below in turn.

First, regarding technical inputs, technology pathways, and resulting outputs, ICCT stated that the agencies must compare (1) whether the models have been routinely strengthened by incorporating cutting edge 2020-2025 automotive technologies to ensure they reflect the available improvements; (2) every efficiency technology in the 2016 Draft TAR and original EPA TSD and Proposed and Final Determination analysis against the NPRM; (3) all the major technology package pathways (i.e., all combinations with high uptake in the Adopted and Augural 2025 standards) in the current NPRM versus the 2016 Draft TAR and the 2016 TSD and original Final Determination analysis; (4) each of the major 2025 technology package synergies; (5) the modeling work of EPA's, Ricardo's, and Argonne's 2014-2018 model year engine benchmarking and modeling of top engine and transmission models; and "defend why they appear to have chosen to dismiss the superior and better vetted technology modeling approach."

ICCT stated that the agencies must make these comparisons because, "[o]therwise, it seems obvious that the agencies have subjectively decided to use the modeling that increases the modeled cost, providing further evidence of a high degree of bias without an objective accounting of the methodological differences and the sensitivity of the results to their new decision." Moreover, ICCT stated that "[b]ecause ALPHA is the dominant, preferred, and better-vetted modeling and was used in the original Proposed and Final Determination, the agencies are responsible for assessing and describing how the use of the ALPHA modeling would result in a different regulatory result for their analysis of the 2017-2025 adopted [CO_2] and Augural CAFE standards."

The agencies do not believe that it is necessary to conduct a retrospective comparison of ALPHA/LPM and Autonomie effectiveness for every technology in the Draft TAR and Proposed Determination to the NPRM and final rule analyses, between the two models for technologies and packages used in the NPRM and final rule analysis, or to explain where and why Autonomie provided different results from ALPHA and the LPM, to assess and describe how the use of the ALPHA modeling would result in a different regulatory result of CAFE and CO_2 standards, per ICCT's request. While it is anticipated that different values will be produced using different tools in an analysis, it is not appropriate to select the tool for use based on preferred results. The selection of an analysis tool should be based on an evaluation of the tool's capabilities and appropriateness for the analysis task. The analysis tool should support the full extent of the analysis and support the level of input and output resolution required. To compare the output of the two models for the purpose of selecting a tool for the analysis would likely be biased and disingenuous to the purpose of the analysis. In this case, Autonomie was selected for this analysis for the reasons discussed throughout this section, and accordingly the agencies believe that it was reasonable to consider effectiveness estimates developed with Autonomie.

That said, comparison of how the tools *behave* is discussed here to further support the agencies' decision process. To demonstrate, in addition to everything discussed previously in this section, differences in how each model handles powertrain systems modeling with specific examples are discussed below as a reference, and differences between the agencies' approaches to effectiveness modeling for specific technologies is discussed in Section VI.C where appropriate. While the improved approach to estimating technology effectiveness estimates certainly impacted the regulatory technology penetration, compliance cost estimates, and "major 2025 technology packages and synergies," how technologies are applied in the compliance modeling and the associated costs of the technologies is equally as important to consider when examining factors that might impact the regulatory analysis; that consideration goes beyond the scope of simply considering which full vehicle simulation model better performs the functions required of this analysis.

The agencies have discussed updates to the technologies considered in the Autonomie modeling throughout this section, in addition to Autonomie's models and sub-models that control advanced technologies like hybrid and electrified powertrains. Autonomie's explicit models, sub-models, and controls for hybrid and electric vehicles have been continuously validated over the past several years,[644] as Autonomie was developed from the beginning to address the complex task of combining two power sources in a hybrid powertrain.

Also regarding the inputs to both models, as highlighted in Section VI.C.3.a), and discussed above, inputs and assumptions for the ALPHA modeling used for the EPA Draft TAR and Proposed Determination analysis were projected from benchmarking testing. While it is straightforward to measure engine fuel consumption and create an engine fuel map, it is extremely challenging to identify the specific technologies and levels of technologies present on a benchmarking engine. Attributing changes in the overall engine fuel consumption to the individual engine technologies that make up the complete engine involves significant uncertainty.

The fixed-point model approach used by the ALPHA model does not develop an effectiveness function and assigns a single value to a technology. The single value is derived from benchmark testing, which often does not isolate the effect of a single technology from the effects of other technologies on the tested vehicle. To isolate a single technology's effect for use in fixed point modeling properly, the agencies would need to benchmark multiple versions of a single vehicle, carefully controlling changes to the vehicles' fuel efficiency technologies. This process would need to be repeated for a large portion of the vehicle fleet and would require significant funding and thousands of lab hours to complete. Without this level of data, fixed-

point effectiveness estimates tend to be too high, as they are unable to account for synergetic effects of multiple technologies. Specifically, when EPA benchmarks vehicles like the 2018 Toyota Camry, the resulting fuel map captures the benefits of many technologies associated with that engine. This data can be helpful when developing controls and validating component operations in modeling, but it is inaccurate to conclude that fuel consumption is directly related to individual engine technologies, such as lubrication and friction reduction, and geometric improvements in efficiency.

Contrasted, the NPRM and final rule Autonomie analyses selected specific base engine maps and applied technologies incrementally, both individually and in known combinations, to better isolate the impacts of the technologies. As discussed above, this also implemented NAS Recommendation 2.1, to use engine-model-generated maps in the full vehicle simulations derived from a validated baseline map in which all parameters except the new technology of interest are held constant.[645] While the different methods are valid for different purposes, the method selected for the analysis presented today was more useful for measuring the incremental effectiveness *increments* as opposed to the *absolute* values of technology effectiveness, *e.g.*, that could be measured by benchmarking a technology package.

To provide an example of another difference in behavior between the simulation tools, a comparison between ALPHA and Autonomie transmissions shifting behavior was conducted. The comparison highlighted the differences in how each simulation tool approaches transmission shift logic. The ALPHA simulation tool used ALPHAShift. ALPHAShift is an optimization algorithm that uses numerous vehicle characteristics to find a best shifting strategy. The primary inputs for the algorithm includes the fuel consumption (or cost) map for the vehicle engine.[646] Although a public version of ALPHA is available for evaluation, the ALPHAShift algorithm used by the tool is hard coded with fixed values.[647, 648] This is an issue, because despite peer reviewed documentation on how to tune the algorithm,[649] no documentation of how the algorithm logic works is available for review. This is confounding for the use of the software, particularly when the observed behavior of the model departs from expected behavior. Figure VI-8 below shows simulated gear shift (left) versus actual gear shift (right), demonstrating an unexpected shift to neutral before shifting to the requested gear.

By contrast, and discussed further in VI.C.2 Transmission Paths, Autonomie uses a fully documented algorithm to develop a best shifting strategy for each unique vehicle configuration. The algorithm develops shifting strategies unique to each individual vehicle based on gear ratio, final drive ratio, engine BSFC and other vehicle characteristics. This is one example of model behavior, in addition to the availability of more transparency on this behavior for greater

stakeholder review, that led the agencies to determine it was reasonable and appropriate to use Autonomie for this analysis.

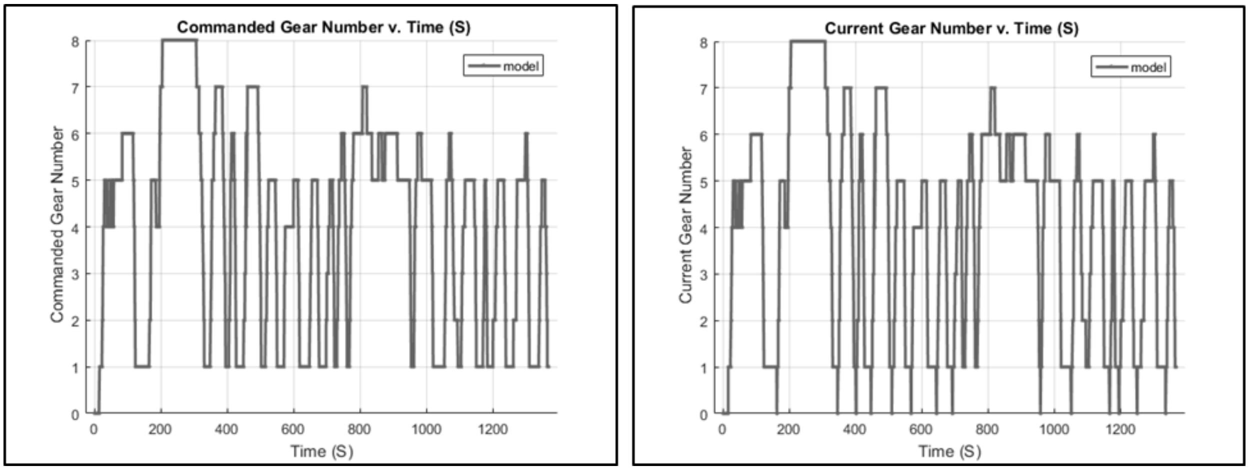

Figure VI-8 – Comparison of Commanded Gear Shift versus Actual Gear Shift for the UDDS[650]

Regarding the technical expertise of the team conducting the effectiveness modeling, ICCT commented:

> [T]he agencies should also disclose how much commercial business is conducted by the Ricardo, IAV, and Argonne Autonomie teams that underpin the modeling of EPA and NHTSA, respectively, including how much related research they have done for auto industry clients over the past ten years. We mention this because we strongly suspect that Ricardo, upon which EPA built its ALPHA model, has done at least an order of magnitude (in number of projects, person-hours, and budget) more work with and for the automotive industry than the IAV and Autonomie teams have in direct work for automotive industry clients. A conventional government procurement effort that competitively vets potential research expert teams would presumably have selected for such automotive industry credentials and experience, yet it appears that the agencies are wholly deferring to Autonomie's less rigorous research-grade modeling framework and data due to convenience and easier access by the NHTSA research team, rather than for any technical improvement, and this is to the detriment of showing clear understanding of real-world automotive engineering developments (as demonstrated by many erroneous technology combination results throughout these comments).

First, NHTSA follows Federal Acquisition Regulation (FAR) to award contracts and Interagency Agreements (IAAs),[651] and any awarded contracts and IAAs must follow the FAR

---

[650] ALPHA v2.2 Technology Walk Samples. Jan. 12, 2017. https://www.epa.gov/sites/production/files/2017-01/alpha-20170112.zip. Last accessed Dec 9, 2019.
[651] Federal Acquisition Regulation (FAR). https://www.acquisition.gov/.

requirements. Importantly, FAR 3.101-1 includes key aspects of conduct and ethics that NHTSA must follow in awarding a contract or IAA:

> Government business shall be conducted in a manner above reproach and, except as authorized by statute or regulation, with complete impartiality and with preferential treatment for none. Transactions relating to the expenditure of public funds require the highest degree of public trust and an impeccable standard of conduct. The general rule is to avoid strictly any conflict of interest or even the appearance of a conflict of interest in Government-contractor relationships. While many Federal laws and regulations place restrictions on the actions of Government personnel, their official conduct must, in addition, be such that they would have no reluctance to make a full public disclosure of their actions.[652]

While some factors are more relevant than others in considering whether to award a contract or enter into an IAA, the amount of work that an organization has performed, characterized by projects, person-hours, and budget, is only one of a multitude of factors that is considered (if it is even considered at all—an agency might not request this information and an organization might decline to provide it because of contractual clauses or to protect commercial business interests) when assessing whether an organization meets the agency's needs for a specific task. Other factors, such as the federal budget, also set boundaries for the scope of work that can be performed under any competitive government procurement effort.

As discussed throughout this section, the team at Argonne National Laboratory behind Autonomie has developed and refined a state-of-the-art tool that is used by the automotive industry, government agencies, and research or other nongovernmental institutions around the world. The tool has been and continues to be validated to production vehicles, and updated to include models, sub-models, and controls representing the state-of-the-art in fuel economy improving technology. To the extent that ICCT believes that "research done for auto industry clients," "work with and for the automotive industry," and "automotive industry credentials and experience," are metrics upon which to base this type of important decision, the agencies point ICCT to the statements from the automotive industry, above, recommending Autonomie be used for technology effectiveness modeling.

ICCT concluded that "[w]hile the agencies are in their process of conducting a proper vetting of their NPRM's foundational Autonomie-based modeling, we recommend that they rely on what appears to be the superior and better vetted technology modeling approach with more thorough and state-of-the-art advanced powertrain systems modeling and engine maps from the EPA ALPHA modeling."

The agencies properly vetted the Autonomie modeling and decided that Autonomie represented a reasonable and appropriate tool to provide technology effectiveness estimates for this rulemaking. To the extent that commenters' concerns were more about the effectiveness results than the tools used to model technology effectiveness, modeling updates detailed in the Section VI.B.3.c), below, address those comments. While some commenters may still be

---

[652] FAR 3.101-1.

dissatisfied with Autonomie's technology effectiveness estimates, the agencies believe that the refinement of inputs and input assumptions, and associated explanation of why those refinements are appropriate and reasonable, have appropriately addressed comments on these issues. Importantly, none of these refinements have led either agency to reconsider using Autonomie for this rulemaking analysis.

Additional discussion of the agencies' decision to rely on one set of modeling tools for this rulemaking is located in Section VI.A of this FRIA.

c) Technology Effectiveness Values Implementation in the CAFE Model

While the Autonomie model produces a large amount of information about each simulation run—for a single technology combination, in a single technology class—the CAFE model only uses two elements of that information: battery costs and fuel consumption on the city and highway cycles. The agencies combine the fuel economy information from the two cycles to produce a composite fuel economy for each vehicle, on each fuel. Plug-in hybrids, being the only dual-fuel vehicles in the Autonomie simulation, require efficiency estimates of operation on both gasoline and electricity—as well as an estimate of the utility factor, or the number of miles driven on each fuel. The fuel economy information for each technology combination, for each technology class, is converted into a single number for use in the CAFE model.

As described in greater detail below, each Autonomie simulation record represents a unique combination of technologies, and the agencies create a technology "key" or technology state vector that describes all the technology content associated with a record. The 2-cycle fuel economy of each combination is converted into fuel consumption (gallons per mile) and then normalized relative to the starting point for the simulations. In each technology class, the combination with the lowest technology content is the VVT (only) engine, with a 5-speed transmission, no electrification, and no body-level improvements (mass reduction, aerodynamic improvements, or low rolling resistance tires). This is the reference point (for each technology class) for all the effectiveness estimates in the CAFE model. The improvement factors that the model uses are a given combination's fuel consumption improvement relative to the reference vehicle in its technology class.

For the majority of the technologies analyzed within the CAFE Model, the fuel economy improvements were derived from the database of Autonomie's detailed full-vehicle modeling and simulation results. In addition to the technologies found in the Autonomie simulation database, the CAFE modeling system also incorporated a handful of technologies that were required for CAFE modeling, but were not explicitly simulated in Autonomie. The total effectiveness of these technologies either could not be captured on the 2-cycle test, or there was no robust data that could be used as an input to the full-vehicle modeling and simulation, like with emerging technologies such as advanced cylinder deactivation (ADEAC). These additional technologies are discussed further in Sections VI.B.3 Technology Effectiveness and individual technologies sections. For calculating fuel economy improvements attributable to these additional technologies, the model used defined fuel consumption improvement factors that are constant across all technology combinations in the database and scale multiplicatively when applied together. The Autonomie-simulated and additional technologies were then externally combined, forming a single dataset of simulation results (referred to as the vehicle simulation database, or simply, database), which may then be utilized by the CAFE modeling system.

To incorporate the results of the combined database of Autonomie-simulated and additional technologies, while still preserving the basic structure of the CAFE Model's technology subsystem, it was necessary to translate the points in this database into corresponding locations defined by the technology pathways. By recognizing that most of the pathways are unrelated, and are only logically linked to designate the direction in which technologies are allowed to progress, it is possible to condense the paths into a smaller number of groups based on the specific technology. In addition, to allow for technologies present on the Basic Engine and Dynamic Road Load (DLR—i.e., MASS, AERO, and ROLL) paths to be evaluated and applied in any given combination, a unique group was established for each of these technologies.

As such, the following technology groups are defined within the modeling system: engine cam configuration (CONFIG), VVT engine technology (VVT), VVL engine technology (VVL), SGDI engine technology (SGDI), DEAC engine technology (DEAC), non-basic engine technologies (ADVENG), transmission technologies (TRANS), electrification and hybridization (ELEC), low rolling resistance tires (ROLL), aerodynamic improvements (AERO), mass reduction levels (MR), EFR engine technology (EFR), electric accessory improvement technologies (ELECACC), LDB technology (LDB), and SAX technology (SAX). The combination of technologies along each of these groups forms a unique technology state vector and defines a unique technology combination that corresponds to a single point in the database for each technology class evaluated within the modeling system.

As an example, a technology state vector describing a vehicle with a SOHC engine, variable valve timing (only), a 6-speed automatic transmission, a belt-integrated starter generator, rolling resistance (level 1), aerodynamic improvements (level 2), mass reduction (level 1), electric power steering, and low drag brakes, would be specified as "SOHC; VVT; AT6; BISG; ROLL10; AERO20; MR1; EPS; LDB."[653] By assigning each unique technology combination a state vector such as the one in the example, the CAFE Model can then assign each vehicle in the analysis fleet an initial state that corresponds to a point in the database.

Once a vehicle is assigned (or mapped) to an appropriate technology state vector (from one of approximately three million unique combinations, which are defined in the vehicle simulation database as CONFIG; VVT; VVL; SGDI; DEAC; ADVENG; TRANS; ELEC; ROLL; AERO; MR; EFR; ELECACC; LDB; SAX), adding a new technology to the vehicle simply represents progress from a previous state vector to a new state vector. The previous state vector simply refers to the technologies that are currently in use on a vehicle. The new state vector, however, is computed within the modeling system by adding a new technology to the

[653] In the example technology state vector, the series of semicolons between VVT and AT6 correspond to the engine technologies which are not included as part of the combination, while the gap between MR1 and EPS corresponds to EFR and the omitted technology after LDB is SAX. The extra semicolons for omitted technologies are preserved in this example for clarity and emphasis, and will not be included in future examples.

combination of technologies represented by the previous state vector, while simultaneously removing any other technologies that are superseded by the newly added one.

For example, consider the vehicle with the state vector described as: SOHC; VVT; AT6; BISG; ROLL10; AERO20; MR1; EPS; LDB. Assume the system is evaluating PHEV20 as a candidate technology for application on this vehicle. The new state vector for this vehicle is computed by removing SOHC, VVT, AT6, and BISG technologies from the previous state vector,[654] while also adding PHEV20, resulting in the following: PHEV20; ROLL10; AERO20; MR1; EPS; LDB.

From here, it is relatively simple to obtain a fuel economy improvement factor for any new combination of technologies and apply that factor to the fuel economy of a vehicle in the analysis fleet. The formula for calculating a vehicle's fuel economy after application of each successive technology represented within the database is defined, simply put, as the difference between the fuel economy improvement factor associated with the technology state vector before application of a candidate technology, and after the application of a candidate technology.[655] This is applied to the original compliance fuel economy value for a discrete vehicle in the MY 2017 analysis fleet, as discussed previously in Section VI.B.3 Technology Effectiveness.

The fuel economy improvement factor is defined in a way that captures the incremental improvement of moving between points in the database, where each point is defined uniquely as a combination of up to 15 distinct technologies describing, as mentioned above, the engine's cam configuration, multiple distinct combinations of engine technologies, transmission, electrification type, and various vehicle body level technologies.

Unlike the preceding versions of the modeling system, the current version of the CAFE Model relies entirely on the vehicle simulation database for calculating fuel economy improvements resulting from all technologies available to the system. The fuel economy improvements are derived from the factors defined for each unique technology combination or state vector. Each time the improvement factor for a new state vector is added to a vehicle's existing fuel economy, the factor associated with the old technology combination is entirely removed. In that sense, application of technologies obtained from the Autonomie database is "self-correcting" within the model. As such, special-case adjustments defined by the previous version of the model are not applicable to this one.

Meszler Engineering Services, commenting on behalf of Natural Resources Defense Council, commented that "[w]ith very limited exception, technology is not included in the NPRM CAFE model if it was not included in the simulation modeling that underlies the Argonne database," citing the "add-on" technologies and technologies with fixed effectiveness values.[656] Meszler continued, "[t]his same limitation controls the coupling of technologies, and by

[655] For more discussion of how the CAFE Model calculates a vehicle's fuel economy where the vehicle switches from one type of fuel to another, for example, from gasoline operation to diesel operation or from gasoline operation to plug-in hybrid/electric vehicle operation, *see* Section VI.A CAFE Model.
[656] NHTSA-2018-0067-11723, at 4-5.

extension the definition of the CAFE model technology pathways. If a combination of technologies were not modeled during the development of the Argonne database, that package (or combination) of technologies is not available for adoption in the CAFE model. Both of these design constraints serve to limit the slate of technologies available to respond to fuel economy standards. The slate of available technologies is basically constrained to those included in NHTSA's research activity. If a technology or technology combination was not in the NHTSA research planning process, it is not available in the model." Finally, Meszler stated that "because of the constrained model architecture and the reliance on the Argonne database for impact estimates, independently expanding the model to include additional technologies or technology combinations is not trivial."

We agree that expanding the database to include new technologies is not trivial. However, it is possible. The set of available technologies is part of the model code, and the code is made public upon each release of the model. Many commenters made modifications to the model code, conducted additional tests of their own, and presented their results to the agencies in the form of public comments before the end of the public comment period. A user could add the new technology, identify the associated engineering restrictions that determine combinations for which that technology should not be considered, and add the relevant rows (representing possible technology combinations that include the new technology) in the database (which exists locally on every computer that runs the model). An enterprising user could also take an existing technology along a given path and replace the efficiency values with new values—presumably from their own full vehicle simulations for each technology combination that contains the technology in question. Given the length of time and computing power required to simulate vehicle fuel economy on the test cycle for every possible combination that could be considered by the CAFE model, using a pre-defined database that represents a large ensemble of simulated technology combinations is preferable to the alternative of fully integrating a vehicle simulation model that would be required to run in real-time during the compliance simulation to evaluate the effectiveness of every combination considered (not just applied) by the model.

4. Technology Costs

In the proposal, the agencies estimated present and future costs for fuel-saving technologies, taking into consideration the type of vehicle, or type of engine if technology costs vary by application. These cost estimates are based on three main inputs. First, the agencies estimated direct manufacturing costs (DMCs), or the component and labor costs of producing and assembling the physical parts and systems, with estimated costs assuming high volume production. DMCs generally do not include the indirect costs of tools, capital equipment, financing costs, engineering, sales, administrative support or return on investment. Second, the agencies accounted for these indirect costs via a scalar markup of direct manufacturing costs (the retail price equivalent, or RPE). Finally, costs for technologies may change over time as industry streamlines design and manufacturing processes. The agencies therefore estimated potential cost improvements with learning effects (LE). The retail cost of equipment in any future year is estimated to be equal to the product of the DMC, RPE, and LE. Considering the retail cost of equipment, instead of merely direct manufacturing costs, is important to account for the real-world price effects of a technology, as well as market realities. Absent a government mandate, motor vehicle manufacturers will not undertake expensive development and production efforts to implement technologies without realistic prospects of consumers being willing to pay enough for such technology to allow for the manufacturers to recover their investment.

a) Direct Manufacturing Costs

Direct manufacturing costs (DMCs) are the component costs of the physical parts and systems that make up a complete vehicle. The analysis used agency-sponsored tear-down studies of vehicles and parts to estimate the DMCs of individual technologies, in addition to independent tear-down studies, other publications, and confidential business information. In the simplest cases, the agency-sponsored studies produced results that confirmed third-party industry estimates, and aligned with confidential information provided by manufacturers and suppliers. In cases with a large difference between the tear-down study results and credible independent sources, study assumptions were scrutinized, and sometimes the analysis was revised or updated accordingly.

Due to the variety of technologies and their applications, and the cost and time required to conduct detailed tear-down analyses, the agencies did not sponsor teardown studies for every technology. In addition, many fuel-saving technologies were considered that are pre-production, or sold in very small pilot volumes. For those technologies, a tear-down study could not be conducted to assess costs because the product is not yet in the marketplace for evaluation. In these cases, the agencies relied upon third-party estimates and confidential information from suppliers and manufacturers were relied upon; however, there are some common pitfalls with relying on confidential business information to estimate costs. The agencies and the source may have had incongruent or incompatible definitions of "baseline." The source may have provided DMCs at a date many years in the future, and assumed very high production volumes, important caveats to consider for agency analysis. In addition, a source, under no contractual obligation to the agencies, may provide incomplete and/or misleading information. In other cases, intellectual property considerations and strategic business partnerships may have contributed to a manufacturer's cost information and could be difficult to account for in the model as not all manufacturer's may have access to proprietary technologies at stated costs. The agencies carefully evaluated new information in light of these common pitfalls, especially regarding emerging technologies.

Specifically, the analysis used third-party, forward-looking information for advanced cylinder deactivation and variable compression ratio engines. While these cost estimates may be preliminary (as is the case with many emerging technologies prior to commercialization), the agencies consider them to be reasonable estimates of the likely costs of these technologies.

While costs for fuel-saving technologies reflect the best estimates available today, technology cost estimates will likely change in the future as technologies are deployed and as production is expanded. For emerging technologies, the best information available at the time of the analysis was utilized, and cost assumptions will continue to be updated for any future analysis. Below, discussion of each category of technologies (*e.g.*, engines, transmissions, electrification) summarizes comments on corresponding direct cost estimates, and reviews estimates the agencies have applied for today's analysis.

b) Indirect Costs

As discussed above, direct costs represent the cost associated with acquiring raw materials, fabricating parts, and assembling vehicles with the various technologies manufacturers are expected to use to meet future CAFE and CO_2 standards. They include materials, labor, and variable energy costs required to produce and assemble the vehicle. However, they do not include overhead costs required to develop and produce the vehicle, costs incurred by manufacturers or dealers to sell vehicles, or the profit manufacturers and dealers make from their investments. All of these items contribute to the price consumers ultimately pay for the vehicle. These components of retail prices are illustrated in Table VI-24 below.

Table VI-24 – Retail Price Components

DIRECT COSTS	
Manufacturing Cost	Cost of materials, labor, and variable energy needed for production
INDIRECT COSTS	
Production Overhead	
Warranty	Cost of providing product warranty
Research and Development	Cost of developing and engineering the product
Depreciation and amortization	Depreciation and amortization of manufacturing facilities and equipment
Maintenance, repair, operations	Cost of maintaining and operating manufacturing facilities and equipment
Corporate Overhead	
General and Administrative	Salaries of nonmanufacturing labor, operations of corporate offices, etc.
Retirement	Cost of pensions for nonmanufacturing labor
Health Care	Cost of health care for nonmanufacturing labor
Selling Costs	
Transportation	Cost of transporting manufactured goods
Marketing	Manufacturer costs of advertising manufactured goods
Dealer Costs	
Dealer selling expense	Dealer selling and advertising expense
Dealer profit	Net Income to dealers from sales of new vehicles
Net income	Net income to manufacturers from production and sales of new vehicles

In addition to direct manufacturing costs, the agencies estimated and considered indirect manufacturing costs. To estimate indirect costs, direct manufacturing costs are multiplied by a factor to represent the average price for fuel-saving technologies at retail.

In the Draft TAR and preceding CAFE and safety rulemaking analyses, NHTSA relied on a factor, referred to as the retail price equivalent (RPE), to account for indirect manufacturing costs. The RPE accounts for indirect costs like engineering, sales, and administrative support, as well as other overhead costs, business expenses, warranty costs, and return on capital considerations. In the Draft TAR (and subsequent Determination) as well as the 2012 rulemaking analysis, EPA applied an "Indirect Cost Multiplier" (ICM) approach that it first applied in the 2010 rulemaking regarding standards for MYs 2012-2016, which also accounted for indirect manufacturing costs, albeit in a different way than the RPE approach.

Some commenters recommended the agencies rely on the ICM approach for the current rulemaking, citing EPA's prior peer review and use of this approach.[657] Others supported the agencies' reliance on the RPE approach, citing the National Research Council's observations in 2015 that the ICM approach lacks an empirical basis.[658] The agencies have carefully considered these comments, and conclude that while the ICM approach has conceptual merit, its application requires a range of specific estimates, and data to support such estimates is scant and, in some cases, nonexistent. The agencies have, therefore, applied the RPE approach for this final rule, as in the NPRM analysis and other rulemaking analyses. The following sections discuss both approaches in detail to explain why the RPE approach was chosen for this final rule.

(1) Retail Price Equivalent

Historically, the method most commonly used to estimate indirect costs of producing a motor vehicle has been the retail price equivalent (RPE). The RPE markup factor is based on an examination of historical financial data contained in 10-K reports filed by manufacturers with the Securities and Exchange Commission (SEC). It represents the ratio between the retail price of motor vehicles and the direct costs of all activities that manufacturers engage in, including the design, development, manufacturing, assembly, and sales of new vehicles, refreshed vehicle designs, and modifications to meet safety or fuel economy standards.

Figure VI-9 indicates that for more than three decades, the retail price of motor vehicles has been, on average, roughly 50 percent above the direct cost expenditures of manufacturers. This ratio has been remarkably consistent, averaging roughly 1.5 with minor variations from year to year over this period. At no point has the RPE markup exceeded 1.6 or fallen below 1.4.[659] During this time frame, the average annual increase in real direct costs was 2.5 percent, and the average annual increase in real indirect costs was also 2.5 percent. Figure VI-9 illustrates the historical relationship between retail prices and direct manufacturing costs.[660]

An RPE of 1.5 does not imply that manufacturers automatically mark up each vehicle by exactly 50 percent. Rather, it means that, over time, the competitive marketplace has resulted in pricing structures that average out to this relationship across the entire industry. Prices for any individual model may be marked up at a higher or lower rate depending on market demand. The

consumer who buys a popular vehicle may, in effect, subsidize the installation of a new technology in a less marketable vehicle. But, on average, over time and across the vehicle fleet, the retail price paid by consumers has risen by about $1.50 for each dollar of direct costs incurred by manufacturers.

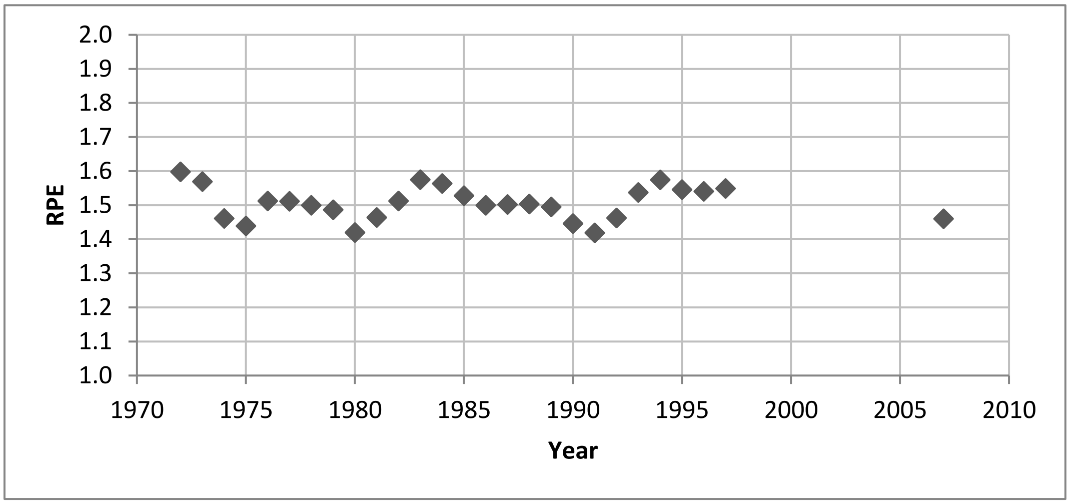

Figure VI-9 – Historical Data for Retail Price Equivalent (RPE), 1972-1997 and 2007

It is also important to note that direct costs associated with any specific technology will change over time as some combination of learning and resource price changes occurs. Resource costs, such as the price of steel, can fluctuate over time and can experience real long-term trends in either direction, depending on supply and demand. However, the normal learning process generally reduces direct production costs as manufacturers refine production techniques and seek out less costly parts and materials for increasing production volumes. By contrast, this learning process does not generally influence indirect costs. The implied RPE for any given technology would thus be expected to grow over time as direct costs decline relative to indirect costs. The RPE for any given year is based on direct costs of technologies at different stages in their learning cycles, and which may have different implied RPEs than they did in previous years. The RPE averages 1.5 across the lifetime of technologies of all ages, with a lower average in earlier years of a technology's life, and, because of learning effects on direct costs, a higher average in later years.

The RPE has been used in all NHTSA safety and most previous CAFE rulemakings to estimate costs. The National Academy of Sciences recommends RPEs of 1.5 for suppliers and 2.0 for in-house production be used to estimate total costs. The Alliance of Automobile Manufacturers also advocates these values as appropriate markup factors for estimating costs of technology changes. An RPE of 2.0 has also been adopted by a coalition of environmental and research groups (NESCCAF, ICCT, Southwest Research Institute, and TIAX-LLC) in a report on reducing heavy truck emissions, and 2.0 is recommended by the U.S. Department of Energy for estimating the cost of hybrid-electric and automotive fuel cell costs (see Vyas et al. (2000) in Table VI-25 below).

Table VI-25 below lists other estimates of the RPE. Note that all RPE estimates vary between 1.4 and 2.0, with most in the 1.4 to 1.7 range.

Table VI-25 – Alternate Estimates of the RPE[661]

Author and Year	Value, Comments
Jack Faucett Associates for EPA, 1985	1.26 initial value, later corrected to 1.7+ by Sierra research
Vyas et al., 2000	1.5 for outsourced, 2.0 for OEM, electric, and hybrid vehicles
NRC, 2002	1.4 (corrected to > by Duleep)
McKinsey and Company, 2003	1.7 based on European study
CARB, 2004	1.4 (derived using the JFA initial 1.26 value, not the corrected 1.7+ value)
Sierra Research for AAA, 2007	2.0 or >, based on Chrysler data
Duleep, 2008	1.4, 1.56, 1.7 based on integration complexity
NRC, 2010	1.5 for Tier 1 supplier, 2.0 for OEM

The RPE has thus enjoyed widespread use and acceptance by a variety of governmental, academic, and industry organizations. The RPE has been the most commonly used basis for indirect cost markups in regulatory analyses. However, as noted above, the RPE is an aggregate measure across all technologies applied by manufacturers and is not technology specific. A more detailed examination of these technologies is possible through an alternative measure, the indirect cost multiplier, which was developed to focus more specifically on technologies used to meet CAFE and CO_2 standards.

(2) Indirect Cost Multiplier

A second approach to accounting for indirect costs is the indirect cost multiplier (ICM). ICMs specifically evaluate the components of indirect costs likely to be affected by vehicle modifications associated with environmental regulation. EPA developed the ICM concept to enable the application of markups more specific to each technology. For example, the indirect cost implications of using tires with better rolling resistance would not be the same as those for developing an entire new hybrid vehicle technology, which would require far more R&D, capital investment, and management oversight. With more than 80 different technologies available to incrementally achieve fuel economy improvements,[662] a wide range of indirect cost effects might

Santini, D., & Cuenca, R. 2000. Comparison of Indirect Cost Multipliers for Vehicle Manufacturing. Center for Transportation Research, Argonne National Laboratory, April. Argonne, Ill.
[662] There are roughly 40 different basic unique technologies, but variations among these technologies roughly double the possible number of different technology applications.

be expected. ICMs attempt to isolate only those indirect costs that would have to change to develop a specific technology. Thus, for example, if a company were to hire additional staff to sell vehicles equipped with fuel economy improving technology, or to search the technology requirements of new CO_2 or CAFE standards, the cost of these staff would be included in ICMs. However, if these functions were accomplished by existing staff, they would not be included. For example, if an executive who normally devoted 10 percent of his time to fuel economy standards compliance were to devote 50 percent of his time in response to new more stringent requirements, his salary would not be included in ICMs because he would be paid the same salary regardless of whether he devoted his time to addressing CAFE requirements, developing new performance technologies, or improving the company's market share. ICMs thus do not account for the diverted resources required for manufacturers to meet these standards, but rather for the net change in costs manufacturers might experience because of hiring *additional* personal or acquiring *additional* assets or services.

For past rulemakings EPA developed both short-term and long-term ICMs. Long-term ICMs are lower than short-term ICMs. This decline reflects the belief that many indirect costs will decline over time. For example, research is initially required to develop a new technology and apply it throughout the vehicle fleet, but a lower level of research will be required to improve, maintain, or adapt that new technology to subsequent vehicle designs.

While the RPE was derived from data in financial statements (reflecting real-world operating and financial results), no similar data sources were available to estimate ICMs. ICMs are based on the RPE, broken into its components, as shown in Table VI-26 . Adjustment factors were then developed for those components, based on the complexity and time frame of low-, medium-, and high-complexity technologies. The adjustment factors were developed from two panels of engineers with background in the automobile industry. Initially, a group of engineers met and developed an estimate of ICMs for three different technologies. This "consensus" panel examined one low complexity technology, one medium complexity technology, and one high complexity technology, with the initial intent of using these technologies to represent ICM factors for all technologies falling in those categories. At a later date, a second panel was convened to examine three more technologies (one low, one medium, and one high complexity), using a modified Delphi approach to estimate indirect cost effects. The results from the second panel identified the same pattern as those of the original report - the indirect cost multipliers increase with the complexity of the technology and decrease over time. The values derived in process are higher than those in the RPE/IC Report by values ranging from 0.09 (that is, the multiplier increased from 1.20 to 1.29) to 0.19 (the multiplier increased from 1.45 to 1.64). This variation may be due to differences in the technologies used in each panel. The results are shown in Figure VI-10, together with the historical average RPE.

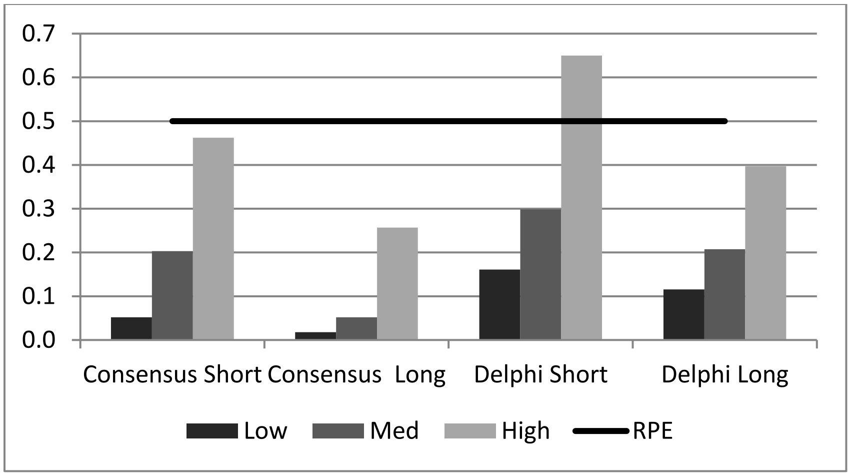

Figure VI-10 – Indirect Cost Estimates from EPA Consensus and Delphi Panels, Short and Long Term

In subsequent CAFE and CO_2 analyses for MYs 2011, as well as for the 2012-2016 rulemaking, a simple average of the two resulting ICMs in the low and medium technology complexity categories was applied to direct costs for all unexamined technologies in each specific category. For high complexity technologies, the lower consensus-based estimate was used for high complexity technologies currently being produced, while the higher modified Delphi-based estimate was used for more advanced technologies, such as plug-in hybrid or electric vehicles, which had little or no current market penetration. Note that ICMs originally did not include profit or "return on capital," a fundamental difference from the RPE. However, prior to the 2012-2016 CAFE analysis, ICMs were modified to include provision for return on capital.

(3) Application of ICMs in the 2017-2025 Analysis

For the model year 2017-2025 rulemaking analysis, NHTSA and EPA revisited technologies evaluated by EPA staff and reconsidered their method of application. The agencies were concerned that averaging consensus and modified Delphi ICMs might not be the most accurate way to develop an estimate for the larger group of unexamined technologies. Specifically, there was concern that some technologies might not be representative of the larger groups they were chosen to represent. Further, the agencies were concerned that the values developed under the consensus method were not subject to the same analytical discipline as those developed from the modified Delphi method. As a result, the agencies relied primarily on the modified Delphi-based technologies to establish their revised distributions. Thus, for the MY 2017-2025 analysis, the agencies used the following basis for estimating ICMs:

- All low complexity technologies were estimated to equal the ICM of the modified Delphi-based low technology-passive aerodynamic improvements.
- All medium complexity technologies were estimated to equal the ICM of the modified Delphi-based medium technology-engine turbo downsizing.
- Strong hybrids and non-battery plug-in hybrid electric vehicles (PHEVs) were estimated to equal the ICM of the high complexity consensus-based high technology-hybrid electric vehicle.

- PHEVs with battery packs and full electric vehicles were estimated to equal the ICM of the high complexity modified Delphi-based high technology-plug-in hybrid electric vehicle.

In addition to shifting the proxy basis for each technology group, the agencies reexamined each technology's complexity designation in light of the examined technologies that would serve as the basis for each group. The resulting designations together with the associated proxy technologies are shown in Table VI-26.

Table VI-26 – Technology Designations by ICM Category, with Proxy Technology

Low Technology	Medium Technology	High Tech 1	High Tech 2
Passive Aerodynamic Improvements	Engine Turbo Downsizing	Hybrid Electric Vehicle	Plug-in Hybrid Electric Vehicle
Passive Aerodynamic Improv.	6-speed DCTs	Strong Hybrids	PHEV battery packs
Lubricant improvements	Mass Reduction 15-20%	PHEV and EV chargers	All Electric vehicles
Mass Reductions 3-10%	Turbocharging	PHEVs w/o batteries	
Aggressive Shift Logic	Cylinder deactivation		
Engine Friction Reduction	Dual valve timing and discreet lift		
Engine Downsizing	8-speed transmissions		
6 speed transmissions	12 volt start-stop systems		
Low Drag Brakes	Active aerodynamics		
Electro-hydraulic power steering	Diverting OHV/SOHC to DOHC		
Electronic power steering	Gasoline direct injection		
WT intake or coupled	Turbo downsizing		
Improved accessories	Turbo downsizing +EGR		
Early torque converter lockup	Diesel vehicles		
	Variable valve lift and timing		
	Lean-burn gasoline engines		

Many basic technologies noted in Table VI-26 have variations sharing the same complexity designation and ICM estimate. Table VI-27 lists each technology used in the CAFE model together with their ICM category and the year through which the short-term ICM would be applied. Note that the number behind each ICM category designation refers to the source of the ICM estimate, with 1 indicating the consensus panel and 2 indicating the modified Delphi panel.

Table VI-27 – ICM categories and Short Term ICM Schedules for CAFE Technologies

Technology	ICM Category	Short Term Through
Low Friction Lubricants - Level 1	Low2	2018
Engine Friction Reduction - Level 1	Low2	2018
Low Friction Lubricants and Engine Friction Reduction - Level 2	Low2	2024

Aero Drag Reduction, Level 1	Low2	2018
Aero Drag Reduction, Level 2	Medium2	2024

An additional adjustment was made to ICMs to account for the fact that they were derived from the RPE analysis for a specific year (2007). The agencies believed it would be more appropriate to base ICMs on the expected long-term average RPE rather than that of one specific year. To account for this, ICMs were normalized to an average RPE multiplier level of 1.5.

Table VI-28 lists values of ICMs by technology category used in the previous MY 2017-2025 rulemaking. As noted previously, the Low 1 and Medium 1 categories, which were derived using the initial consensus panel, are not used. Short-term values applied to CAFE technologies thus range from 1.24 for Low complexity technologies, 1.39 for Medium complexity technologies, 1.56 for High1 complexity technologies, and 1.77 for High2 complexity technologies. When long-term ICMs are applied in the year following that noted in the far-right column of Table VI-28, these values will drop to 1.19 for Low, 1.29 for Medium, 1.35 for High1 and 1.50 for High2 complexity technologies.

Table VI-28 – ICMs by Technology Category Previously Used in 2017-2025 CAFE Rule

	ICM-Warranty		**ICM-Other Indirect Costs**		**ICM Ratio -All Costs**	
ICMs2017+	Short Term	Long Term	Short Term	Long Term	Short Term	Long Term
Low1	0.0384	0.0197	0.0833	0.0658	1.1217	1.0855

Medium2	0.0446	0.0310	0.3427	0.2587	1.3872	1.2897
High1	0.0647	0.0318	0.4989	0.3136	1.5636	1.3454
High2	0.0736	0.0488	0.6964	0.4478	1.7700	1.4966

Note that ICMs for warranty costs are listed separately in Table VI-28. This was done because warranty costs are treated differently than other indirect costs. In some previous analyses (prior to MY 2017-2025), learning was applied directly to total costs. However, the agencies believe learning curves are more appropriately applied only to direct costs, with indirect costs established up front based on the ICM and held constant while direct costs are reduced by learning. Warranties are an exception to this because warranty costs involve future replacement of defective parts, and the cost of these parts would reflect the effect of learning. Warranty costs were thus treated as being subject to learning along with direct costs.[663]

The effect of learning on direct costs, together with the eventual substitution of lower long-term ICMs, causes the effective markup from ICMs to differ from the initial ICM on a yearly basis. An example of how this occurs is provided in Table VI-29.[664] This table, which was originally developed for the MY 2017-2025 analysis, traces the effect of learning on direct costs and its implications for both total costs and the ICM-based markup. Direct costs are assigned a value (proportion) of 1 to facilitate analysis on the same basis as ICMs (in an ICM markup factor, the proportion of direct costs is represented by 1 while the proportion of indirect costs is represented by the fraction of 1 to the right of the decimal.) Table VI-29 examines the effects of these factors on turbocharged downsized engines, one of the more prevalent CAFE technologies.

Table VI-29 – Derived Annual ICMs for Turbocharged Downsized Engines

Year	**Learning #11**	**Direct Costs**	**Other Indirect**	**Warranty**	**Total Costs**	**Effective ICM-based Markup**
2010	0.03					
2011	0.03

2030	0.01	0.7019361	0.2587	0.0261223	0.9867	1.406

[663] Note that warranty costs also involve labor costs for installation. This is typically done at dealerships, and it is unlikely labor costs would be subject to learning curves that affect motor vehicle parts or assembly costs. However, the portion of these costs that is due to labor versus that due to parts is unknown, so for this analysis, learning is applied to the full warranty cost.

[664] Table VI-2922 illustrates the learning process from the base year consistent with the direct cost estimate obtained by the agencies. It is a mature technology well into the flat portion of the learning curve. Note that costs were actually applied in this rulemaking example beginning with MY 2017.

Year	Learning #11	Direct Costs	Other Indirect	Warranty	Total Costs	Effective ICM-based Markup
Average ICM-based markup 2017 through 2030 -						1.389

The second column of Table VI-29 lists the learning schedule applied to turbocharged downsized engines. Turbocharged downsized engines are a mature technology, so the learning schedule captures the relatively flat portion of the learning curve occurring after larger decreases have already reduced direct costs. The cost basis for turbocharged downsized engines in the analysis was effective in 2012, so this is the base year for this calculation when direct costs are set to 1. The third column shows the progressive decline in direct costs as the learning schedule in column 2 is applied to direct costs. Column 4 contains the value of all indirect costs except warranty. Turbocharged downsized engines are a medium-complexity technology, so this value is taken from the Medium2 row of Table VI-28. The initial value in 2012 is the short-term value, which is used through 2018. During this time, these indirect costs are not affected by learning, and they remain constant. Beginning in 2019, the long-term ICM from Table VI-28 is applied.

The fifth column contains warranty costs. As previously mentioned, these costs are considered to be affected by learning like direct costs, so they decline steadily until the long-term ICM is applied in 2019, at which point they drop noticeably before continuing their gradual decline. In the sixth column, direct and indirect costs are totaled. Results indicate a decline in total costs of roughly 30 percent during this 14-year period. The last column shows the effective ICM-based markup, which is derived by dividing total costs by direct costs. Over this period, the ICM-based markup rose from the initial short-term ICM level of 1.39 to 1.45 in 2018. It then declined to 1.35 in 2019 when the long-term ICM was applied to the 2019 direct cost. Over the remaining years, it gradually rises back up to 1.41 as learning continues to degrade direct costs.

There are thus two somewhat offsetting processes affecting total costs derived from ICMs. The first is the learning curve, which reduces direct costs, which raises the effective ICM-based markup. As noted previously, learning reflects learned efficiencies in assembly methods as well as reduced parts and materials costs. The second is the application of a long-term ICM, which reduces the effective ICM-based markup. This represents the reduced burden needed to maintain new technologies once they are fully developed. In this case, the two processes largely offset one another and produce an average real ICM over this 14-year period that roughly equals the original short-term ICM.

Figure VI-11 illustrates this process for each of the 4 technologies used to represent the universe of fuel economy and CO_2 improving technologies. As with the turbocharged engines, aerodynamic improvements and mild hybrid vehicles show a gradual increase in the effective ICM-based markup through the point where the long-term ICM is applied. At that time, the ICM-based markup makes an abrupt decline before beginning a gradual rise. The decline due to application of long-term ICMs is particularly pronounced in the case of the mild hybrid—even more so than for the advanced hybrid. The advanced hybrid ICM behaves somewhat differently because it is shown through its developing stages when more radical learning is applied, but only every few years. This produces a significant step-up in ICM levels concurrent with each learning application, followed by a sharp decline when the long-term ICM is applied. After that, it begins a gradual rise as more moderate learning is applied to reflect its shift to a mature technology. Note that as with the turbocharged downsized engine example above, for the aerodynamic improvements and mild hybrid technologies, the offsetting processes of learning and long-term ICMs result in an average ICM over the full time frame that is roughly equal to the initial short-term ICM. However, the advanced hybrid ICM rose to a level significantly higher than the initial ICM. This is a direct function of the rapid learning schedule applied in the early years to this developing technology. Brand new technologies might thus be expected to have effective lifetime ICM markups exceeding their initial ICMs, while more mature technologies are more likely to experience ICMs over their remaining life span that more closely approximate their initial ICMs.

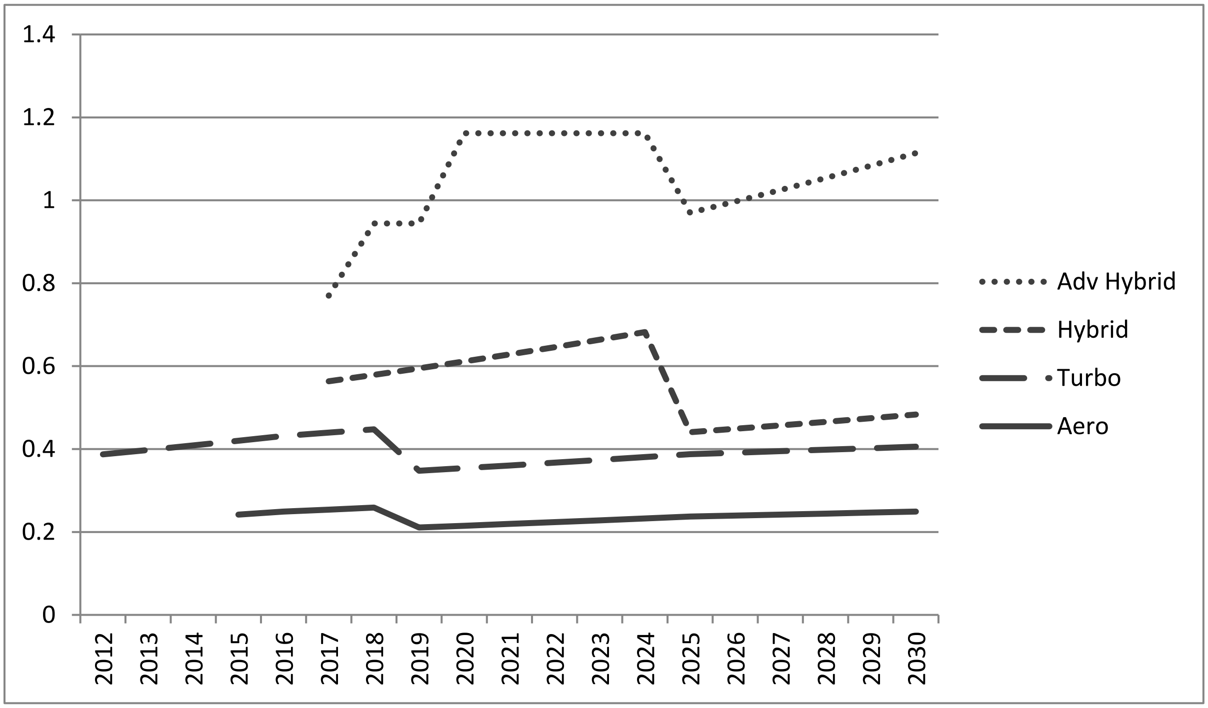

Figure VI-11 – Derived ICM-Based Markups for Advanced Hybrids, Weak Hybrids, Turbo Downsized Engines, and Passive Aerodynamic Improvements

ICMs for these 4 technologies would drive the indirect cost markup rate for the analysis. However, the effect on total costs is also a function of the relative incidence of each of the 50+ technologies shown in Table VI-27 which are assumed to have ICMs similar to one of these 4 technologies. The net effect on costs of these ICMs is also influenced by the learning curve appropriate to each technology, creating numerous different and unique ICM paths. The average ICM applied by the model is also a function of each technology's direct cost and because ICMs are applied to direct costs, the measured indirect cost is proportionately higher for any given ICM when direct costs are higher. The average ICM applied to the fleet for any given model year is calculated as follows:

Equation VI-1 - Average ICM Calculation

$$\sum_{1}^{88} \frac{D_n A_n}{\sum_1^{88} D_n A_n} * ICM_n$$

where —

D = direct cost of each technology
A = application rate for each technology
ICM = average ICM applied to each technology
and n=1,2….88

The CAFE model predicts technology application rates assuming manufacturers will apply technologies to meet standards in a logical fashion based on estimated costs and benefits. The application rates will thus be different for each model year and for each alternative scenario examined. For the MY 2017-2025 FRIA, to illustrate the effects of ICMs on total technology costs, NHTSA calculated the weighted average ICM across all technologies for the preferred alternative.[665] This was done separately for each vehicle type and then aggregated based on predicted sales of each vehicle type used in the model. Results are shown in Table VI-30.

Table VI-30 – Average ICM-Based Markups Applied in Preferred Alternative Scenario MY 2017-2025 FRIA

Model Year	Passenger Cars	Light Trucks	All Vehicles
2017	0.393	0.370	0.383
2018	0.40	0.377	0.390
2019	0.315	0.308	0.312
2020	0.322	0.317	0.320
2021	0.330	0.323	0.327
2022	0.336	0.329	0.333
2023	0.344	0.337	0.341
2024	0.357	0.343	0.351
2025	0.340	0.319	0.331
All Years	0.348	0.336	0.343

The ICM-based markups in Table VI-30 were derived in a manner consistent with the way the RPE is measured, that is, they reflect combined influences of direct cost learning and changes in indirect cost requirements weighted by both the incidence of each technology's adaptation and the relative direct cost of each technology. The results indicate generally higher ICMs for passenger cars than for light trucks. This is a function of the technologies estimated to be adopted for each respective vehicle type, especially in later years when hybrids and electric vehicles become more prevalent in the passenger car fleet. The influence of these advanced vehicles is driven primarily by their direct costs, which greatly outweigh the costs of other technologies. This results in the application of much more weight to their higher ICMs. This is most notable in MYs 2024 and 2025 for passenger cars, when electric vehicles begin to enter the fleet. The average ICM increased 0.013 in 2024 primarily because of these vehicles. It

[665] For each alternative, this rulemaking examined numerous scenarios based on different assumptions, and these assumptions could influence the relative frequency of selection of different technologies, which in turn could affect the average ICM. The scenario examined here assumed a 3 percent discount rate, a 1-year payback period, real world application of expected civil penalties, and reflects expected voluntary over-compliance by manufacturers.

immediately dropped 0.017 in 2025 because both an additional application of steep (20 percent) learning is applied to the direct cost of these vehicles (which reduces their relative weight), and the long-term ICM becomes effective in that year (which decreases the absolute ICM factor). Both influences occur one year after these vehicles begin to enter the fleet because of CAFE requirements.

ICMs also change over time, again, reflecting the different mix of technologies present during earlier years but that are often replaced with more expensive technologies in later years. Across all model years, the wide-ranging application of diverse technologies required to meet CAFE and CO_2 standards produced an average ICM-based markup (or RPE equivalent) of approximately 1.34, applying only 67 percent of the indirect costs found in the RPE and implying total costs 11 percent below those predicted by the RPE-based calculation.

(4) Uncertainty

As noted above, the RPE and ICM assign different markups over direct manufacturing costs, and thus imply different total cost estimates for CAFE and CO_2 technologies. While there is a level of uncertainty associated with both markups, this uncertainty stems from different issues. The RPE is derived from financial statements and is thus grounded in historical data. Although compilation of this data is subject to some level of interpretation, the two independent researchers who derived RPE estimates from these financial reports each reached essentially identical conclusions, placing the RPE at roughly 1.5. All other estimates of the RPE fall between 1.4 and 2.0, and most are between 1.4 and 1.7. There is thus a reasonable level of consistency among researchers that RPEs are 1.4 or greater. In addition, the RPE is a measure of the cumulative effects of all operations manufacturers undertake in the course of producing their vehicles, and is thus not specific to individual technologies, nor of CAFE or CO_2 technologies in particular. Because this provides only a single aggregate measure, using the RPE multiplier results in the application of a common incremental markup to all technologies. This assures the aggregate cost effect across all technologies is consistent with empirical data, but it does not allow for indirect cost discrimination among different technologies or over time. Because it is applied across all changes, this implies the markup for some technologies is likely to be understated, and for others it is likely to be overstated.

By contrast, the ICM process derives markups specific to several CAFE and CO_2 technologies, but these markups have no basis in empirical data. They are based on informed judgment of a panel of engineers with auto industry experience regarding cost effects of a small sample (roughly 8 percent) of the 50+ technologies applied to achieve compliance with CAFE and CO_2 standards. Uncertainty regarding ICMs is thus based both on the accuracy of the initial assessments of the panel on the examined technologies and on the assumption that these 4 technologies are representative of the remaining technologies that were not examined. Both agencies attempted to categorize these technologies in the most representative way possible. However, while this represented the best judgment of EPA and NHTSA's engineering staffs at that time, the actual effect on indirect costs remains uncertain for most technologies. As with RPEs, this means that even if ICMs were accurate for the specific technologies examined, indirect cost will be understated for some technologies and overstated for others.

There was considerable uncertainty demonstrated in the ICM panel's assessments, as illustrated by the range of estimates among the 14 modified Delphi panel members surrounding the central values reported by the panel. These ranges are shown in Table VI-31 and Figure VI-12 , Figure VI-13, and Figure VI-14 below. For the low complexity technology, passive aerodynamic improvements, panel responses ranged from a low of basically no indirect costs (1.001 short term and 1.0 long term), to a high of roughly a 40 percent markup (1.434 and 1.421). For the medium complexity technology, turbo charged and downsized engines, responses ranged from a low estimate implying almost no indirect cost (1.018 and 1.011), to a high estimate implying that indirect costs for this technology would roughly equal the average RPE (1.5) for all technologies (1.527 and 1.445). For the high complexity technology, plug-in hybrid electric vehicles, responses ranged from a low estimate that these vehicles would require significantly less indirect cost than the average RPE (1.367 and 1.121) to a high estimate implying they would require more indirect costs than the average RPE (2.153 and 1.691). There was considerable diversity of opinion among the panel members.[666] This is apparent in Figure VI-12, Figure VI-13, and Figure VI-14, which show the 14 panel members' final estimates for short-term ICMs as scatter plots.

Table VI-31 – Indirect Cost Multipliers - Modified Delphi Panel

	Short Run			**Long Run**		
	Low	Medium	High	Low	Medium	High
Average	1.16	1.29	1.64	1.12	1.2	1.39
Median	1.24	1.264	1.659	1.062	1.199	1.396
Minimum	1.001	1.018	1.367	1	1.011	1.121
Maximum	1.434	1.527	2.153	1.421	1.445	1.691
Std Deviation	0.141	0.145	0.207	0.137	0.131	0.152
t-distribution - Low	1.079	1.206	1.521	1.041	1.124	1.302
t-distribution - High	1.241	1.374	1.759	1.199	1.276	1.478

[666] Sample confidence intervals, which mitigate the effect of outlying opinions, indicate a less extreme but still significant range of ICMs. Applying mean ICMs helps mitigate these potential differences, but there is clearly a significant level of uncertainty regarding indirect costs. A t-distribution is used to estimate confidence intervals because of the small sample size (14 panel members).

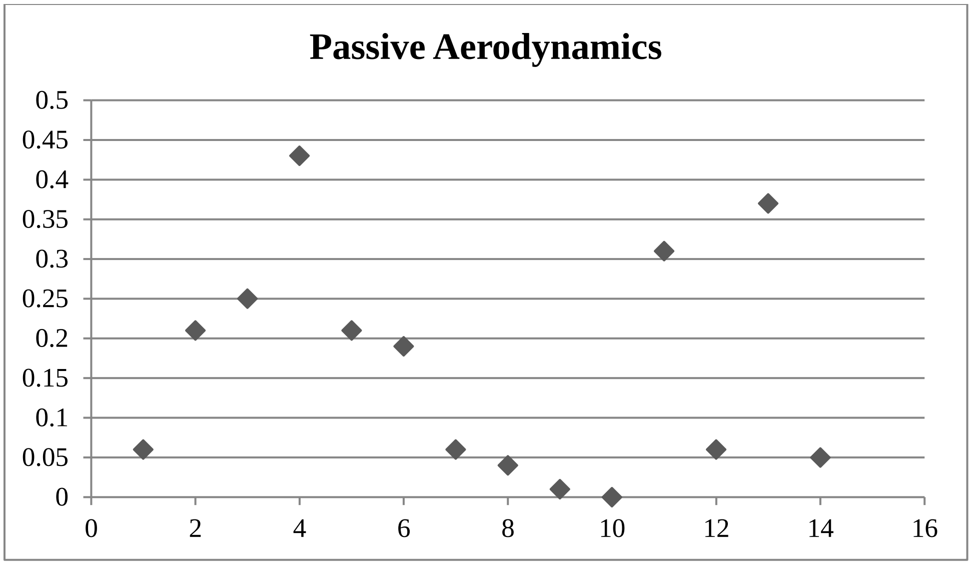

Figure VI-12 – Low Complexity ICM Panel Results

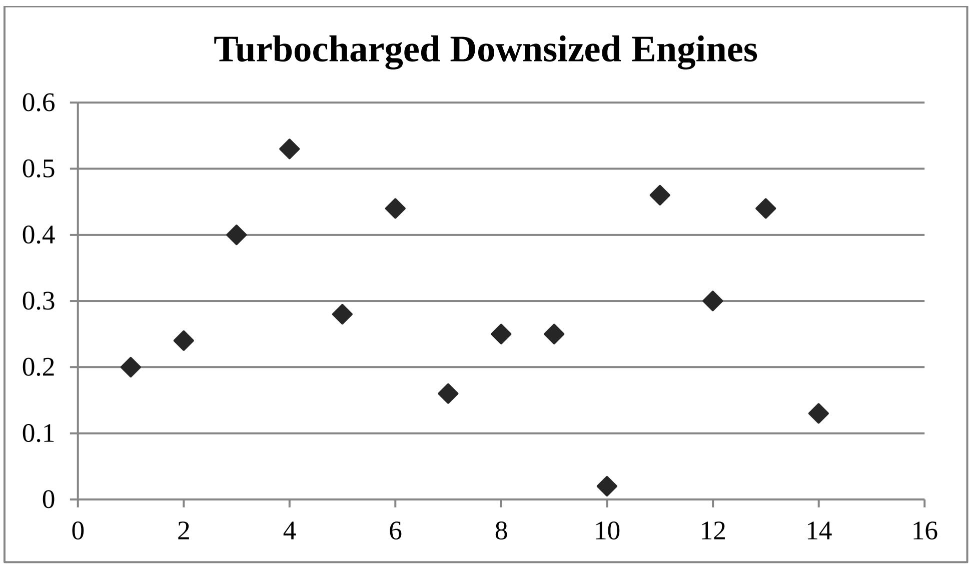

Figure VI-13 – Medium Complexity ICM Panel Results

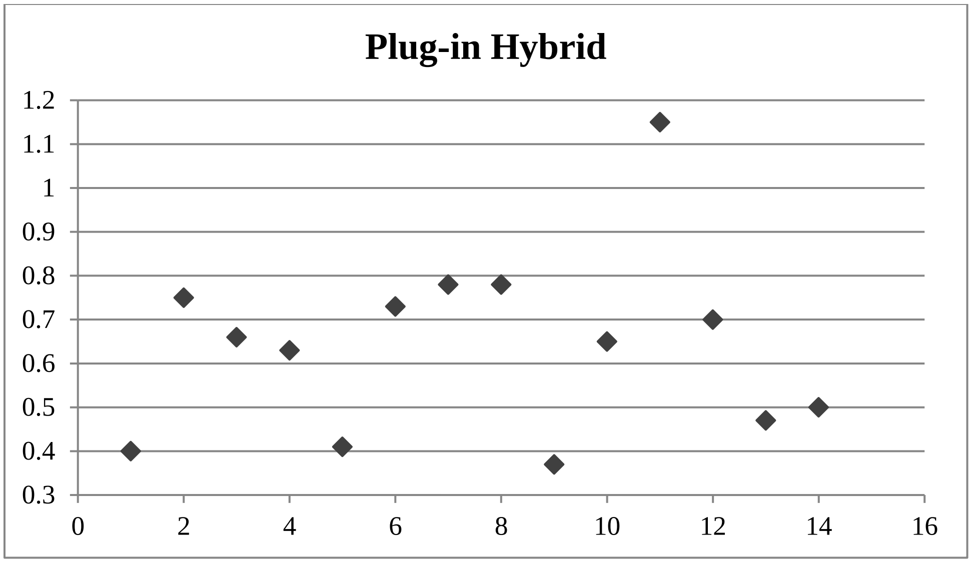

Figure VI-14 – High Complexity ICM Panel Results

Although these results were based on modified Delphi panel techniques, it is apparent the goal of the Delphi process, an eventual consensus or convergence of opinion among panel experts, was not achieved. Given this lack of consensus and the divergence of ICM-based results from the only available empirical measure (the RPE), there is considerable uncertainty that current ICM estimates provide a realistic basis of estimating indirect costs. ICMs have not been validated through a direct accounting of actual indirect costs for individual technologies, and they produce results that conflict with the only available empirical evidence of indirect cost markups. Further, they are intended to represent indirect costs specifically associated with the most comprehensive redesign effort ever undertaken by the auto industry, with virtually every make/model requiring ground-up design modifications to comply. This includes entirely new vehicle design concepts, extensive material substitution, and complete drivetrain redesigns, all of which require significant research efforts and assembly plant redesign. Under these circumstances, one might expect indirect costs to equal or possibly increase above the historical average, but not to decrease, as implied by estimated ICMs. For regulations, such as the CAFE and CO_2 emission standards under consideration, that drive changes to nearly every vehicle system, the overall average indirect costs should align with the RPE value. Applying RPE to the cost for each technology assures that alignment.

In the 2015 NAS study, the Committee stated a conceptual agreement with the ICM method because ICM takes into account design challenges and the activities required to implement each technology. However, although endorsing ICMs as a concept, the NAS Committee stated "the empirical basis for such multipliers is still lacking, and, since their application depends on expert judgment, it is not possible to determine whether the Agencies'

ICMs are accurate or not."[667] NAS also stated "the specific values for the ICMs are critical because they may affect the overall estimates of costs and benefits for the overall standards and the cost effectiveness of the individual technologies."[668] The Committee encouraged continued research into ICMs given the lack of empirical data for them to evaluate ICMs used by the agencies in past analyses. On balance, and considering the relative merits of both approaches for realistically estimating indirect costs, the agencies consider the RPE method to be a more reliable basis for estimating indirect costs.

(5) Using RPE to Evaluate Indirect Costs in this Analysis

To ensure overall indirect costs in the analysis align with the historical RPE value, the primary analysis has been developed based on applying the RPE value of 1.5 to each technology. As noted previously, the RPE is the ratio of aggregate retail prices to aggregate direct manufacturing costs. The ratio already reflects the mixture of learned costs of technologies at various stages of maturity. Therefore, the RPE is applied directly to the learned direct cost for each technology in each year. This was previously done in the MY 2017-2025 FRIA for the preferred alternative for that rulemaking, used in the above analysis of average ICMs. Results are shown in Table VI-32.

Recognizing there is uncertainty in any estimate of indirect costs, a sensitivity analyses of indirect costs has also been conducted by applying a lower RPE value as a proxy for the ICM approach. This value was derived from a direct comparison of incremental technology costs determined in the MY 2017-2025 FRIA.[669] This analysis is summarized in Table VI-32 below. From this table, total costs were estimated to be roughly 18 percent lower using ICMs compared to the RPE. As previously mentioned, there are two different reasons for these differences. The first is the direct effect of applying a higher retail markup. The second is an indirect effect resulting from the influence these differing markups have on the order of the selection of technologies in the CAFE model, which can change as different direct cost levels interact with altered retail markups, shifting their relative overall effectiveness.

The relative effects of ICMs may vary somewhat by scenario, but in this case, the application of ICMs produces total technology cost estimates roughly 18 percent lower than those that would result from applying a single RPE factor to all technologies, or, conversely, the RPE produces estimates that averaged 21 percent higher than the ICM. Under the CAFE model construct, which will apply an alternate RPE to the same base technology profile to represent ICMs, this implies an RPE equivalent of 1.24 would produce similar net impacts [1.5/(1+x) = 1.21, x=0.24]. This value is applied for the ICM proxy estimate. Additional values were also examined over a range of 1.1-2.0. The results, as well as the reference case using the 1.5 RPE, are summarized in Table VI-33.

Several responders submitted comments on the issue of indirect costs. The International Council on Clean Transportation (ICCT) stated that "The agencies abandoned their previously-used indirect cost multiplier method for estimating total costs, which was vetted with peer review, and more complexly handled differing technologies with different supply chain and manufacturing aspects. The agencies have, at this point, opted to use a simplistic retail price equivalent method, which crudely assumes all technologies have a 50 percent markup from the direct manufacturing technology cost. We recommend the agencies revert back to the previously-used and better substantiated ICM approach."[670]

A private commenter, Thomas Stephens, noted that "In Section II. Technical Foundation for NPRM Analysis, under 1. Data Sources and Processes for Developing Individual Technology Assumptions, the agencies state that indirect costs are estimated using a Retail Price Equivalent (RPE) factor. Concerns with RPE factors and the difficulty of accounting for differences in indirect costs of different technologies when using this approach were identified by the EPA (Rogozhin et al., Using indirect cost multipliers to estimate the total cost of adding

[670] NHTSA-2018-0067-11741.

new technology in the automobile industry, International Journal of Production Economics 124, 360-368, 2010), which suggested using indirect cost (IC) multipliers instead of RPE factors. The EPA developed and updated IC multipliers for relevant vehicle technologies with automotive industry input and review. The agencies should consider using these IC multipliers to estimate indirect manufacturing costs instead of RPE factors."[671]

By contrast, the Alliance of Automobile Manufacturers (The Alliance) "supports the use of retail price equivalents in the compliance cost modeling to estimate the indirect costs associated with the additional added technology required to meet a given future standard. The alternative indirect cost multiplier ("ICM") approach is not sufficiently developed for use in rulemaking. As noted by the National Research Council, the indirect cost multipliers previously developed by EPA have not been validated with empirical data.[672] Furthermore, in reference to the memorandum documenting the development of ICMs previously used by EPA, Exponent Failure Analysis Associates found that,

> Large variations were observed between questionnaire responses found in an August 2009 memorandum (average coefficient of variations across all cost contributors was greater than 1, indicating potential disagreement between the experts on the relative impact of the different cost contributors), and review of the respondents' comments indicates confusion and lack of expertise in some areas. The discrepancies between questionnaire responses from the EPA experts, and these experts' potential lack of understanding of the different cost contributors, are not consistent with a rigorous and scientifically sound analysis."[673]

In response to these comments the agencies continue to find the RPE approach preferable to the ICM approach, at least at this stage in the development ICM estimates, for the reasons discussed both above and previously in the NPRM. The agencies note that the concerns are not with the concept of ICMs, but rather with the judgment-based values suggested for use as ICMs, which have not been validated, and which conflict with the empirically derived RPE value. The agencies will continue to monitor any developments in ICM methodologies as part of future rulemakings.

c) Stranded Capital Costs

Past analyses accounted for costs associated with stranded capital when fuel economy standards caused a technology to be replaced before its costs were fully amortized. The idea behind stranded capital is that manufacturers amortize research, development, and tooling expenses over many years, especially for engines and transmissions. The traditional production life-cycles for transmissions and engines have been a decade or longer. If a manufacturer launches or updates a product with fuel-saving technology, and then later replaces that technology with an unrelated or different fuel-saving technology before the equipment and

[672] Cost, Effectiveness, and Development of Fuel Economy Technologies for Light-Duty Vehicles, pages 248-49, National research Council, the National Academies Press (2015).
[673] NHTSA-2018-0067-12073.

research and development investments have been fully paid off, there will be unrecouped, or stranded, capital costs. Quantifying stranded capital costs accounts for such lost investments.

In the Draft TAR and NPRM analyses, only a few technologies for a few manufacturers were projected to have stranded capital costs. As more technologies are included in this analysis, and as the CAFE model has been expanded to account for platform and engine sharing and updated with redesign and refresh cycles, accounting for stranded capital has become increasingly complex. Separately, manufacturers may be shifting their investment strategies in ways that may alter how stranded capital calculations were traditionally considered. For example, some suppliers sell similar transmissions to multiple manufacturers. Such arrangements allow manufacturers to share in capital expenditures, or amortize expenses more quickly.

Manufacturers share parts on vehicles around the globe, achieving greater scale and greatly affecting tooling strategies and costs. Given these trends in the industry and their uncertain effect on capital amortization, and given the difficulty of handling this uncertainty in the CAFE model, this analysis does not account for stranded capital. The agencies' analysis continues to rely on the CAFE model's explicit year-by-year accounting for estimated refresh and redesign cycles, and shared vehicle platforms and engines, to moderate the cadence of technology adoption and thereby limit the implied occurrence of stranded capital and the need to account for it explicitly. The agencies will monitor these trends to assess the role of stranded capital moving forward

d) Cost Learning

Manufacturers make improvements to production processes over time, which often result in lower costs. "Cost learning" reflects the effect of experience and volume on the cost of production, which generally results in better utilization of resources, leading to higher and more efficient production. As manufacturers gain experience through production, they refine production techniques, raw material and component sources, and assembly methods to maximize efficiency and reduce production costs. Typically, a representation of this cost learning, or learning curves, reflect initial learning rates that are relatively high, followed by slower learning as additional improvements are made and production efficiency peaks. This eventually produces an asymptotic shape to the learning curve, as small percent decreases are applied to gradually declining cost levels. These learning curve estimates are applied to various technologies that are used to meet CAFE standards.

For the NPRM and this final rule, the agencies estimated cost learning by considering methods established by T.P. Wright[674] and later expanded upon by J.R. Crawford. Wright, examining aircraft production, found that every doubling of cumulative production of airplanes resulted in decreasing labor hours at a fixed percentage. This fixed percentage is commonly referred to as the progress rate or progress ratio, where a lower rate implies faster learning as

---

[674] Wright, T. P., Factors Affecting the Cost of Airplanes. *Journal of Aeronautical Sciences*, Vol. 3 (1936), pp.124-125. Available at http://www.uvm.edu/pdodds/research/papers/others/1936/wright1936a.pdf.

cumulative production increases. J.R. Crawford expanded upon Wright's learning curve theory to develop a single unit cost model,[675] that estimates the cost of the n^{th} unit produced given the following information is known: (1) cost to produce the first unit; (2) cumulative production of *n* units; and (3) the progress ratio.

As pictured in Figure VI-15, Wright's learning curve shows the first unit is produced at a cost of $1,000. Initially cost per unit falls rapidly for each successive unit produced. However, as production continues, cost falls more gradually at a decreasing rate. For each doubling of cumulative production at any level, cost per unit declines 20 percent, so that 80 percent of cost is retained. The CAFE model uses the basic approach by Wright, where cost reduction is estimated by applying a fixed percentage to the projected cumulative production of a given fuel economy technology.

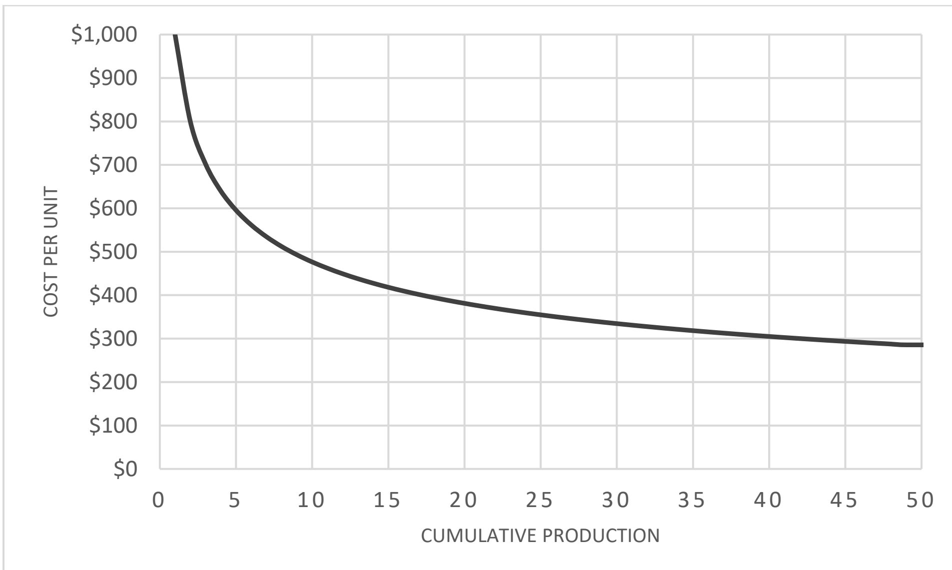

Figure VI-15 – Wright's Learning Curve (Progress Ratio = 0.8)

The analysis accounts for learning effects with model year-based cost learning forecasts for each technology that reduce direct manufacturing costs over time. The agencies evaluated the historical use of technologies, and reviewed industry forecasts to estimate future volumes for the purpose of developing the model year-based technology cost learning curves.

The following section discusses the agencies' development of model year-based cost learning forecasts, including how the approach has evolved from the 2012 rulemaking for MY 2017-2025 vehicles, and how the progress ratios were developed for different technologies

[675] Crawford, J.R., *Learning Curve, Ship Curve, Ratios, Related Data*, Burbank, California-Lockheed Aircraft Corporation (1944).

considered in the analysis. Finally, the agencies discuss how these learning effects are applied in the CAFE Model.

(1) Time versus Volume-Based Learning

For the 2012 joint CAFE/CO_2 rulemaking, the agencies developed learning curves as a function of vehicle model year.[676] Although the concept of this methodology is derived from Wright's cumulative production volume-based learning curve, its application for CAFE and CO_2 technologies was more of a function of time. More than a dozen learning curve schedules were developed, varying between fast and slow learning, and assigned to each technology corresponding to its level of complexity and maturity. The schedules were applied to the base year of direct manufacturing cost and incorporate a percentage of cost reduction by model year declining at a decreasing rate through the technology's production life. Some newer technologies experience 20 percent cost reductions for introductory model years, while mature or less complex technologies experience 0-3 percent cost reductions over a few years.

In their 2015 report to Congress, the National Academy of Sciences (NAS) recommended the agencies should "continue to conduct and review empirical evidence for the cost reductions that occur in the automobile industry with volume, especially for large-volume technologies that will be relied on to meet the CAFE/GHG standards."[677]

In response, the agencies have incorporated statically projected cumulative volume production data of fuel economy improving technologies, representing an improvement over the previously used time-based method. Dynamic projections of cumulative production are not feasible with current CAFE model capabilities, so one set of projected cumulative production data for most vehicle technologies was developed for the purpose of determining cost impact. For many technologies produced and/or sold in the U.S., historical cumulative production data was obtained to establish a starting point for learning schedules. Groups of similar technologies or technologies of similar complexity may share identical learning schedules.

The slope of the learning curve, which determines the rate at which cost reductions occur, has been estimated using research from an extensive literature review and automotive cost tear-down reports (see below). The slope of the learning curve is derived from the progress ratio of manufacturing automotive and other mobile source technologies.

(2) Deriving the Progress Ratio Used in this Analysis

Learning curves vary among different types of manufactured products. Progress ratios can range from 70 to 100 percent, where 100 percent indicates no learning can be achieved.[678]

[677] *Cost, Effectiveness, and Deployment of Fuel Economy Technologies for Light-Duty Vehicles*, National Research Council of the National Academies (2015), available at https://www.nap.edu/resource/21744/deps_166210.pdf.
[678] Martin, J., "What is a Learning Curve?" Management and Accounting Web, University of South Florida, available at: https://www.maaw.info/LearningCurveSummary.htm.

Learning effects tend to be greatest in operations where workers often touch the product, while effects are less substantial in operations consisting of more automated processes. As automotive manufacturing plant processes become increasingly automated, a progress ratio towards the higher end would seem more suitable. The agencies incorporated findings from automotive cost-teardown studies with EPA's literature review of learning-related studies to estimate a progress ratio used to determine learning schedules of fuel economy improving technologies.

EPA's literature review examined and summarized 20 studies related to learning in manufacturing industries and mobile source manufacturing.[679] The studies focused on many industries, including motor vehicles, ships, aviation, semiconductors, and environmental energy. Based on several criteria, EPA selected five studies providing quantitative analysis from the mobile source sector (progress ratio estimates from each study are summarized in Table VI-34, below). Further, those studies expand on Wright's Learning Curve function by using cumulative output as a predictor variable, and unit cost as the response variable. As a result, EPA determined a best estimate of 84 percent as the progress ratio in mobile source industries. However, of those five studies, EPA at the time placed less weight on the *Epple et al. (1991)* study, because of a disruption in learning due to incomplete knowledge transfer from the first shift to introduction of a second shift at a North American truck plant. While learning may have decelerated immediately after adding a second shift, the agencies note that unit costs continued to fall as the organization gained experience operating with both shifts. The agencies now recognize that disruptions are an essential part of the learning process and should not, in and of themselves, be discredited. For this reason, the analysis uses a re-estimated average progress ratio of 85 percent from those five studies (equally-weighted).

Table VI-34 – Progress Ratios from EPA's Literature Review

Author (Publication Date)	**Industry**	**Progress Ratio (Cumulative Output Approach)**
Argote et al. (1997)[680]	Trucks	85%
Benkard (2000)[681]	Aircraft (commercial)	82%
Epple et al. (1991)[682]	Trucks	90%
Epple et al. (1996)[683]	Trucks	85%
Levitt et al. (2013)[684]	Automobiles	82%

In addition to EPA's literature review, this progress ratio estimate was informed based on NHTSA's findings from automotive cost-teardown studies. NHTSA routinely performs evaluations of costs of previously issued Federal Motor Vehicle Safety Standards (FMVSS) for new motor vehicles and equipment. NHTSA's engages contractors to perform detailed engineering "tear-down" analyses for representative samples of vehicles, to estimate how much specific FMVSS add to the weight and retail price of a vehicle. As part of the effort, cost and production volume are examined for automotive safety technologies. In particular, the agency estimated costs from multiple cost tear-down studies for technologies with actual production data from the *Cost and weight added by the Federal Motor Vehicle Safety Standards for MY 1968-2012 passenger cars and LTVs* (2017).[685]

NHTSA chose five vehicle safety technologies with sufficient data to estimate progress ratios of each, because these technologies are large-volume technologies and are used by almost all vehicle manufacturers. Table VI-35 below includes these five technologies and yields an average progress rate of 92 percent:

Table VI-35 – Progress Ratios Researched by NHTSA

Technology	Progress Ratio
Anti-lock Brake Systems	87%
Driver Airbags	93%
Manual 3-pt lap shoulder safety belts	96%
Adjustable Head Restraints	91%
Dual Master Cylinder	95%

For a final progress ratio used in the CAFE model, the five progress rates from EPA's literature review and five progress rates from NHTSA's evaluation of automotive safety technologies results were averaged. This resulted in an average progress rate of approximately 89 percent. Equal weight was placed on progress ratios from all 10 sources. More specifically, equal weight was placed on the *Epple et al. (1991)* study, because disruptions have more recently been recognized as an essential part in the learning process, especially in an effort to increase the rate of output. Further discussion of how the progress ratios were derived for this analysis is located in FRIA Section 9.

ICCT commented that the choice to use safety technology as a model for fuel efficiency led to lower learning rates in the NPRM analysis compared to prior analyses.[686] ICCT stated that safety technologies were chosen for the NPRM because they are used by almost every manufacturer, in contrast to fuel efficiency technologies, where not every manufacturer will use them, particularly when they are first introduced. ICCT stated that to show the impact of changing learning rates, the agencies should run a sensitivity analysis using the learning rates in the TAR, as well as EPA's learning rates in its Final Determination. ICCT concluded that "[w]ithout doing so and without conducting a peer review of the change in approach, it appears clear the agencies have decided to switch to a new costing method that affects all future costs, but without any significant research justification, vetting, or review."

The agencies' selection of a progress rate of 0.89 is based on an average of findings across research and literature reviews conducted by NHTSA and EPA. The EPA cited rates were derived from five studies selected from a sample of 20 transportation modal learning studies that were examined by an EPA contractor, ICF International.[687] One of these 5 studies (Benkard (2000) examines learning in the commercial aircraft industry, which the author notes has many unique features that influence marginal costs. It also has the lowest progress rate. The agencies note that EPA regulates all mobile sources, and while the inclusion of non-passenger vehicle studies in their report was justified, it may have biased the estimate of learning attributable to the motor vehicle industry. Notably, nearly all of the other studies included in the ICF International

---

[686] NHTSA-2018-0067-11741.
[687] *Cost Reduction through Learning in Manufacturing Industries and in the Manufacture of Mobile Sources*. United States Environmental Protection Agency. Prepared by ICF International and available at: https://19january2017snapshot.epa.gov/sites/production/files/2016-11/documents/420r16018.pdf.

study found progress rates higher than the 0.84 rate selected by the authors at that time. In reviewing the ICF study, NHTSA found many other studies not included in the report, including many specific to the motor vehicle and environmental technology industries. Over 90 percent of those studies indicated higher progress ratios than ICF recommended.[688] The agencies' current approach includes a broader and more representative sample of these studies rather than the narrow sample selected by ICF.

The agencies do not agree that safety technologies are adopted by all manufacturers at an early stage. Most safety technologies are initially offered as options or standard equipment on only a small segment of the vehicle fleet, typically luxury vehicles. After a number of years, these technologies may be adopted on less expensive vehicles, and eventually they will become required equipment on all vehicles, but the production process is gradual, as it is with fuel efficiency technologies. FMVSS are necessarily established as performance standards—and automakers are free to develop or choose from existing technologies to achieve such performance requirements—much like automakers can develop or choose from a number of established fuel efficiency technologies to achieve fuel economy requirements. Further, the derivation of progress ratios is based on the concept of a doubling of cumulative production, not time. Therefore, even if production continues at a different pace, it should not disqualify non-fuel efficiency studies. Moreover, the derivation of the progress ratio used in the TAR and Final Determination document were not confined to fuel efficiency technologies. In fact, as noted above, they even included at least one entirely unrelated study of the aircraft industry.

Finally, the agencies note that the previous learning schedules used in the TAR and EPA's Final Determination were only developed through 2025, whereas this final rule projects learning through 2050. The previous learning schedules are thus not directly compatible with the analysis conducted in this Final Rule, making a sensitivity analysis problematic.

(3) Obtaining Appropriate Baseline Years for Direct Manufacturing Costs to Create Learning Curves

Direct manufacturing costs for each fuel economy improving technology were obtained from various sources, as discussed above. To establish a consistent basis for direct manufacturing costs in the rulemaking analysis, each technology cost is adjusted to MY 2018 dollars. For each technology, the DMC is associated with a specific model year, and sometimes a specific production volume, or cumulative production volume. The base model year is established as the MY in which direct manufacturing costs were assessed (with learning factor of 1.00). With the aforementioned data on cumulative production volume for each technology and the assumption of a 0.89 progress ratio for all automotive technologies, the agencies can solve for an implied cost for the first unit produced. For some technologies, the agencies used

[688] *See*, for example, progress ratios of multiple technologies referenced in The Carbon Productivity Challenge: Curbing Climate Change and Sustaining Economic Growth, McKinsey Climate Change Special Initiative, McKinsey Global Institute, June 2008 (quoting from UC Berkeley Energy Resource Group, Navigant Consulting) and Technology Innovation for Climate Mitigation and its Relation to Government Policies, Edward S. Rubin, Carnegie Mellon University, Presentation to the UNFCCC Workshop on Climate Change Mitigation, Bonn, Germany, June 19, 2004.

modestly different progress ratios to match detailed cost projections if available from another source (for instance, batteries for plug-in hybrids and battery electric vehicles).

This approach produced reasonable estimates for technologies already in production, and some additional steps were required to set appropriate learning rates for technologies not yet in production. Specifically, for technologies not yet in production in MY 2017(the baseline analysis fleet), the cumulative production volume in MY 2017 is zero, because manufacturers have not yet produced the technologies. For pre-production cost estimates in the NPRM, the agencies often relied on confidential business information sources to predict future costs. Many sources for pre-production cost estimates include significant learning effects, often providing cost estimates assuming high volume production, and often for a timeframe late in the first production generation or early in the second generation of the technology. Rapid doubling and re-doubling of a low cumulative volume base with Wright's learning curves can provide unrealistic cost estimates. In addition, direct manufacturing cost projections can vary depending on the initial production volume assumed. Accordingly, the agencies carefully examined direct costs with learning, and made adjustments to the starting point for those technologies on the learning curve to better align with the assumptions used for the initial direct cost estimate.

(4) Cost Learning as Applied in the CAFE Model

For the NPRM analysis, the agencies updated the manner in which learning effects apply to costs. In the Draft TAR analysis, the agencies had applied learning curves only to the incremental direct manufacturing costs or costs over the previous technology on the technology tree. In practice, two things were observed: (1) if the incremental direct manufacturing costs were positive, technologies could not become less expensive than their predecessors on the technology tree, and (2) absolute costs over baseline technology depended on the learning curves of root technologies on the technology tree. For the NPRM and final rule analysis, the agencies applied learning effects to the incremental cost over the null technology state on the applicable technology tree. After this step, the agencies calculated year-by-year incremental costs over preceding technologies on the tech tree to create the CAFE model inputs. As discussed below, for the final rule, the agencies revised the CAFE model to replace incremental cost estimates with absolute estimates, each specified relative to the null technology state on the applicable technology tree. This change facilitated quality assurance and is expected to make cost inputs more transparently relatable to detailed model output. Likewise, this change made it easier to apply learning curves in the course of developing inputs to the CAFE model.

The agencies grouped certain technologies, such as advanced engines, advanced transmissions, and non-battery electric components and assigned them to the same learning schedule. While these grouped technologies differ in operating characteristics and design, the agencies chose to group them based on their complexity, technology integration, and economies of scale across manufacturers. The low volume of certain advanced technologies, such as hybrid and electric technologies, poses a significant issue for suppliers and prevents them from producing components needed for advanced transmissions and other technologies at more efficient high scale production. The technology groupings were carried over from the NPRM analysis for the final rule analysis.[689] Like the NPRM, this final rule analysis uses the same groupings that considers market availability, complexity of technology integration, and production volume of the technologies that can be implemented by manufacturers and suppliers. For example, technologies like ADEAC and VCR are grouped together; these technologies were not in production or were only in limited introduction in MY 2017, and are planned to be introduced in limited production by a few manufacturers. The details of these technologies are discussed in Section VI.C.

In addition, for the final rule, as discussed in Section VI.A.4 Compliance Simulation, the agencies expanded model inputs to extend the explicit simulation of technology application through MY 2050, in response to comments on the NPRM. Accordingly, the agencies updated the learning curves for each technology group to cover MYs through 2050. For MYs 2017-2032, the agencies expect incremental improvements in all technologies, particularly in electrification technologies because of increased production volumes, labor efficiency, improved manufacturing methods, specialization, network building, and other factors. While these and other factors contribute to continual cost learning, the agencies believe that many fuel economy improving technologies considered in this rule will approach a flat learning level by the early 2030s. Specifically, older and less complex internal combustion engine technologies and transmissions will reach a flat learning curve sooner when compared to electrification technologies, which have more opportunity for improvement. For batteries and non-battery electrification components, the agencies estimated a steeper learning curve that will gradually flatten after MY 2040. For a more detailed discussion of the electrification learning curves used for the final rule analysis, see Section VI.C.3.e) Electrification Costs. The following Table VI-36 and Table VI-37 show the learning curve schedules for CAFE model technologies for MYs 2017-2033 and MYs 2034-2050.

[689] *See* PRIA Chapter 6 for technology groupings.

Each technology in the CAFE Model is assigned a learning schedule developed from the methodology explained previously. For example, the following chart shows learning rates for several technologies applicable to midsize sedans, demonstrating that while the agencies estimate that such learning effects have already been almost entirely realized for engine turbocharging (a technology that has been in production for many years), the agencies estimate that significant opportunities to reduce the cost of the greatest levels of mass reduction (*e.g.*, MR5) remain, and even greater opportunities remain to reduce the cost of batteries for HEVs, PHEVs, BEVs. In fact, for certain advanced technologies, the agencies determined that the results predicted by the standard learning curves progress ratio was not realistic, based on unusual market price and production relationships. For these technologies, the agencies developed specific learning estimates that may diverge from the 0.89 progress rate. As shown in Figure VI-16, these technologies include: turbocharging and downsizing level 1 (TURBO1), variable turbo geometry electric (VTGE), aerodynamic drag reduction by 15 percent (AERO15), mass reduction level 5 (MR5), 20 percent improvement in low-rolling resistance tire technology over the baseline, and battery integrated starter/generator (BISG).

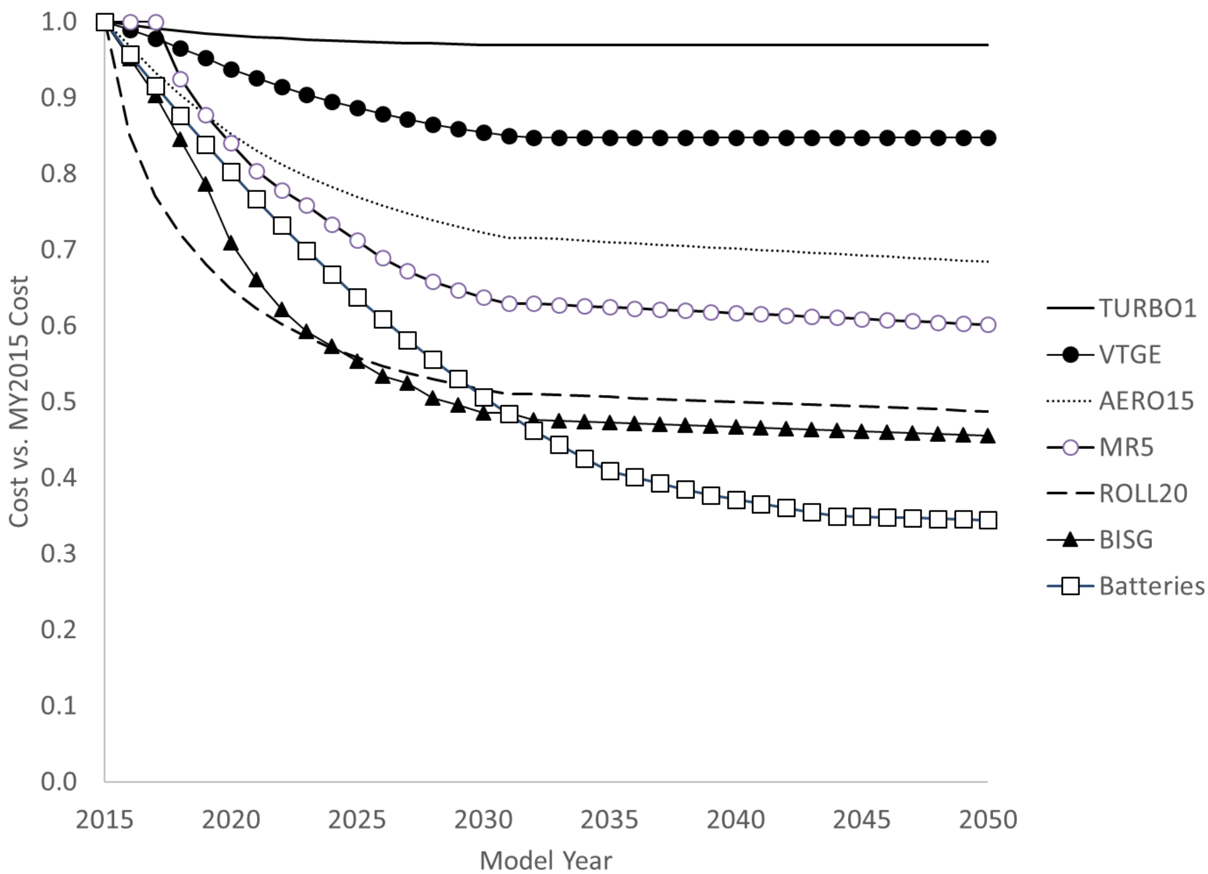

Figure VI-16 – Examples of Year-by-Year Cost Learning Effects (Midsize Sedan)

(5) Potential Future Approaches to Considering Cost Learning in the CAFE Model

As discussed above, cost inputs to the CAFE model incorporate estimates of volume-based learning. As an alternative approach, the agencies have considered modifications to the CAFE model that would calculate degrees of volume-based learning dynamically, responding to the model's application of affected technologies. While it is intuitive that the degree of cost reduction achieved through experience producing a given technology should depend on the actual accumulated experience (*i.e.*, volume) producing that technology, such dynamic implementation in the CAFE model is thus far infeasible. Insufficient data have been available regarding manufacturers' historical application of specific technology. Further, insofar as the agencies' estimates of underlying direct manufacturing costs already make some assumptions about volume and scale, insufficient information is currently available to determine how to dynamically adjust these underlying costs. It should be noted that if learning responds dynamically to volume, and volume responds dynamically to learning, an internally consistent model solution would likely require iteration of the CAFE model to seek a stable solution within the model's representation of multiyear planning. As discussed below, the CAFE model now supports iteration to balance vehicle cost and fuel economy changes with corresponding changes in sales volumes, but, this iteration is not yet implemented in a manner that would necessarily support the balance of learning effects on a multiyear basis. The agencies invited comment on the issue, seeking data and methods that would provide the basis for a practicable approach to doing so. Having reviewed comments on cost learning effects, the agencies conclude it remains infeasible to calculate degrees of volume-based learning in a manner that responds dynamically to modeled technology application. The agencies will continue to examine this issue for future development.

e) Cost Accounting

The CAFE model applied for the NPRM analysis used an incremental approach to specifying technology cost estimates, such that the cost for any given technology was specified as an incremental value, relative to the technology immediately preceding on the relevant technology pathway. For example, the cost of a 7-speed transmission was specified as an amount beyond the cost of a 6-speed transmission. This approach necessitated careful dynamic accounting for the progressive application of the technology as the model worked on a step-by-step basis to "build" a technology solution. As discussed in the corresponding model documentation, the model included complex logic to "back out" some of these costs carefully when, for example, replacing a conventional powertrain with a hybrid-electric system.[690]

To facilitate specification of detailed model inputs and review of detailed model outputs, today's CAFE model replaces incremental cost inputs with absolute cost inputs, such that the estimated cost of each technology is specified relative to a common reference point for the relevant technology pathway. For example, the cost of the above-mentioned 7-speed transmission is specified relative to a 4-speed transmission, as is the cost of every other transmission technology. This change in the structure of cost inputs does not, by itself, change model results, but it does make the connection between these inputs and corresponding outputs

[690] The CAFE Model is available at https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system with documentation and all inputs and outputs supporting today's notice.

more transparent. Model documentation accompanying today's analysis presents details of the updated structure for model cost inputs.

5. Other Inputs to the Agencies' Analysis

CAFE Model input files described above defining the analysis fleet and the fuel-saving technologies to be included in the analysis span more than a million records, but deal with a relatively discrete range of subjects (e.g., what vehicles are in the fleet, what are the key characteristics of those vehicles, what fuel-saving technologies are expected to be available, and how might adding those technologies impact vehicles' fuel economy levels and costs). The CAFE Model makes use of a considerably wider range of other types of inputs, and most of these are contained in other model input files. The nature and function of many of these inputs remains unchanged relative to the model and input files applied for the analysis documented in the proposal that preceded today's notice. The CAFE Model documentation accompanying today's notice lists and describes all model inputs, and explains how inputs are used by the model. Many commenters addressed not only the model's function and design, but also specific inputs. Most input values are discussed either above (e.g., the preceding subsection addresses specific inputs regarding technology costs) or below, in subsections discussing specific economic, energy, safety, and environmental factors. The remainder of this subsection provides an overview of the scope of different model input files. The overview is organized based on CAFE Model file types, as in the model documentation.

a) Market Data File

The "Market Data" file contains the detailed description—discussed above—of the vehicle models and model configurations each manufacturer produces for sale in the U.S. The file also contains a range of other inputs that, though not specific to individual vehicle models, may be specific to individual manufacturers. The file contains a set of specific worksheets, as follows:

"Manufacturers" worksheet: Lists specific manufacturers, indicates whether manufacturers are expected to prefer paying CAFE fines to applying technologies that would not be cost-effective, indicates what "payback period" defines buyers' willingness to pay for fuel economy improvements, enumerates CAFE and CO_2 credits banked from model years prior to those represented explicitly, and indicates how sales "multipliers" are to be applied when simulating compliance with CO_2 standards.

"Credits and Adjustments" worksheet: Enumerates estimates—specific to each manufacturer and fleet—of expected CO_2 and CAFE adjustments reflecting improved AC efficiency, reduced AC refrigerant leakage, improvements to "off cycle" efficiency, and production of flexible fuel vehicles (FFVs). The model applies AC refrigerant leakage adjustments only to CO_2 levels, and applies FFV adjustments only to CAFE levels.

"Vehicles" worksheet: Lists vehicle models and model configurations each manufacturer produces for sale in the U.S.; identifies shared vehicle platforms; indicates which engine and transmission is present in each vehicle model configuration; specifies each vehicle model configuration's fuel economy level, production volume, and average price; specifies several engineering characteristics (e.g., curb weight, footprint, and fuel tank volume); assigns each vehicle model configuration to a regulatory class, technology class, engine class, and safety class; specifies schedules on which specific vehicle models are expected to be redesigned and freshened; specifies how much U.S. labor is involved in producing each vehicle model/configuration; and indicates whether specific technologies are already present on specific vehicle model configurations, or, due to engineering or product planning considerations, should be skipped.

"Engines" worksheet: Identifies specific engines used by each manufacturer and for each engine, lists a unique code (referenced by the engine code specified for each vehicle model configuration and identifies the fuel(s) with which the engine is compatible, the valvetrain design (e.g., DOHC), the engine's displacement, cylinder configuration and count, and the engine's aspiration type (e.g., naturally aspirated, turbocharged). The worksheet also indicates whether specific technologies are already present on specific engines, or, due to engineering or product planning considerations, should be skipped.

"Transmissions" worksheet: Similar to the Engines worksheet, identifies specific transmissions used by each manufacturer and for each transmission, lists a unique code (referenced by the transmission code specified for each vehicle model configuration and identifies the type (e.g., automatic or CVT) and number of forward gears. Also indicates whether specific technologies are already present or, due to engineering or product planning considerations, should be skipped.

b) Technologies File

The Technologies file identifies about six dozen technologies to be included in the analysis, indicates when and how widely each technology can be applied to specific types of vehicles, provides most of the inputs involved in estimating what costs will be incurred, and provides some of the inputs involved in estimating impacts on vehicle fuel consumption and weight. The file contains the following types of worksheets:

"Parameters" worksheet: Not to be confused with the "Parameters" file discussed below, this worksheet in the Technologies file indicates, for each technology class, the share of the vehicle's curb weight represented by the "glider" (the vehicle without the powertrain).

"Technologies" worksheet: For each named technology, specifies the share of the entire fleet to which the technology may be additionally applied in each model year.

Technology Class worksheets: In a separate worksheet for each of the 10 technology classes discussed above (and an additional 2—not used for this analysis—for heavy-duty pickup trucks and vans), identifies whether and how soon the technology is expected to be available for wide commercialization, specifies the percentage of miles a vehicle is expected to travel on a secondary fuel (if applicable, as for plug-in hybrid electric vehicles), indicates a vehicle's expected electric power and all-electric range (if applicable), specifies expected impacts on vehicle weight, specifies estimates of costs in each model year (and factors by which electric battery costs are expected to be reduced in each model year), specifies any estimates of maintenance and repair cost impacts, and specifies any estimates of consumers' willingness to pay for the technology.

Engine Type worksheets: In a separate worksheet for each of 28 initial engine types identified by cylinder count, number of cylinder banks, and configuration (DOHC, unless identified as OHV or SOHC), specifies estimates of costs in each model year, as well as any estimates of impacts on maintenance and repair costs.

c) Parameters File

The "Parameters" file contains inputs spanning a range of considerations, such as economic and labor utilization impacts, vehicle fleet characteristics, fuel prices, scrappage and safety model coefficients, fuel properties, and emission rates. The file contains a set of specific worksheets, as follows:

Economic Values worksheet: Specifies a variety of inputs, including social and consumer discount rates to be applied, the "base year" to which to discount social benefits and costs (i.e., the reference years for present value analysis), discount rates to be applied to the social cost of CO_2 emissions, the elasticity of highway travel with respect to per-mile fuel costs (also referred to as the rebound effect), the gap between test (for certification) and on-road (aka real world) fuel economy, the fixed amount of time involved in each refuel event, the share of the tank refueled during an average refueling event, the value of travel time (in dollars per hour per vehicle), the estimated average number of miles between mid-trip EV recharging events (separately for 200 and 300-mile EVs), the rate (in miles of capacity per hour of charging) at which EV batteries are recharged during such events, the values (in dollars per vehicle-mile) of congestion and noise costs, costs of vehicle ownership and operation (e.g., sales tax), economic costs of oil imports, estimates of future macroeconomic measures (e.g., GDP), and rates of growth in overall highway travel (separately for low, reference, and high oil prices).

Vehicle Age Data worksheet: Specifies nominal average survival rates and annual mileage accumulation for cars, vans and SUVs, and pickup trucks. These inputs are used only for displaying estimates of avoided fuel savings and CO_2 emissions while the model is operating. Calculations reported in model output files reflect, among other things, application of the scrappage model.

Fuel Prices worksheet: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, specifies historical and estimated future fuel prices (and average rates of taxation). Includes values reflecting low, reference, and high estimates of oil prices.

Scrappage Model Values worksheet: Specifies coefficients applied by the scrappage model, which the CAFE Model uses to estimate rates at which vehicles will be scrapped (removed from service) during the period covered by the analysis.

Historic Fleet Data worksheet: For model years not simulated explicitly (here, model years through 2016), and separately for cars, vans and SUVs, and pickup trucks, specifies the initial size (i.e., number new vehicles produced for sale in the U.S.) of the fleet, the number still in service in the indicated calendar year (here, 2016), the relative shares of different fuel types, and the average fuel economy achieved by vehicles with different fuel types, and the averages of horsepower, curb weight, fuel capacity, and price (when new).

Safety Values worksheet: Specifies coefficients used to estimate the extent to which changes in vehicle mass impact highway safety. Also specifies statistical value of highway fatalities, the share of incremental risk (of any additional driving) internalized by drivers, rates relating the cost of damages from non-fatal losses to the cost of fatalities, and rates relating the occurrence of non-fatal injuries to the occurrence of fatalities.

Fatality Rates worksheet: Separately for each model year from 1975-2050, and separately for each vehicle age (through 39 years) specifies the estimated nominal number of fatalities incurred per billion miles of travel by which to offset fatalities.

Credit Trading Values worksheet: Specifies whether various provisions related to compliance credits are to be simulated (currently limited to credit carry-forward and transfers), and specifies the maximum number of years credits may be carried forward to future model years. Also specifies statutory (for CAFE only) limits on the quantity of credit that may be transferred between fleets, and specifies amounts of lifetime mileage accumulation to be assumed when adjusting the value of transferred credits. Also accommodates a setting indicating the maximum number of model years to consider when using expiring credits.

Employment Values worksheet: Specifies the estimated average revenue OEMs and suppliers earn per employee, the retail price equivalent factor applied in developing technology costs, the average quantity of annual labor (in hours) per employee, a multiplier to apply to U.S. final assembly labor utilization in order to obtain estimated direct automotive manufacturing labor, and a multiplier to be applied to all labor hours.

Fuel Properties worksheet: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, specifies energy density, mass density, carbon content, and tailpipe SO_2 emissions (grams per unit of energy).

Fuel Import Assumptions worksheet: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, specifies the extent to which (a) changes in fuel consumption lead to changes in net imports of finished fuel, (b) changes in fuel consumption lead to changes in domestic refining output, (c) changes in domestic refining output lead to changes in domestic crude oil production, and (d) changes in domestic refining output lead to changes in net imports of crude oil.

Emissions Health Impacts worksheet: Separately for NOx, SO_2 and $PM_{2.5}$ emissions, separately for upstream and vehicular emissions, and for each of calendar years 2016, 2020, 2025, and 2030, specifies estimates of various health impacts, such as premature deaths, acute bronchitis, and respiratory hospital admissions.

Carbon Dioxide Emission Costs worksheet: For each calendar year through 2080, specifies low, average, and high estimates of the social cost of CO_2 emissions, in dollars per metric ton. Accommodates analogous estimates for CH_4 and N_2O.

Criteria Pollutant Emission Costs worksheet: Separately for NOx, SO_2 and $PM_{2.5}$ emissions, separately for upstream and vehicular emissions, and for each of calendar years 2016, 2020, 2025, and 2030, specifies social costs on a per-ton basis.

Upstream Emissions (UE) worksheets: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, and separately for calendar years 2017, 2020, 2025, 2030, 2035, 2040, 2045, and 2050, and separately for various upstream processes (e.g., petroleum refining), specifies emission factors (in grams per million BTU) for each included criteria pollutant (e.g., NOx) and toxic air contaminant (e.g., benzene).

Tailpipe Emissions (TE) worksheets: Separately for gasoline and diesel, for each of model years 1975-2050, for each vehicle vintage through age 39, specifies vehicle tailpipe emission factors (in grams per mile) for CO, VOC, NOx, $PM_{2.5}$, CH_4, N_2O, acetaldehyde, acrolein, benzene, butadiene, formaldehyde, and diesel PM_{10}.

d) Scenarios File

The CAFE Model represents each regulatory alternative as a discrete scenario, identifying the first-listed scenario as the baseline relative to which impacts are to be calculated. Each scenario is described in a worksheet in the Scenarios input file, with standards and related provisions specified separately for each regulatory class (passenger car or light truck) and each model year. Inputs specify the standards' functional forms and defining coefficients in each model year. Multiplicative factors and additive offsets are used to convert fuel economy targets to CO_2 targets, the two being directly mathematically related by a linear transformation. Additional inputs specify minimum CAFE standards for domestic passenger car fleets, determine whether upstream emissions from electricity and hydrogen are to be included in CO_2 compliance calculations, specify the governing rates for CAFE civil penalties, specify estimates of the value of CAFE and CO_2 credits (for CAFE Model operating modes applying these values), specify how flexible fuel vehicles (FFVs) and PHEVs are to be accounted for in CAFE compliance calculations, specific caps on adjustments reflecting improvements to off-cycle and AC efficiency and emissions, specify any estimated amounts of average Federal tax credits earned by HEVs, PHEVs, BEVs, and FCVs. The worksheets also accommodate some other inputs, such those as involved in analyzing standards for heavy-duty pickups and vans, not used in today's analysis.

e) "Run Time" Settings

In addition to inputs contained in the above-mentioned files, the CAFE Model makes use of some settings selected when operating the model. These include which standards (CAFE or CO_2) are to be evaluated; what model years the analysis is to span; when technology application is to begin; what "effective cost" mode is to be used when selecting among technologies; whether use of compliance credits is to be simulated and, if so, until what model year; whether dynamic economic models are to be exercised and, if so, how many sales model iterations are to be undertaken and using what price elasticity; whether low, average, or high estimates are to be applied for fuel prices, the social cost of carbon, and fatality rates; by how much to scale benefits to consumers; and whether to report an implicit opportunity cost.

f) Simulation Inputs

As mentioned above, the CAFE Model makes use of databases of estimates of fuel consumption impacts and, as applicable, battery costs for different combinations of fuel saving technologies. For today's analysis, the agencies developed these databases using a large set of full vehicle and accompanying battery cost model simulations developed by Argonne National Laboratory. To be used as files provided separately from the model and loaded every time the model is executed, these databases are prohibitively large, spanning more than a million records and more than half a gigabyte. To conserve space and speed model operation, the agencies have integrated the databases into the CAFE Model executable file. When the model is run, however, the databases are extracted and placed in an accessible location on the user's disk drive. The databases, each of which is in the form of a simple (if large) text file, are as follows:

"FE1_Adjustments.csv:" This is the main database of fuel consumption estimates. Each record contains such estimates for a specific indexed (using a multidimensional "key") combination of technologies for each of the technology classes in the Market Data and Technologies files. Each estimate is specified as a percentage of the "base" technology combination for the indicated technology class.

"FE2_Adjustments.csv:" Specific to PHEVs, this is a database of fuel consumption estimates applicable to operation on electricity, specified in the same manner as those in the main database.

"Battery_Costs.csv:" Specific to technology combinations involving vehicle electrification (including 12V stop-start systems), this is a database of estimates of corresponding base costs (before learning effects) for batteries in these systems.

g) On Road Fuel Economy and CO_2 Emissions Gap

Rather than rely on the compliance values of fuel economy for either historical vehicles or vehicles that go through the full compliance simulation, the model applies an "on-road gap" to represent the expected difference between fuel economy on the laboratory test cycle and fuel economy under real-world operation. In other words, all of the reported physical impacts analysis (including emissions impacts) are based on actual real world fuel consumption and emissions, not on values based on 2-cycle fuel economy ratings and CO_2 emission rates, nor on regulatory incentives such as sales multipliers that treat a single vehicle as two vehicles, or that set aside emissions resulting from generation of electricity to power electric vehicles. This was a topic of interest in the recent peer review of the CAFE model. While the model currently allows the user to specify an on-road gap that varies by fuel type (gasoline, E85, diesel, electricity, hydrogen, and CNG), it does not vary over time, by vehicle age, or by technology combination. It is possible that the "gap" between laboratory fuel economy and real-world fuel economy has changed over time, that fuel economy changes as a vehicle ages, or that specific combinations of fuel-saving technologies have a larger discrepancy between laboratory and real-world fuel economy than others. For today's analysis, and considering data EPA collects from manufacturers regarding vehicles' fuel economy and CO_2 as tested for both fuel economy and emissions compliance and for vehicle fuel economy and emissions labeling (labeling making use of procedures spanning a wider range of real-world vehicle operating conditions), the agencies have determined that the future gap is, at this time, best estimated using the same values applied for the analysis documented in the NPRM. The agencies will continue to assess such test data and any other available data regarding real-world fuel economy and emissions and, as warranted, will revise methods and inputs representing the gap between laboratory and real-world fuel economy and CO_2 emissions in future rulemakings. The sensitivity analysis includes cases representing narrower and wider gaps.

C. The Model Applies Technologies Based on a Least-cost Technology Pathway to Compliance, Given the Framework Above

The CAFE model, discussed in detail above, is designed to simulate compliance with a given set of CAFE or tailpipe CO_2 emissions standards for each manufacturer that sells vehicles in the United States. For the final rule analysis, the model began with a representation of the MY 2017 vehicle model offerings for each manufacturer that included the specific engines and transmissions on each model variant, observed sales volumes, and all fuel economy improving technology that is already present on those vehicles. From there the model added technology, in response to the standards being considered, in a way that minimized the cost of compliance and reflected many real-world constraints faced by automobile manufacturers. The model addressed fleet year-by-year compliance, taking into consideration vehicle refresh and redesign schedules and shared platforms, engines, and transmissions among vehicles.

The agencies evaluated a wide array of technologies manufacturers could use to improve the fuel economy of new vehicles, in both the immediate future and during the timeframe of this rulemaking, to meet the fuel economy and CO_2 standards. The agencies evaluated costs for these technologies, and looked at how costs may change over time. The agencies also considered how fuel-saving technologies may be used on many types of vehicles (ranging from small cars to trucks) and how the technologies may perform in improving fuel economy and CO_2 emissions in combination with other technologies. With cost and effectiveness estimates for technologies, the agencies forecast how manufacturers may respond to potential standards and can estimate the associated costs and benefits related to technology and equipment changes. This assists the assessment of technological feasibility and is a building block for the consideration of economic practicability of the standards.

The agencies described in the NPRM that the characterization of current and anticipated fuel-saving technologies relied on portions of the analysis presented in the Draft TAR, in addition to new information that had been gathered and developed since conducting that analysis, and the significant, substantive input that was received during the Draft TAR comment period.[691] The Draft TAR considered many technologies previously assessed in the 2012 final rule;[692] in some cases, manufacturers have nearly universally adopted a technology in today's new vehicle fleet (for example, electric power steering), but in other cases, manufacturers only occasionally use a technology in today's new vehicle fleet (like turbocharged engines). For a few technologies considered in the 2012 rulemaking, manufacturers began implementing the technologies but have since largely pivoted to other technologies due to consumer acceptance

[691] 83 FR 43021-22 (Aug. 24, 2018).
[692] 77 FR 62624 (Oct. 15, 2012).

issues (for instance, drivability and performance feel issues associated with some dual clutch transmissions without a torque converter) or limited commercial success.

In some cases, EPA and NHTSA presented different analytical approaches in the Draft TAR. However, for the NPRM and final rule analysis, the agencies harmonized their analytical approach to use one set of effectiveness values (developed with one tool), one set of cost assumptions, and one set of assumptions about the limitations of some technologies. To develop these assumptions, the agencies evaluated many sources of data, in addition to many stakeholder comments received on the Draft TAR. The preferred approach was to harmonize on sources and methodologies that were data-driven and reproducible for independent verification, produced using tools utilized by OEMs, suppliers, and academic institutions, and using tools that could support both CAFE and CO_2 analysis. As the agencies noted in the NPRM, a single set of assumptions also facilitated and focused public comment by reducing burden on stakeholders who sought to review all of the supporting documentation surrounding the analysis.

The agencies also identified a preference to use values developed from careful review of commercialized technologies; however, in some cases for technologies that are new, and are not yet for sale in any vehicle, the analysis relied on information from other sources, including CBI and third-party research reports and publications. The agencies strived to keep the technology analysis as current as possible in light of the ongoing technology development and implementation in the automotive industry. Additional emerging technologies added for the final rule analysis are described in further detail, below.

The agencies' process to develop effectiveness assumptions is described in detail in Section VI.B.3 Technology Effectiveness, and summarized here. The NPRM and final rule analysis modeled combinations of more than 50 fuel economy-improving technologies across 10 vehicle types (an increase from five vehicle types in NHTSA's Draft TAR analysis). Only 10 vehicle technology classes were used because large portions of the production volume in the analysis fleet have similar specifications, especially in highly competitive segments. For instance, many mid-sized sedans, small SUVs, and large SUVs coalesce around similar specifications, respectively. Baseline simulations have been aligned around these modal specifications. Parametrically combining these technologies generated more than 100,000 unique combinations per vehicle class. Multiplying the unique technology combinations by the 10 technology classes resulted in the simulation of more than one million individual full-vehicle system models. Modeling was also conducted to determine appropriate levels of engine downsizing required to maintain baseline vehicle performance when advanced mass reduction technology or advanced engine technology were applied. Performance neutrality is discussed in detail in VI.B.3.

Some baseline vehicle assumptions used in the simulation modeling were updated since the Draft TAR based on public comments, and further assessment of the NPRM and final rule analysis fleets. The agencies updated assumptions about curb weight, as well as technology properties like baseline rolling resistance, aerodynamic drag coefficients, and frontal areas. Many of the assumptions are aligned with published research from the Department of Energy and other independent sources.[693] Additional transmission technologies and more levels of aerodynamic technologies than NHTSA presented in the Draft TAR analysis were also added for the analysis. Having additional technologies in the model allowed the agencies to assign baselines and estimate fuel-savings opportunities with more precision.

To develop technology cost assumptions, the agencies estimated present and future costs for fuel-saving technologies, taking into consideration the type of vehicle, or type of engine if technology costs vary by application. Since the 2012 final rule, many cost assessments, including tear down studies, were funded and completed, and presented as part of the Draft TAR analysis. These studies evaluated transmissions, engines, hybrid technologies, and mass reduction.[694] The NPRM and final rule analyses use the 2016 Draft TAR's cost estimates for many technologies. In addition to those studies, the analysis also leveraged research reports from other organizations to assess costs.[695] Consistent with past analyses, this analysis used BatPaC to provide estimates for future battery costs for hybrids, plug-in hybrids, and electric vehicles, taking into account the different battery design characteristics and taking into account the size of the battery for different applications.[696] The agencies also updated technology costs for the NPRM to 2016 dollars, because, as in many cases, technology costs were estimated several years ago, and since then have further updated technology costs to 2018 dollars for the final rule.

Cost and effectiveness values were estimated for each technology included in the analysis. As mentioned above, more than 50 technologies were considered in the NPRM and final rule analyses, and the agencies evaluated many combinations of these technologies in many applications. In the NPRM, the agencies identified overarching potential issues in assessing technology effectiveness and cost, including:

[693] *See, e.g.*, Islam, E., A. Moawad, N. Kim, and A. Rousseau, 2018a, An Extensive Study on Vehicle Sizing, Energy Consumption and Cost of Advance Vehicle Technologies, Report No. ANL/ESD-17/17, Argonne National Laboratory, Lemont, Ill., Oct 2018. https://www.autonomie.net/pdfs/ANL_BaSce_FY17_Report_10042018.pdf Last accessed March 18, 2020; Pannone, G. "Technical Analysis of Vehicle Load Reduction Potential for Advanced Clean Cars," April 29, 2015. Available at https://www.arb.ca.gov/research/apr/past/13-313.pdf. Last accessed December 28, 2019.

[694] FEV prepared several cost analysis studies for EPA on subjects ranging from advanced 8-speed transmissions to belt alternator starter, or Start/Stop systems. NHTSA also contracted with Electricore and EDAG on teardown studies evaluating mass reduction. The 2015 NAS report on fuel economy technologies for light-duty vehicles also evaluated the agencies' technology costs developed based on these teardown studies, and the technology costs used in this proposal were updated accordingly.

[695] For example, the agencies relied on reports from the Department of Energy's Office of Energy Efficiency & Renewable Energy's Vehicle Technologies Office. More information on that office is available at https://www.energy.gov/eere/vehicles/vehicle-technologies-office. Other agency reports that were relied on for technology or other information are referenced throughout the NPRM and accompanying PRIA, and this FRIA and final rule.

[696] For instance, battery electric vehicles with high levels of mass reduction may use a smaller battery than a comparable vehicle with less mass reduction technology and still deliver the same range on a charge. *See, e.g.*, Ward, J. & Gohlke, D. & Nealer, Rachael. (2017). The Importance of Powertrain Downsizing in a Benefit–Cost Analysis of Vehicle Lightweighting. JOM. 69.

- *Baseline vehicle technology level assessed as too low, or too high*. Compliance information was extensively reviewed and supplemented with available literature on the vehicle models considered in the analysis fleet. Manufacturers could also review the baseline technology assignments for their vehicles, and the analysis incorporates feedback received from manufacturers.

- *Technology costs too low or too high*. Tear down cost studies, CBI, literature, and the 2015 NAS study information were referenced to estimate technology costs. In cases where one technology appeared to exceed all other technologies on cost and effectiveness, information was acquired from additional sources to confirm or reject assumptions. Cost assumptions for emerging technologies were reassessed in cases where new information became available.

- *Technology effectiveness too high or too low in combination with other vehicle technologies*. Technology effectiveness was evaluated using the Autonomie full-vehicle simulation modeling, taking into account the impact of other technologies on the vehicle and the vehicle type. Inputs and modeling for the analysis took into account laboratory test data for production and some pre-production technologies, technical publications, manufacturer and supplier CBI, and simulation modeling of specific technologies. Evaluating recently introduced production products to inform the technology effectiveness models of emerging technologies was preferred; however, some technologies that are not yet in production were considered using CBI. Simulation modeling used carefully chosen baseline configurations to provide a consistent, reasonable reference point for the incremental effectiveness estimates.

- *Vehicle performance not considered or applied in an infeasible manner*. Performance criteria, including low speed acceleration (0-60 mph time), high speed acceleration (50-80 mph time), towing, and gradeability (six percent grade at 65 mph) were also considered. In the simulation modeling, resizing was applied to achieve the same performance level as the baseline for the least capable performance criteria but only with significant design changes. The analysis struck a balance by employing a frequency of engine downsizing that took product complexity and economies of scale into account.

- *Availability of technologies for production application too soon or too late*. A number of technologies were evaluated that are not yet in production. CBI was gathered on the maturity and timing of these technologies and the cadence at which manufacturers could adopt these technologies.

- *Product complexity and design cadence constraints too low or too high*. Product platforms, refresh and redesign cycles, shared engines, and shared transmissions were also considered in the analysis. Product complexity and the cadence of product launches were matched to historical values for each manufacturer.

- *Customer acceptance under estimated or over estimated*. Resale prices for hybrid vehicles, electric vehicles, and internal combustion engine vehicles were evaluated to assess consumer willingness to pay for those technologies. The analysis accounts for the differential in the cost for those technologies and the amount consumers have actually paid for those technologies. Separately, new dual-clutch transmissions and manual transmissions were applied to vehicles already equipped with these transmission architectures.

The agencies sought comments on all assumptions for fuel economy technology costs, effectiveness, availability, and applicability to vehicles in the fleet.

Several commenters compared the technology effectiveness and cost estimates from prior rulemaking actions to the NPRM, some commenting that the NPRM analysis represented a better balance of input from all stakeholders regarding the potential costs and benefits of future fuel economy improving technologies,[697] and some commenting that the NPRM analysis represented a step back from the Draft TAR and EPA's Proposed Determination in terms of both the analysis itself and the resulting conclusions about the level of technology required to meet the augural standards.[698] Specifically, while some commenters stated that the Draft TAR and subsequent EPA midterm review documents had recently concluded that augural standards were achievable with very low levels of electrification based on currently available information on technology effectiveness and cost,[699] other commenters reiterated that conventional gasoline powertrains alone were insufficient to achieve post-2021 model year targets.[700]

Generally, the automotive industry supported the agencies' NPRM analysis over previous analyses. In addition to the automotive industry's support of the agencies' use of one modeling tool for analysis, discussed in Section IV, above, the industry also commented in support of specific technology effectiveness, cost, and adoption assumptions used in the updated analysis.

The Alliance commented in support of the NPRM modeling approach, and referenced important technology-specific features of the modeling process, including "The acknowledgement and application of real-world limitations on technology application including a limit on the number of engine displacements available to any one manufacturer, application of shared platforms, engines, and transmissions, and the reality that improvements and redesigns of components are not only extended across vehicles but sometimes constrained in implementation opportunity to common vehicle redesign cycles; recognition of the need for manufacturers to follow "technology" pathways that retain capital and implementation expertise, such as specializing in one type of engine or transmission instead of following an unconstrained optimization that would cause manufacturers to leap to unrelated technologies and show overly optimistic costs and benefits; the application of specific instead of generic technology descriptions that allow for the above-mentioned real-world constraints; [and] the need to accommodate for intellectual property rights in that not all technologies will be available to all manufacturers."[701]

More specifically, the Alliance commented that the analysis appropriately restricted the application of some technologies, like the application of low rolling resistance tires on performance vehicles, and limited aerodynamic improvements for trucks and minivans.[702] Similarly, the Alliance commented in support of the decision to exclude HCR2 technology from the analysis, citing previous comments stating that "the inexplicably high benefits ascribed to this theoretical combination of technologies has not been validated by physical testing."

Ford commented more broadly that "[t]he previous analyses performed by the Agencies too often selected technology benefits from the high-end of the forecasted range, and cost from the lower-end, in part because deference was given to supplier or other third-party claims over manufacturers' estimates."[703] Ford noted that, "[m]anufacturer estimates, while viewed as conservative by some, are informed by years of experience integrating new technologies into vehicle systems in a manner that avoids compromising other important attributes (NVH, utility, safety, etc.)," continuing that "[t]he need to preserve these attributes often limits the actualized benefit of a new technology, an effect insufficiently considered in projections from most non-OEM sources." Ford concluded, as mentioned above, that the NPRM analysis better balanced these considerations.

Toyota commented that the discrepancy between the automotive industry and prior regulatory assessments stemmed from "agency modeling relying on overly optimistic assumptions about technology cost effectiveness and deployment rates."[704] Toyota pointed to a prior analysis that projected compliance for Toyota's MY 2025 lineup using the ALPHA model as an example of how "the agency's analysis failed to account for customer requirements (cost, power, weight-adding options, etc.) that erode optimal fuel economy, and normal business considerations that govern the pace of technology deployment." In contrast, Toyota stated that the "[m]odeled technology cost, effectiveness, and compliance pathways in the proposed rulemaking rely on more recent data as well as more realistic assumptions about the level of technology already on the road today, the pace of technology deployment, and trade- offs between vehicle efficiency and customer requirements."

Honda, in its feedback on the models used in the standard setting process, commented that "the current version of the CAFE model is reasonably accurate in terms of technology efficiency, cost, and overall compliance considerations, and reflects a notable improvement over previous agency modeling efforts conducted over the past few years."[705]

FCA commented in recognition of the CAFE model improvements over the Draft TAR version, but noted they "continue to believe that the cost and benefits used as inputs to the model are overly optimistic."[706] FCA used its updated Jeep Wrangler Unlimited and Ram 1500 pickup models as examples of vehicles that "provide real life examples of the costs and benefits that can be achieved with fuel and weight saving technology;" however, "after all of the real world

[706] NHTSA-2018-0067-11943.

concerns such as emissions, drivability, OBD, and fuels are considered, the benefits observed remain less than those derived by the Autonomie model and used as inputs to the Volpe model."

Conversely, environmental groups, consumer groups, and some States and localities commented that the Draft TAR and subsequent EPA analyses were more representative of the current state of vehicle technologies. These groups all generally commented, in different terms, that the NPRM analysis technology effectiveness was understated and technology costs were overstated, and additional constraints the agencies placed on the analysis, like excluding technologies already in production or constraining technology pathways, also helped lead to that result.[707]

ICCT commented that the agencies "ignored their own rigorous 2015-2017 technological assessment, and have adopted a series of invalid and unsupportable decisions which artificially constrain the availability and dramatically under-estimate levels of effectiveness of many different fuel economy improvement and GHG-reduction technologies and unreasonably increase modeled compliance costs."[708] ICCT also commented that the agencies ignored, suppressed, dismissed, or restricted the use of work done to update technologies and technology cost and effectiveness assessments since the 2012 final rule for MYs 2017-2025. ICCT stated that the "invalid high cost result [of the modeled augural standards in 2025] was created by the agencies by making many dozens of unsupported changes in the technology effectiveness and availability inputs, the technology cost inputs, and the technology package constraints." ICCT stated that "the agencies failed to capture the latest available information and, as a result, their assessment incorrectly and artificially overstates technology costs."

CARB commented that the agencies did not present sufficient new evidence to change previous technical findings, specifically in regards to conventional vehicle technologies.[709] CARB stated that instead of relying on new information, as had been asserted as justification for the proposal, the analysis was based on older data that did not reflect current technology. Accordingly, CARB pointed out that previous analysis by the agencies projected far less need for electrification than what was required in the proposal, stating that the underlying cause is a reduction in the assumed cumulative improvements for what advanced gasoline technology is able to achieve.

A coalition of States and Cities similarly commented that "[t]he Agencies' conclusions regarding the technology necessary to meet the 2025 standards and the cost of that technology run counter to the evidence before the agency, diverge from prior factual findings without explanation and without transparency as to the source of data relied on, and are unsupported by

[707] NHTSA-2018-0067-11873; NHTSA-2018-0067-11984.
[708] NHTSA-2018-0067-11741 full comments.
[709] NHTSA-2018-0067-11873.

any reasoned analysis. Such analysis bears many hallmarks of an arbitrary and capricious action."[710]

Roush Industries, commenting on behalf of CARB, commented that "the 2018 PRIA projected average costs for technology implementation to achieve the existing standards to be significantly overstated and in conflict with the 2016 Draft TAR cost estimates generated by the Agencies only two years earlier."[711] Roush commented that the Draft TAR analyses of cost and incremental fuel economy improvement necessary to achieve the augural standards was consistent with Roush's own estimates and other published data.

Similarly, H-D Systems (HDS), commenting on behalf of the California DOJ, commented that "the estimates in the 2016 TAR on technology cost and effectiveness still represent the correct estimates based on the latest available data."[712] HDS, in its analysis of the costs of technologies to meet different potential standards between the Draft TAR and the NPRM, noted that "costs for most conventional (i.e., non-electric) drivetrain technologies were similar in both reports in that costs were within +5% of the average of the costs from the two reports. The only exception was the cost estimate for the High CR second generation Atkinson cycle or HCR2 engine which was estimated to be much more expensive. Due to differences in nomenclature, transmission technology costs could not be directly compared but were similar at the highest efficiency level. In contrast, cost of hybrid technology was estimated to be much higher in the PRIA and were 200 to 250% higher for strong hybrids. Costs of drag reduction, rolling resistance reduction and auxiliary system technologies were also quite similar but the cost of mass reduction was substantially higher in the PRIA by a factor of 2 to 3. Costs of engine friction reduction appear not to be included in the cost computation for the PRIA although the technology appears to be integrated into some of the engine technology packages analyzed in the PRIA to estimate effectiveness."

CFA commented that "[t]he overarching discussion of technology developments that introduces the NHTSA analysis is fundamentally flawed and infects the entire proposal," taking issue with the NPRM statement that "some options considered in the original order for the National Program ha[d] not worked out as EPA/NHTSA anticipated."[713] CFA commented that the agencies failed to note that some technology options have performed better than anticipated, and "the fact that some technologies have done better than expected is a basis for increasing the standards, not in the context of a mid-term review that was supposed to tweak the long-term program."

NCAT commented that the "inflation of projected technology costs does not appear to be attributable primarily to the projected cost of any given technology, but rather to modeling constraints on the application of such technologies to vehicles. Many of these constraints appear

to be arbitrary and NHTSA's departure from prior analyses in these respects is not adequately supported."[714]

Environmental groups and States also commented that the agencies either should reincorporate all the Draft TAR or the EPA Proposed and Final Determination analyses' technologies, technology effectiveness values, and technology costs into the analysis, and/or compare the final rule analysis with those prior analyses to show how the updated assumptions changed the results from those prior analyses.

For example, ICCT commented that "[f]or the agencies to conduct a credible regulatory assessment they must remove all the technology availability constraints, re-incorporate and make available the full portfolio of technology options as was available in EPA's analysis for the original 2017 Final Determination, and include at least 15 g/mile CO_2 for off-cycle credits by 2025, to credibly reflect the real-world technology developments in the auto industry."[715] ICCT also stated that "[t]he agencies need to identify each and every technology cost input used in their modeling, and provide a clear engineering and evidence based justification for why that cost differs from the costs employed in the extremely well documented and well justified Draft TAR and in EPA's 2016 TSD and 2017 Final Determination, taking into account the above discussion of significant new evidence developed since those prior estimates were made. Absent such disclosure and justification, the default assumption needs to be that the prior costs estimated based on the most recent data are more appropriate than the estimates used for the proposal."

In addition, groups of commenters were equally split on the ability of technologies to meet different compliance targets. For example, the Alliance commented that "the only technologies that have demonstrated the improvements necessary to meet the MY 2025 standards are strong hybrids, plug-in electric vehicles, and fuel cell electric vehicles. The Agencies' analysis for this Proposed Rule predict the need for significant growth in sales of electrified vehicles, a finding consistent with third-party analyses."[716] In contrast, UCS commented that electrified powertrains "are not especially relevant for the MY 2022-2025 regulations."[717]

The agencies are aware that the prior analyses concluded that compliance with the augural standards could largely be met through advances in gasoline vehicle technologies, and with only very low levels of strong hybrids and electric vehicles. As the agencies stated in the NPRM, consistent with both agencies' statutes, the proposal was entirely *de novo,* based on an entirely new analysis reflecting the best and most up-to-date information available to the agencies at the time of this rulemaking.[718] As discussed in Section IV, Section VI.B, and further below, the NPRM and final rule analyses reflect updates to technology effectiveness estimates, technology costs, and the methodology for applying technologies to vehicles that the agencies believed better represent the state of technology and the associated costs compared to prior

analyses, that result in pathways to compliance that look both similar and different to those in prior analyses.

That said, several of the effectiveness and cost values used in the NPRM and final rule analysis were directly carried over from the 2012 rule for MYs 2017-2025, Draft TAR, and EPA Midterm Evaluation analyses.[719] Several others were carried over from the 2015 NAS report,[720] which the agencies heavily relied upon in past analyses even if specific cost or effectiveness values were not used. Different technology effectiveness estimates, cost estimates, or adoption constraints were employed where the agencies had information, from technical reports, manufacturers, or other stakeholders, indicating that a technology could or could not be feasibly adopted in the rulemaking timeframe, or a technology could or could not be adopted in the way that the agencies had previously modeled it. Notably, most differences in pathways to compliance are attributable to only a few significant differences between this rulemaking analysis and prior rulemaking analyses.

For example, as discussed in Section VI.B.3 Technology Effectiveness and modeling and Section VI.C.1 Engine Paths, in the EPA Draft TAR and Proposed Determination analyses, effectiveness of HCR engine technologies and downsized turbocharged engine technologies were estimated using Tier 2 certification fuel. Tier 2 certified fuel has a higher octane rating compared to regular octane fuel.[721,722,723] As summarized by EPA in the PD TSD, “EPA's estimate of effectiveness for gasoline-fueled engines and engine technologies was based on Tier 2 Indolene fuel although protection for operation in-use on Tier 3 gasoline (87 AKI E10) was included in the analysis of engine technologies considered both within the Draft TAR and Proposed Determination. Additionally, in the technology assessment for this Proposed Determination, EPA has considered the required engine sizing and associated effectiveness adjustments when performance neutrality is maintained on 87AKI gasoline typical of real-world use.”[724]

NHTSA’s effectiveness analysis for the Draft TAR used some engine maps also developed using premium octane gasoline. However, at the time NHTSA stated the agency would ensure all future engine model development will be performed with regular grade octane gasoline.[725] Commenters like Ford stated the effectiveness estimates for turbo downsized engine packages were too high, in part because of the use of high octane fuel. However they also commented in appreciation of NHTSA’s acknowledgement that any subsequent analysis would be based on fuel at an appropriate octane level, as they stated the impact of the change needed to be reflected in future analyses.[726]

Engine specifications used to create the engine maps for the NPRM and the final rule analysis were developed using Tier 3 fuel to assure the engines were capable of operating on real

world regular octane (87 pump octane = (R+M/2)). The process was similar to what manufacturers must do to ensure engines have acceptable noise, vibration, harshness, drivability, performance, and will not fail prematurely when operated on regular octane fuel. This eliminated the need for any adjustments that were applied in the 2016 Draft TAR and PD TSD to account for Tier 2 to Tier 3 fuel properties. This accounts for some of the effectiveness and cost differences for engine technologies between the Draft TAR/Proposed Determination and the NPRM/final rule. For more details, see Section VI.C.1 Engine Paths.

The agencies believe ICCT's and other commenters' assertions that the engine maps should reflect Tier 2 fuel and not be updated for Tier 3 fuel would ignore these important considerations, and would provide engine maps that could not achieve the fuel economy improvements unless operated on high octane fuel. Therefore, the agencies determined that engine maps developed for the Draft TAR and EPA Proposed Determination that were based on Tier 2 fuel should not be used for the NPRM and final rule analyses for these technical reasons.

As another related example, the agencies described that prior analyses had relied heavily on the availability of the HCR2 (or ATK2) "future" Atkinson Cycle engine as a cost-effective pathway to compliance for stringent alternatives, but many engine experts questioned its technical feasibility and near-term commercial practicability.[727] The agencies explained that EPA staff began theoretical development of this conceptual engine with a best-in-class 2.0L Atkinson cycle engine and then increased the efficiency of the engine map further, through the theoretical application of additional technologies in combination, including cylinder deactivation, engine friction reduction, and cooled exhaust gas recirculation. While the potential of such an engine is interesting, nevertheless the engine remains entirely speculative. No production HCR2/ATK2 engine, as outlined in the EPA SAE paper,[728] has ever been commercially produced. Furthermore, the engine map has not been validated with hardware, bench data, or even on a prototype level (as no such engine exists to test to validate the engine map).

Vehicle manufacturers also commented on EPA's effectiveness assumptions and estimates of HCR2/ATK2 model's future penetration levels in the Draft TAR, stating "[t]he effectiveness values for the 'futured' ATK2 package—projected at 40% penetration in 2025MY and includes cooled exhaust gas recirculation (CEGR) and cylinder deactivation (DEAC)—are too high, primarily due to overtly-optimistic efficiencies in the base engine map, insufficient accounting of CEGR and DEAC integration losses, and no accounting of the impact of 91RON Tier 3 test fuel," and that "44% fleet-wide penetration of ATK2 in 2025MY is unrealistic given the limited number of powertrain refresh cycles available before 2025MY. In addition, it is unreasonable to assume that OEMs already heavily invested in different high-efficiency

[727] 83 FR 43038.
[728] Schenk, C. and Dekraker, P., "Potential Fuel Economy Improvements from the Implementation of cEGR and CDA on an Atkinson Cycle Engine," SAE Technical Paper 2017-01-1016, 2017. Available at https://doi.org/10.4271/2017-01-1016.

powertrain pathways (e.g., turbo-downsizing) would be able to commit the immense resources needed to reach these high ATK2 penetration levels in such a short time."[729]

Accordingly, the agencies decided to not include HCR2 technology in the NPRM and final rule analysis. The engine model was not used because no observable physical demonstration of the speculative technology combination model has yet been created. Further, many questions remain about the model's practicability as specified, especially in high load, low engine speed operating conditions. The HCR2 model combines multiple technologies to provide cumulative estimate of benefits without consideration the practical interaction of technologies. This approach runs contrary to the modeling approach attempted in the NPRM and final rule analysis. The approach the agencies tried to follow restricted models to adding discrete advanced technologies. This approach allowed an accounting of synergetic effects, identified incremental benefits, and increased the precision of cost estimates.

As another example, further discussed in Section VI.B.1 Analysis Fleet, the agencies had traditionally taken different approaches to assigning baseline road load reduction technology assignments. For analyzing baseline levels of mass reduction in an analysis fleet, NHTSA had developed for the Draft TAR a regression model to summarize a vehicle's weight savings using a relative performance approach and accounting for vehicle content, using cost curves developed from teardown studies of a MY 2011 Honda Accord and MY 2014 Chevrolet Silverado pickup truck. EPA developed its own methodology that classified vehicles based on weight reductions from a MY 2008 vehicle, compared to the MY 2014 version of the same vehicle, using a cost curve from a tear-down study of a MY 2010 Toyota Venza. In the EPA's mass reduction technology costing approach, a cost reduction was applied when mass reduction 1 technology was applied to a system at mass reduction 0 technology level. NHTSA's approach, used in the NPRM and final rule analysis, set baseline mass reduction assignments so costs of implementing mass reduction technologies are fully applied as vehicle platforms move along the mass reduction technology path.

The agencies also included additional advanced powertrain technologies and other vehicle-level technologies in the technology pathways between the Draft TAR and NPRM, and between the NPRM and final rule. However, manufacturers and suppliers have repeatedly told the agencies that there are diminishing returns to increasing the complexity of advanced gasoline engines, including in the amount of fuel efficiency benefit that they can provide. For example, Toyota commented, in response to the EPA SAE paper benchmarking the 2018 Camry with the 2.5L Atkinson-cycle engine and "futuring" midsize exemplar vehicles based on the generated engine map,[730] that although EPA's addition of cylinder deactivation to the hypothetical 2025 exemplar vehicle is technically possible and would provide some fuel economy and CO_2 benefit, the primary function of cylinder deactivation is to reduce engine pumping losses which the Atkinson cycle and EGR already accomplish on the 2018 Camry.[731] Toyota concluded, "The overlapping and redundant measures to reduce engine pumping losses would add costs with

[730] Kargul, J., Stuhldreher, M., Barba, D., Schenk, C. et al., "Benchmarking a 2018 Toyota Camry 2.5-Liter Atkinson Cycle Engine with Cooled-EGR," SAE Technical Paper 2019-01-0249, 2019, doi:10.4271/2019-01-0249.
[731] NHTSA-2018-0067-12431, at 8.

diminishing efficiency returns." Similarly, BorgWarner commented that they "do not expect that variable compression ratio (VCR) or homogeneous charge compression ignition (HCCI) will see broad application in the short term, if ever. While each of these technologies can offer marginal efficiency gains at some engine speed-load conditions, the use of down-sized boosted engines with 8-10 speed transmissions makes it possible to run engines at near optimum conditions and effectively minimizes gains from VCR or HCCI. VCR mechanisms result in additional mass, cost and complexity, and true HCCI has yet to be demonstrated in a production vehicle. The agencies do not believe that OEMs will judge these technologies to be cost effective."[732]

So, while previous analyses may have shown pathways to compliance with increasingly complex advanced gasoline engines, the NPRM and final rule analyses more appropriately reflect that the most complex gasoline engine technologies will account for a smaller share of manufacturers' products during the rulemaking timeframe. However, despite this fact, the NPRM and final rule analysis include *more* advanced powertrain technologies than previous analyses, in part to account for important considerations like intellectual property and the fact that some manufacturers have already started down the path of incorporating a certain advanced engine technology in their product portfolio, and that abrupt switching to another advanced engine technology would result in unrealistic stranding of capital costs. In addition, greater precision in how cumulative technologies applied to engines, as estimated through the Autonomie effectiveness modeling, appropriately reflects the diminishing returns to efficiency benefits that those advanced engines can provide. Moreover, as identified by a wide range of commenters, battery costs are projected to fall in the rulemaking timeframe to a point where, in the compliance modeling, it becomes more cost effective to add electrification technologies to vehicles than to apply other advanced gasoline engine technologies.

Finally, the agencies declined to incorporate some information and data for the NPRM or final rule central analysis for reasons discussed in the following sections. In general, the data produced by agencies or submitted by commenters failed to isolate effectiveness impacts of individual technologies (or in some cases a combination of two or several technologies). The data included effects from additional unaccounted and undocumented technologies. Because the effectiveness improvement measured or claimed resulted from more than just the reported sources, the actual effectiveness of the technology or technologies is obfuscated and easily under or over predicted. Using effectiveness values generated in this manner carries a high risk of double counting effectiveness and undercounting costs.

In many cases, this problem exists where data or information is based on laboratory testing or on-road testing of production vehicles or components including engines and transmissions. Production vehicles and components usually include multiple technology improvements from one redesign to the next, and rarely incorporate just a single technology change. Furthermore, technology improvements on production vehicles in some cases cannot be readily observed, such as the level of mechanical friction in an engine, and isolation and identification of the improvement attributable to each technology would be impractical given the costs and time required to do so. That said, in some cases, where possible to do so, the agencies

---

[732] NHTSA-2018-0067-11895.

used the data or information from production vehicles to corroborate information from the Autonomie simulations. However, the agencies declined to apply that data or information directly in the analysis if the effectiveness improvement attributable to a particular technology could not be isolated.

The agencies made these updates from prior analyses not, as some commenters have suggested, to "artificially overstate technology costs,"[733] or to "ignore the knowledge and expertise of the EPA engineering and compliance staff,"[734] "so that the model in many instances selects more expensive, less fuel efficient technology while excluding less expensive and more efficient alternatives,"[735] but because the updates reflected the agencies' reasonable assessment of the current state of vehicle technologies and their costs, and the state of future vehicle technologies and costs in the rulemaking timeframe.

Separate from the decision to update assumptions used for the NPRM analysis from prior analyses, the agencies did refine some technology effectiveness and cost assumptions from the NPRM to this final rule analysis. In addition to being appropriate for technical reasons, this should address some commenters' overarching concerns about understated technology effectiveness and overstated technology costs. For example, several commenters noted that the costs of BISG/CISG systems were higher for small Cars/SUVs and medium cars than for medium SUVs and pickup trucks, which the Alliance and FCA described as "implausible" and "misaligned with industry understanding," and which ICCT described as "contrary to basic engineering logic, which holds that a system which would be smaller and have lower energy and power requirements would be less expensive, not more."[736] The agencies agree, and have made changes to address this issue, as described in Section VI.C.3.a) Electrification.

After considering comments, the agencies also added several engine technologies and technology combinations for the final rule analysis. These included a basic high compression ratio Atkinson cycle engine, a variable compression ratio engine, a variable turbo geometry engine, and a variable turbo geometry with electric assist engine (VTGe). The NPRM discussed and provided engine maps for each of these technologies. The agencies also added new technology combinations including diesel engines with cylinder deactivation, turbocharged engines with advanced cylinder deactivation, diesel engines paired with manual transmissions, and diesel engines paired with 12-volt start-stop technology. Transmission revisions included updating the effectiveness of 6-speed automatic transmissions, applying updated shift logic for 10-speed automatic transmissions, and increasing the gear span for efficient 10-speed automatic transmissions. Mass reduction technology was expanded to include up to 20 percent curb weight reduction, compared with up to 10 percent for the NPRM. These changes, and the comments upon which they were based, are described in further detail in the following sections.

1. Engine paths

The internal combustion (IC) engine is a heat engine that converts chemical energy in a fuel into mechanical energy. Chemical energy of the fuel is first converted to thermal energy by means of combustion or oxidation with air inside the engine. This thermal energy raises the temperature and pressure of the gases within the engine, and the high-pressure gas then expands against the internal mechanisms of the engine. This expansion is converted by the mechanical linkages of the engine to a rotating crankshaft, which is the output of the engine. The crankshaft, in turn, is connected to a transmission to transmit the rotating mechanical energy to the desired final use, particularly the propulsion of vehicles.

IC engines can be categorized in a number of different ways depending upon which technologies are designed into the engine: by type of ignition (e.g., spark ignition or compression ignition), by engine cycle (e.g., Otto cycle or Atkinson cycle), by valve actuation (e.g., overhead valve (OHV), single overhead camshaft (SOHC), or dual overhead camshaft (DOHC)), by basic design (e.g., reciprocating or rotary), by configuration and number of cylinders (e.g., inline four-cylinder (I4) or V-shaped six-cylinder (V6)), by air intake (e.g., forced induction (turbo or super charging) or naturally aspirated), by method of fuel delivery (e.g., port injection or direction injection), by fuel type (e.g., gasoline or diesel), by application (e.g., passenger car or light truck),or by type of cooling (e.g., air-cooled or water-cooled). For each combination of technologies among the various categories, there is a theoretical maximum efficiency for all engines within that set. There are various metrics that can be used to compare engine efficiency, and the four metrics the agencies use or discuss in this FRIA are:

- Brake specific fuel consumption (BSFC), which is the mass of fuel consumed per unit of work output (amount of fuel used to produce power);
- Brake thermal efficiency (BTE), which is the total fuel energy released per unit of work output (percentage of fuel used to produce power);
- Fuel consumption (gallons per mile), which looks at the gallons of fuel consumed per unit of work output (mile travelled); and
- Fuel economy (in MPG), which is the amount of work output (miles travelled) per unit (gallon) of fuel consumed.

When comparing the efficiency of IC engines, it is important to identify the metric(s) used and the test cycle for the measurement because results vary widely when engines operate over different test cycles. Two-cycle fuel economy tests used to certify vehicles' compliance with the CAFE standards tend to overestimate the average fuel economy motorists will typically achieve during on-road operation.[737] In the NPRM and for this final rule analysis, the agencies considered technology effectiveness for the 2-cycle test procedures and AC and off-cycle test procedures to evaluate how technologies could be applied for manufacturers to comply with standards. The agencies also considered real world operation beyond these test procedures when

---

[737] 77 FR 62988.

considering IC engine technologies in order to assure the technologies were configured and specified in a manner that could be used in real world vehicle applications.

a) Fuel Octane

As mentioned in other sections of the Preamble, the agencies go to great lengths to ensure engine technologies considered for potential compliance pathways are feasible for real-world implementation and effectiveness. An important facet of this evaluation are both the fuels that are used for efficiency testing and also the fuels that consumers may purchase in the marketplace.

In the NPRM, the agencies included a general overview of fuel octane (stability) level, including levels currently available, and the potential impact of fuel octane on engines developed for the U.S. market.[738] The agencies described that a typical, overarching goal of optimal spark-ignited engine design and operation is to maximize the greatest amount of energy from the fuel available, without manifesting detrimental impacts to the engine over expected operating conditions. Design factors, such as compression ratio, intake and exhaust value control specifications, and combustion chamber and piston characteristics, among others, are all impacted by the octane of the fuel consumers are anticipated to use.[739]

The agencies also discussed potential challenges associated with octane levels available currently, and how those octane levels may play a role in potential vehicle fuel efficiency improvements. Vehicle manufacturers typically develop their engines and engine control system calibrations based on the fuel available to consumers. In many cases, manufacturers may recommend a fuel grade for best performance and to prevent potential damage. In some cases, manufacturers may *require* a specific fuel grade for both best performance, to achieve advertised power ratings, and/or to prevent potential engine damage.

Consumers, though, may or may not choose to follow the manufacturer's recommendation or requirement for a specific fuel grade for their vehicle. As such, vehicle manufacturers often choose to employ engine control strategies for scenarios where the consumer uses a lower than recommended, or required, fuel octane level, as a way to mitigate potential engine damage over the life of a vehicle. These strategies limit the extent to which some efficiency improving engine technologies can be implemented, such as increased compression ratio and intake system and combustion chamber designs that increase burn rates and rate of in-cylinder pressure rise. If the minimum octane level available in the market were higher (especially the current sub-octane regular grade in the mountain states), vehicle manufacturers might not feel compelled to design vehicles sub-optimally to accommodate such blends.

When knock (also referred to as detonation) is encountered during engine operation, at the most basic level, non-turbocharged engines can adjust the timing of the spark that ignites the

[738] PRIA at 253.

[739] In addition, PRIA Chapter 6 contains a brief discussion of fuel properties, octane levels used for engine simulation and in real-world testing, and how octane levels can impact performance under these test conditions.

fuel, as well as the amounts of fuel injected at each intake stroke ("fueling"). In turbocharged applications, knocking is typically controlled by adjusting boost levels along with spark timing and/or the amount of fuel injected. Past rulemakings discussed other techniques that may be employed to allow higher compression ratios, including optimizing spark timing, and adding of cooled exhaust gas recirculation (EGR). Regardless of the type of spark-ignition engine or technology employed, efforts to reduce or prevent knock with the lower-octane fuels that are available in the market result in the loss of potential power output, creating a "knock-limited" constraint on performance and efficiency.

The agencies noted that despite limits imposed by available fuel grades, manufacturers continue to make progress in extracting more power and efficiency from spark-ignited engines. Production engines are safely operating with regular 87 AKI fuel with compression ratios and boost levels once viewed as only possible with premium fuel. According to the Department of Energy, the average gasoline octane level has remained fundamentally flat starting in the early 1980's and decreased slightly starting in the early 2000s. During this time, however, the average compression ratio for the U.S. fleet has increased from 8.4 to 10.52, a more than 20 percent increase. As explained by the Department of Energy, "[t]here is some concern that in the future, auto manufacturers will reach the limit of technological increases in compression ratios without further increases in the octane of the fuel."[740] As such, manufacturers are still limited by the fuel grades available to consumers and the need to safeguard the durability of their products for all of the available fuels; thus, the potential improvement in the design of spark-ignition engines continues to be overshadowed by the fuel grades available to consumers.

EPA and NHTSA also described ongoing research and positions from automakers and advocacy groups on fuel octane levels, including comments received during past agency rulemakings and on the 2016 Draft TAR regarding the potential for increasing octane levels in the U.S. market. The agencies described arguments for adjusting to octane levels, including making today's premium grade the base grade of fuel available, which could enable low cost design changes to improve fuel economy and reduce tailpipe CO_2 emissions. Challenges associated with this approach include the increased cost to consumers who drive vehicles designed for current regular octane grade fuel, who would not benefit from the use of the higher cost higher-octane fuel. The costs of such a transition to higher-octane fuel would be high and persist well into the future, since unless current regular octane fuel were unavailable in the North American market, manufacturers would be effectively unable to redesign their engines to operate on higher-octane fuel. In addition, the full benefits of such a transition would not be realized until vehicles with such redesigned engines were produced for a sufficient number of model years largely to replace the current on-road vehicle fleet. The transition to net positive benefits would take many years.

The agencies also described input received from renewable fuel industry stakeholders and from the automotive industry supporting high-octane gasoline fuel blends to enable fuel economy and CO_2 improving technologies such as higher compression ratio engines.

---

[740] Fact of the Week, *Fact #940: August 29, 2016 Diverging Trends of Engine Compression Ratio and Gasoline Octane Rating*, U.S. Department of Energy, https://www.energy.gov/eere/vehicles/fact-940-august-29-2016-diverging-trends-engine-compression-ratio-and-gasoline-octane (last visited Mar. 21, 2018).

Stakeholders suggested that mid-level (e.g., E30) high-octane ethanol blends should be considered and that EPA should consider requiring that mid-level blends be made available at service stations. Stakeholders supporting higher-octane blends suggested that higher-octane gasoline could provide auto manufacturers with more flexibility to meet more stringent standards by enabling opportunities for use of lower tailpipe CO_2 emitting technologies (e.g., higher compression ratio engines, improved turbocharging, optimized engine combustion).

The agencies sought additional comment in the NPRM on various aspects of current fuel octane levels and how fuel octane could play a role in the future. More specifically, the agencies sought comment on how increasing fuel octane levels could have an impact on product offerings and engine technologies, as well as what improvements to fuel economy and tailpipe CO_2 emissions could result from higher-octane fuels. The agencies sought comment on an ideal octane level for mass-market consumption, and whether there were downsides with increasing the available octane levels and, potentially, eliminating lower-octane fuel blends. EPA also requested comment on whether and how EPA could require the production and use of higher-octane gasoline consistent with Title II of the Clean Air Act.

The agencies received numerous, wide-ranging comments in response to the NPRM discussion, and some direct responses to the agencies' requests for comments. The commenters included fuel producers, individual vehicle manufactures, environmental groups, vehicle suppliers, fuel advocacy groups, and agricultural organizations, among others. Commenters provided a broad range of comments ranging from explication of the many challenges to increasing available octane levels, to claims of the substantial efficiency increases that could be easily obtained by requiring higher-octane levels.

Several ethanol industry stakeholders commented in support of requiring higher-octane fuels using mid-level ethanol blends. The High-Octane, Low Carbon (HOLC) Alliance commented that it believes "NHTSA and EPA have a critical opportunity to cost-effectively ensure progress in fuel efficiency and CO_2 emissions standards. Scientific experts agree that high-octane, low-carbon fuel can yield greater fuel economy and emissions benefits when paired with internal combustion engines (ICEs). But, to realize such benefits, automobile manufacturers require approval sooner rather than later to such fuels. Alternatively, automobile manufacturers will be limited in their ability to maximize the environmental performance of their vehicles until non-liquid fuel engines become more readily available. In finalizing the Proposed Rule, the HOLC Alliance strongly urges EPA and NHTSA to establish a pathway forward toward incentivizing the production and adoption of higher-octane, lower carbon fuels. By doing so, EPA and NHTSA can continue to incrementally increase CO_2 and fuel economy standards, respectively."[741]

Renewable Fuels Associations (RFA) commented that "it strongly believes vehicles and fuels must be considered together as integrated systems. As EPA has recognized in the past, a 'systems approach enables emission reductions that are both technologically feasible and cost

[741] HOLC Alliance, Detailed Comments, EPA-HQ-OAR-2018-0283-4196.

effective beyond what would be possible looking at vehicle and fuel standards in isolation.' Because ethanol-based high-octane low-carbon fuel blends would enable cost-effective gains in fuel economy and carbon dioxide reductions, the agencies should take steps to support [high-octane low-carbon] fuels in the final SAFE rule."[742]

RFA cited several studies indicating benefits are available from raising the floor of fuel octane levels currently available, and, particularly, "[t]he results from the studies reviewed generally support a main conclusion that splash blending ethanol is a highly effective means of raising the octane rating of gasoline and enabling low-cost efficiencies and reduced emissions in modern spark-ignition engines."[743] In addition, National Corn Growers Association stated that, "[w]ithout a change in fuel, automakers are reaching the limits on the efficiency gains that can be achieved with technology changes."[744]

The National Corn Growers Association, in conjunction with associated corn growing and agricultural groups, pointedly stated the EPA should, "[s]et a minimum fuel octane level of 98 RON and phase out low octane fuels as new optimized vehicles enter the market in MY 2023," and concluded that approving a "midlevel ethanol blend vehicle certification fuel would enable automakers to expedite design and testing of optimized vehicles for use with this new fuel."[745]

The 25x25 Alliance commented that "to meet the dual goals of greater fuel efficiency and reduced GHG emissions, the utilization of higher compression spark ignition internal combustion engines will be essential. Increasing engine compression improves thermal efficiency. However, as compression increases, higher-octane fuels will be needed to prevent engine knock. Automakers and advocacy groups have expressed support for increases to fuel octane levels for the US market. Ethanol with its octane rating of 113 offers engine knock resistance at a lower cost than any other octane booster in gasoline. In addition, ethanol's lower direct and life-cycle GHG emissions as compared to gasoline are well documented. For this reason, a fuel produced from a mixture of ethanol and gasoline and used in conjunction with advanced high compression engines presents itself as a technology pathway capable of complying with new CAFE/GHG standards." They continue, "HOLC supporters recognize numerous barriers and other associated regulatory hurdles must be resolved before HOLC ethanol fuels are adopted at large scale… 25x25 believes it is imperative that the vehicle and fuel be treated as a comprehensive system. To date CAFE/GHG standards have largely focused on vehicle engine technology. Advanced engine vehicles perform best in concert with fuels of suitable properties and composition to optimally enable and power them."[746]

[746] 25x25 Alliance, Detailed Comments, EPA-HQ-OAR-2018-0283-4210.

The American Coalition for Ethanol (ACE) commented that "high-octane blends comprised of 25 to 30 percent ethanol would help bring down the cost for consumers compared to the premium-priced octane level advocated by oil refiners. Ethanol has a blending octane rating of nearly 113 and trades at a steep discount to gasoline. In many wholesale markets today, ethanol costs at least 60 cents per gallon less than gasoline. Ethanol delivers the highest octane at the lowest cost, allowing automakers to benefit by continuing to develop high-compression engine technologies and other product offerings to achieve efficiency improvements and reduced emissions. The ideal way to transition from today's legacy fleet to new vehicles with advanced engine technologies designed to run optimally on a high-octane fuel is to utilize FFVs as bridge vehicles that can provide immediate demand for mid-level ethanol blends."[747]

Growth Energy commented that with a mid-level ethanol blend, automakers not only get higher-octane that they can use to optimize engines and gain further fuel efficiency, they will also see a fuel that has demonstrably lower carbon dioxide emissions.[748] The Illinois Corn Growers' Association et al., commented that "NHTSA and EPA must adapt the existing regulatory structure to reflect the specific characteristics of mid-level blend fuels. Working together, the ethanol industry, automakers, EPA and NHTSA can bring about, during the period covered by the SAFE program, a new generation of high efficiency internal combustion engines optimized to take advantage of this new fuel's unique properties."[749]

Ethanol industry commenters provided comment on several EPA actions they believe would be necessary to support higher-octane mid-level fuel blends:

- Set a minimum fuel octane level and phase out low-octane fuels as new optimized vehicles enter the market;
- Approve a high-octane, mid-level ethanol blend vehicle certification fuel;
- Correct the fuel economy formula by updating the R-Factor to be at or nearly "1" to reflect documented operation of modern engine technology;
- Extend a RVP waiver of 1 psi to all gasoline containing at least 10 percent ethanol;
- Adopt the Argonne National Laboratory GREET model to determine updated lifecycle carbon emissions for ethanol;
- Establish meaningful credits to automakers to incentivize transition to higher-octane fuel vehicles and continue to support flex-fuel vehicles; and
- Provide equal treatment to vehicle technologies that reduce carbon emissions.

The Clean Fuels Development Coalition, et al. suggested that, "the 'ideal octane level' to optimize LDV performance, fuel efficiency, and reduce harmful emissions and consumer costs is 98–100 RON produced with E30+ 'clean octane.'"[750] Concurrently, the HOLC Alliance and

[750] Clean Fuels Development Coalition, et al., Detailed Comments, NHTSA-2018-0067-11988.

ACE, among others, also supported that 98 to 100 RON would be ideal octane levels for the nation.[751]

BorgWarner, a supplier to major automobile manufacturers, commented that "[f]uel octane is a limiting factor in the selection of compression ratio for all spark-ignition engines and the amount of boost for turbocharged engines. Higher-octane is particularly effective for using higher compression ratios with boosted engines," and stated that "[t]here is substantial merit to raising the minimum octane required because current fuel pricing penalizes consumers for using higher-octane fuel. A base octane of 95 RON would be consistent with Europe. This would allow consistent development of engines for the broader US-EU market. Prior to the introduction of ethanol into gasoline, the base blend for regular fuel was typically 92 RON. Addition of 10% ethanol to this base blend gave 95 RON regular, so the base blend would be reformulated to retain the 92 RON at a lower cost. Returning to the previous base blend would be cost effective to the consumer."[752]

Auto manufacturers also provided comment on the topic of higher-octane fuels. The Alliance of Automobile Manufacturers (the Auto Alliance) commented that it "has long advocated for the availability of cost-effective, higher-octane fuel. The Alliance also believes the Agencies should require a transition to a higher minimum-octane gasoline (minimum 95–98 RON). There are several ways to produce higher-octane grade gasoline, such as expanding the ethanol availability, but the Alliance does not promote any sole or particular pathway."[753] The Alliance reiterated its position regarding fuel octane levels where, "[t]he Alliance has long supported two goals regarding the octane (anti-knock) properties of gasoline: 1) the availability of cost effective higher-octane fuels, greater than 95 Research Octane Number (RON) and 2) the immediate elimination of subgrade fuel less than 87 anti-knock index (AKI)." The Alliance also noted that "[t]he higher-octane fuel that is available today is sold as a premium grade. To support future engine technologies, the approach taken with today's premium fuel option would not be expected to provide an attractive value proposition to the customer; therefore, a new higher minimum-octane gasoline, 95–98 RON, is needed to achieve anticipated performance."

Ford Motor Company agreed with the Auto Alliance's collective comments on fuel octane level and added specific support to raising minimum octane levels, stating that "Ford concurs with those comments and supports increasing the marketplace octane rating in the U.S. to a minimum of 95 Research Octane Number (RON)." Ford also generally supported the agencies' fuel octane discussion in terms of impacts to vehicle performance, where "[h]igher octane gasoline enables opportunities for the use of key energy-efficient technologies, including: higher compression ratio engines, lighter and smaller engines, improved turbocharging, optimized engine combustion phasing/timing, and low temperature combustion strategies. All of

these technologies paired with higher-octane gasoline permit smaller engines to meet the demands of the consumer while at the same time providing higher overall efficiencies."[754]

Volkswagen commented "[t]here may be several potential ways to achieve a high-octane fuel that may be more costly to the vehicle than others. Achieving an E10 high-octane fuel may mean a different hardware set than on E20 or E30 high-octane fuel. Elimination of sub-grades of market fuel (less than 87AKI) quickly is very important. If current 87 AKI and 85 AKI fuels remain in the market for backward compatibility (such as if an E30 were chosen as the high-octane fuel of the future), a robust method at the fuel dispensing station and incorporated into the fueling station equipment to prevent mis-fueling is necessary. However, an E10 high-octane pathway might have far fewer compatibility problems and might bring extra fuel economy to the drivers of those current vehicles."[755]

The agencies also received comments from the petroleum industry regarding higher-octane fuels. API commented that "[g]iven the multiple engine technology pathways available to the automakers for achieving future fuel economy and CO_2 emissions targets, the challenge of determining future market fuel gasoline octane number needs is complex and not yet settled. API believes that the octane number issue should be part of a comprehensive transport policy that addresses both vehicles and fuels as a system. API and its members are engaged in collaborations with the automakers and other stakeholders to better understand future fuel requirements for emerging powertrain technologies." API also commented "the future for gasoline octane number will be driven by the stringency of regulations that set future fuel economy and CO_2 requirements, the collective responses of the automakers to those regulations, consumer preferences regarding vehicles and fuels, and fuel supply economics. EPA's authority to regulate gasoline octane number is doubtful. Therefore, EPA should not attempt to regulate gasoline octane number at this time."[756]

In terms of challenges associated with potential high-octane fuel deployment, the American Fuel & Petrochemical Manufacturers (AFPM) commented that, "[a]side from a lack of legal authority, EPA faces numerous technical, logistical, and legal challenges and uncertainties in requiring the use of higher-octane fuels. Any such requirement would need a separate rulemaking dedicated to such a purpose with an extensive technical record in support, including test data on vehicles designed for the higher-octane fuel and on the existing fleet with and without higher-octane."[757]

AFPM also commented that it does not support the potential regulatory requirement for the production or use of higher octane gasoline as a compliance option. AFPM commented that EPA lacks the authority to require the use of higher octane fuels under CAA § 211(c)(1)(A). AFPM further commented "[t]he only vehicles legally permitted to use more than 15 percent ethanol blends are flex-fuel vehicles, which are currently certified to utilize both E10 and E85. Without an alternative certification for an auto manufacturer to build an E30 certified vehicle,

[756] API, Detailed Comments, EPA-HQ-OAR-2018-0283-5458.
[757] AFPM, Detailed Comments, EPA-HQ-OAR-2018-0283-5698.

which would require extensive testing and certification procedures as well as sufficient market availability of the certification fuel, it would be inappropriate for the Administration to consider such vehicles as a viable option in the 2022-2026 compliance period."

Gasoline retailers also commented regarding higher-octane fuels. NACS and SIGMA commented that they support examining the use of such fuels as a potential path towards future emissions reductions and that it will be important that the agencies appropriately consider and address a variety of related issues, including:

1. How to allow and handle the expanded sales of higher-octane fuels, which may include fuels that currently face barriers to sale, such as E15;
2. Streamlining the registration and regulation of higher-level blends of ethanol;
3. Addressing misfuelling liability concerns of retailers;
4. Streamlining federal labeling requirements and ensuring federal preemption of state requirements; and
5. Addressing any other regulatory and legislative challenges associated with the use of higher-octane fuels.[758]

NATSO commented that "the Agencies should under no circumstances consider 'requiring that mid-level [ethanol] blends be made available at service stations'" and went on to say that "retailers would need to be assured that they will not be held responsible for customers that misfuel… Federal dispenser labeling requirements would have to be streamlined and state requirements would have to be preempted… Auto manufacturers would have to warrant all new higher-octane vehicles up to at least E15 depending upon vehicles' capabilities, and would have to affirmatively state which cars in the existing fleet can run on E15 and ensure that the cars are warrantied or retroactively warrantied as such."[759]

UCS commented that "[a]n orderly transition to high-octane fuel would take several years to complete. It will take time for the necessary regulations to be finalized, for vehicles optimized for high-octane gasoline to come to market and to build out the fuel distribution infrastructure to make this fuel broadly available. And even once high-octane gasoline is in use, it will take more time for automakers to phase-in new models optimized for high-octane fuel and to fully replace the legacy E10 fleet. Another factor to consider is that the rising share of high-octane gasoline will be buffered by falling sales of gasoline, given increasing fuel efficiency, such that the overall demand for ethanol will change more slowly. The agencies' expectation is that high-octane gasoline will not significantly enter commerce before 2026, and subsequently will only gradually gain market share through 2040. There is no realistic prospect of completing this process before 2025 or 2026, the timeframe of this rulemaking. The appropriate context for this discussion within vehicle rules is the next round of fuel economy and emission standards. Even then, an expeditious rulemaking process will be required to achieve adequate regulatory clarity to facilitate rapid adoption post-2026." UCS also commented "[we] strongly oppose granting fuel

[758] Joint submission on behalf of NACS and SIGMA, Detailed Comments, EPA-HQ-OAR-2018-0283-5824.
[759] NATSO, Detailed Comment, EPA-HQ-OAR-2018-0283-5484.

economy credits based on the technical potential of vehicles to operate on high-octane fuel before there is clear evidence that high-octane fuel is in use and the potential fuel economy benefits are being realized on the road."[760]

The agencies have reviewed the submissions received in response to their solicitation of comments concerning fuel octane levels and recognize the potential that higher-octane fuels, coupled with advanced engine technologies, can provide for improvements to fuel economy and tailpipe CO_2 emissions. The agencies agree with commenters that establishing a higher minimum octane for gasoline is a complex undertaking that would require consideration of a wide array of difficult issues. In light of the complexity of the constellation of issues, the fact that EPA did not propose new octane requirements, and that EPA's authority to set fuel requirements resides in CAA section 211(c)(1), the agencies recognize that the present rulemaking is not the appropriate vehicle to set octane levels. If EPA pursues future rulemaking action on this topic, it would consider these comments in that context and in consideration of the appropriate statutory provisions. The agencies note that the current vehicle certification process provides a path to certify a vehicle requiring the use of high-octane fuel, which allows the impact of such fuels to be captured over the required certification test cycles for CO_2 emissions and fuel economy.

EPA also is declining to adopt new incentives for flex-fueled vehicles (FFVs) (vehicles designed to operate on gasoline or E85 or a mixture), as some commenters suggested. FFV incentives were not identified by EPA in its request for comments in the proposed rule and are outside the scope of this rulemaking.

The analyses conducted for this rulemaking assumed the use of Tier 3 fuels, where applicable, which are considered directly representative, or a reasonable proxy for, fuels available for consumers to purchase. As explained in the previous paragraph, agency actions related to test fuels, consumer available fuels, or flexible-fuel incentives are out of scope of this rulemaking. However, to the extent that the agencies consider any additional rulemaking actions related to fuel octane requirements and/or availability, the agencies note that further analysis to set CAFE and CO_2 standards would also reflect any potential, related impacts of those potential changes.

b) Engine Maps

Engine paths include numerous engine technologies that manufacturers can use to improve fuel economy and reduce CO_2 emissions. Some engine technologies can be incorporated into existing engine design architectures with minor or moderate changes to the engine, but many engine technologies require an entirely new engine architecture or a major refresh. For this final rule analysis, twenty-three unique engine technologies are available for adoption, and are evaluated uniquely across the ten separate vehicle types (technology classes).

For the NPRM and final rule analysis, the impact of engine technologies on fuel consumption, torque, and other metrics was characterized using GT-POWER© modeling

---

[760] UCS, Detailed Comments, NHTSA-2018-0067-12039.

conducted by IAV Automotive Engineering, Inc. (IAV). IAV is one of the world's leading automotive industry engineering service partners and has extensive experience in testing and modeling engines and combustion. GT-POWER is a commercially available engine modeling tool with detailed cylinder and combustion modeling capabilities.[761] GT-POWER is used to simulate engine behavior and provides data on engine metrics, including power, torque, airflow, volumetric efficiency, fuel consumption, turbocharger performance, and other parameters. The primary outputs of IAV's use of GT-POWER for this analysis are the development of engine maps that provide operating characteristics of engines equipped with specific technologies.

When an engine is running, at any given point in time, the operation can be characterized by the engine's crankshaft rotational speed (typically in revolutions per minute, or RPM) and engine output (torque) level. Engines can operate at a range of engine speed and torque levels. Engine maps provide a visual representation of various engine performance characteristics at each engine speed and torque combination across the operating range of the engine. A common example of a performance characteristic is BSFC.[762] Other characteristics include engine emissions, engine efficiency, and engine power.

Engine maps have the appearance of topographical maps, typically with engine speed on the horizontal axis and engine torque on the vertical axis. A third engine characteristic, BSFC, is displayed as contours, defining the operating regions for that BSFC with each contour showing all operating points at a specified BSFC value. Once created, the data they contain is referenced for engine fuel consumption at a given engine speed and torque operating point.

For the NPRM and final rule analysis, the agencies relied on IAV to develop engine maps representing each of the engine technologies. IAV used benchmark production engine test data, component test data, and manufacturers and suppliers' technical publications to develop a one-dimensional GT-POWER engine model for the baseline engine technology configuration. Technologies were incrementally added to the baseline model to assess their impact on fuel consumption. The following is a representative example of how IAV created the engine maps used in this analysis.

First, IAV defined the characteristics of Eng01 (a base VVT engine) and optimized it for all the combustion parameters while minimizing fuel consumption and maintaining performance. The result of this was a fuel map as a function of BMEP and engine RPM. IAV then took the same Eng01 and adopted characteristics of SGDI technology to the base engine. The new engine (Eng18, VVT and SGDI) was then optimized for all combustion parameters while minimizing fuel consumption and maintaining performance. The result was an engine fuel map for Eng18, as a function of BMEP and engine speed. The engine map is directly comparable to the engine map for Eng01 and the difference in those engine maps specifically identifies the effectiveness impact of VVT and SGDI technologies. This process was repeated for all of the IAV engine maps that used Eng01 (VVT) as the baseline engine. This methodology ensured the engine maps

[761] More information regarding GT Power Modeling is available at https://www.gtisoft.com/gt-suite-applications/propulsion-systems/gt-power-engine-simulation-software.
[762] The amount of fuel needed to achieve a specific power, or how efficiently an engine uses fuel to produce work.

represent the maximum improvement in BSFC for each engine configuration change, while considering real world design constraints.

IAV used its global engine database that includes benchmarking data, engine test data, single cylinder test data, prior modeling studies, and technical publications and information presented at conferences to populate the assumptions and inputs used for engine map modeling, and to validate the ultimate results.[763] Argonne used the engine maps resulting from this analysis as inputs for the Autonomie full vehicle modeling and simulation.

As described in the NPRM and PRIA, the agencies developed engine maps for technologies that are in production today or that are expected to be available in the rulemaking timeframe. The agencies recognize that engines with the same combination of technologies produced by different manufacturers will have differences in BSFC and other performance measures, due to differences in the design of engine hardware (*e.g.*, intake runners and head ports, valves, combustion chambers, piston profile, compression ratios, exhaust runners and ports, turbochargers, etc.), control software, and emission calibration. Therefore, the engine maps are intended to represent the levels of performance that can be achieved on average across the industry in the rulemaking timeframe.

Accordingly, the agencies noted that it was expected that the engine maps developed for this analysis will differ from engine maps for manufacturers' specific engines. For a given engine configuration, some production engines may be less efficient and some may be more efficient than the engine maps presented in the analysis. However, the agencies intended and expected that the incremental changes in performance modeled for this analysis, due to changes in technologies or technology combinations, will be similar to the incremental changes in performance observed in manufacturers' engines for the same changes in technologies or technology combinations. Most importantly, using a single engine model as a reference provides a common base for comparison of all incremental changes resulting from technology changes, and anchors incremental technology effectiveness values to a common reference. The effectiveness values from the internal simulation results were validated against detailed engine maps produced from engine benchmarking programs, as well as published information from industry and academia, ensuring reasonable representation of simulated engine technologies.[764]

As discussed in the NPRM, the agencies updated the list of engine technologies, before and after the Draft TAR, based on stakeholder comments and consultations with CARB, Argonne, and IAV. The technology list was built on the technologies that were considered in the

[764] Bottcher,. L, Grigoriadis, P. "ANL – BSFC map prediction Engines 22-26." IAV (April 30, 2019). 20190430_ANL_Eng 22-26 Updated_Docket.pdf.

2012 final rule, and included technologies that are being implemented or that are under development and feasible for production in the rulemaking timeframe. The agencies noted that some advanced engines were included in the simulation that were, and often still are, not yet in production, and the engine maps for those engines were either based on CBI or theoretical data. The agencies also stated in the NPRM that the final rule analysis may include updated engine maps for existing modeled engines, or entirely new maps added to the analysis if either action could improve the quality of the fleet-wide analysis.

While there are a large number of possible combinations of engine technologies, the agencies categorized the IAV engine maps used in the NPRM full vehicle simulations into six categories. The categories were based on engine architecture and include: dual overhead camshaft (DOHC) engines, single overhead camshaft (SOHC) engines, turbocharged engines, hybrid Atkinson cycle engines,[765] non-hybrid Atkinson mode engines, and diesel engines. Another unique technology that was available for adoption for the NPRM analysis was the advanced cylinder deactivation (ADEAC) for the SOHC and DOHC engines, however this technology was modeled using a fixed effectiveness value rather than an engine map, because the agencies did not have sufficient data to be used as input to the engine map or full vehicle simulation modeling. In addition, the agencies provided potential engine maps and additional specifications for several other technologies that could be considered for the final rule analysis. These included a basic high compression ratio Atkinson mode engine, a Miller cycle engine, and an engine with an electric assist.

The full list of engine maps used in the NPRM is presented in Table VI-40 below.

Table VI-40 – Engine Maps Used for NPRM Analysis

Engines	Technologies	Notes	Engine Reference Peak Power (kW)
Eng01	DOHC VVT	Parent NA engine, Gasoline, 2.0L, 4 cyl, NA, PFI, DOHC, dual cam VVT, CR10.2	108

Comments on engine maps varied, with industry commenters generally supporting the maps used in the NPRM analysis and CARB and environmental advocate commenters generally objecting to the maps. The Alliance argued that previously-modeled fuel efficiency improvements for downsized, turbocharged engine technologies were "highly optimistic," and stated that the updated engine maps used for the NPRM analysis were an improvement.

ICCT argued that the IAV engine maps used for the NPRM analysis were out of date, and better engine maps benchmarked by EPA staff were available and should have been used instead.[766] UCS similarly stated that Argonne work used for previous CAFE technical documents had relied on outdated engine maps, and that the new IAV engine maps used in this rulemaking were developed for a different purpose and had not been benchmarked against the latest engines either on the road or in development.[767] ICCT questioned whether the agencies had validated engines 13 and 14 with physical testing and/or simulation modeling to the level of quality of EPA's simulation modeling.[768] ICCT further asserted that EPA's benchmarked engine maps had been "knowingly disregarded" for the NPRM analysis, and stated that the NPRM analysis was therefore arbitrary.[769] ICCT commented that the agencies must conduct and disclose a systematic investigation and comparison of engine benchmarking, engine modeling, and transmission modeling completed by EPA, Ricardo, and Argonne for model year 2014-2018 vehicles. ICCT recommended that the agencies rely on engine maps used for past EPA ALPHA modeling while the agencies conduct such an investigation.

The agencies believe it is most important for engine map data to provide accurate BSFC information for known technologies and technology levels. The agencies disagree with statements that IAV engine maps are outdated. The majority of the engine maps were developed specifically to support the midterm review and encompass engine technologies that are present in the analysis fleet and technologies that could be applied in the rulemaking timeframe. In many cases those engine technologies are mainstream today and will continue to be during the rulemaking timeframe. For example, the engines on some MY 2017 vehicles in the analysis fleet have technologies that were initially introduced ten, or more, years ago. Having engine maps representative of those technologies is important for the analysis. The most basic engine technology levels also provide a useful baseline for the incremental improvements for other engine technologies. The timeframe for the testing or modeling is unimportant, because time by itself doesn't impact engine map data. A given engine or model will produce the same BSFC map regardless of when testing or modeling is conducted. Simplistic discounting of engine maps based on temporal considerations alone could result in discarding useful technical information. Also, narrow use of temporal considerations would also result in the discarding of several engine maps from Ricardo that were used for the EPA Draft TAR and Proposed Determination

analyses.[770] Therefore, with the engine maps used representing current technologies regardless of development date, the agencies do not agree with commenter assertions.

The same commenters also appear to misunderstand how the agencies' effectiveness data, including engine maps, were used in the NPRM analysis (and in past rulemakings). The analysis never applies *absolute* BSFC levels from the engine maps to any vehicle model or configuration for the rulemaking analysis. The *absolute* fuel economy values from the full vehicle Autonomie simulations are used only to determine *incremental* effectiveness for switching from one technology to another technology. The *incremental* effectiveness is applied to the absolute fuel economy of vehicles in the analysis fleet, which are based on CAFE compliance data. For subsequent technology changes, incremental effectiveness is applied to the absolute fuel economy level of the previous technology configuration. Therefore, for a technically sound analysis, it is most important that the *differences in BSFC among the engine maps* be accurate, and not the absolute values of the individual engine maps. However, achieving this can be challenging.

A technically sound approach is to use a single or very small number of baseline engine configurations with well-defined BSFC maps, and then, in a very systematic and controlled process, add specific well-defined technologies and create a BSFC map for each unique technology combination. This could theoretically be done through engine or vehicle testing, but testing would need to be conducted on a single engine, and each configuration would require physical parts and associated engine calibrations to assess the impact of each technology configuration, which is impractical for the rulemaking analysis because of the extensive design, prototype part fabrication, development, and laboratory resources that are required to evaluate each unique configuration. Modeling is an approach used by industry to assess an array of technologies with more limited testing. Modeling offers the opportunity to isolate the effects of individual technologies by using a single or small number of baseline engine configurations and incrementally adding technologies to those baseline configurations. This provides a consistent reference point for the BSFC maps for each technology and for combinations of technologies which enables the differences in effectiveness among technologies to be carefully identified and quantified. The agencies selected this approach for the NPRM and final rule. Engine maps were created by IAV using this technically sound and rigorous methodology. Both absolute engine maps and the incremental differences in engine maps were presented in the PRIA.

Using a mix of engine maps from engine modeling and from benchmarking data provides no common reference for measuring impacts of adding specific technological improvements. In addition, as discussed in further detail in Section VI.C.1.e), manufacturers often implement multiple fuel-saving technologies simultaneously when redesigning a vehicle and it is not possible to isolate the effect of individual technologies by using laboratory measurements of a single production engine or vehicle with a combination of technologies. Because so many vehicle and engine changes are involved, it is not possible to attribute effectiveness

[770] Ricardo, Inc. "Computer Simulation of Light-Duty Vehicle Technologies for Greenhouse Gas Emission Reduction in the 2020-2025 Timeframe." Ricardo (December 2011). https://nepis.epa.gov/Exe/ZyPDF.cgi/P100D57R.PDF?Dockey=P100D57R.PDF. Last accessed Jan 14, 2020.

improvements accurately for benchmarked engines to specific technology changes. This leads to overcounting or undercounting technology effectiveness.

Further, while two or more different manufacturers may produce engines with the same high level technologies (such as a DOHC engine with VVT and SGDI), each manufacturer's engine will have unique component designs that cause its version of the engine to have a unique engine map. For example, engines with the same high level technologies have unique intake manifold and exhaust manifold runners, cylinder head ports and combustion chamber geometry that impact charge motion, combustion and efficiency, as well as unique valve control, compression ratios, engine friction, cooling systems, and fuel injector spray characteristics, among other factors. The agencies developed and used a single engine map to represent each technology and each combination of engine technologies.

Therefore, it should not be expected that any of the agencies' engine maps would necessarily align with a specific manufacturer's engine, unless of course the engine map was developed from that specific engine. The agencies do not agree that comparing an engine map used for the rulemaking analysis to a single specific benchmarked engine has technical relevance, beyond serving as a general corroboration for the engine map. When a vehicle is benchmarked, the resulting data is dictated by the unique combination of technologies and design constraints for the whole vehicle system. For these reasons, the agencies do not agree with ICCT that Eng13 and Eng14 should be validated by conducting full vehicle modeling and comparing the results with a single benchmarked vehicle. The engine maps used in this analysis are precisely controlled for specific incremental technology adoption and not for comparisons of absolute performance of a specific vehicle's engine.

Differences are also explained by the NPRM and final rule analyses using large-scale full vehicle Autonomie simulations to estimate effectiveness instead of rough LPM approximations based on limited ALPHA simulation work.[771] These issues are discussed in more detail in Section VI.B.3.

Accordingly, the agencies declined directly to use the Ricardo and other EPA engine maps created from engine benchmarking as inputs for this rulemaking because, among other reasons discussed below, they did not afford the opportunity to evaluate the effectiveness improvements for specific, individual technologies. For example, the 2018 Toyota Camry 2.5L engine that EPA benchmarked had a broad array of observable technologies, and several more that were not observable.[772] However, there was no baseline from which to isolate or compare any of the *individual* technology improvements. For example, Toyota commented on this benchmarking, stating:

---

[771] 2016 EPA Proposed Determination TSD at p.2-276 to 2-279
[772] EPA Test Data. 2018 Toyota Camry 2.5L A25A-FKS Engine Tier 3 Fuel. Available at https://www.epa.gov/sites/production/files/2019-04/2018-toyota-2.5l-a25a-fks-engine-tier3-fuel-test-data-package-dated-04-08-19.zip. Last accessed Nov. 20, 2019.

Past Toyota comments on Atkinson-cycle benefits have addressed only those derived from variable valve timing (VVT) with late intake valve closing (LIVC) that enables a 13:1 compression ratio. The total 18.6 percent improvement of the 2018 Camry 2.5L over the previous generation also includes benefits from cEGR and internal engine design changes such as to the block, cylinder head, pistons, valvetrain, as well as drivetrain and body/chassis enhancements.[773]

Toyota's comments emphasize that the efficiency improvements in this engine were driven by several additional technological improvements, and not merely the cEGR, Atkinson cycle engine and higher compression ratio design that was assumed for the EPA Draft TAR and Proposed Determination analyses.[774]

The agencies do agree component, engine, and vehicle test data are very important for validating systems models, such as Autonomie, and for validating model inputs, such as engine maps. Accordingly, the agencies *did* fully consider engine maps used in prior rulemakings, along with a broad array of other data as part of the process for evaluating the IAV engine maps used for the NPRM and the final rule analysis simulation work. Engine maps from Ricardo, EPA benchmarking, NHTSA-sponsored benchmarking,[775] information from technical papers and conferences,[776] extensive data and expertise from the Argonne AMTL vehicle testing group and

Energy modeling group, [777] and the 2015 NAS report,[778] were all sources used to confirm that incremental technology effectiveness estimates were appropriate. The engine maps developed by IAV provided reliable and reasonable estimates for the incremental impacts of engine technologies. The use of this approach explains some of the effectiveness differences between the NPRM and final rule analyses, and the EPA Draft TAR and Proposed Determination analyses.

In considering ICCT's comment about using IAV engine maps or EPA's engine maps, as an exercise, the agencies compared two IAV engine maps to the EPA's benchmarked Toyota 2.5L naturally aspirated engine and Honda's 1.5L turbocharged downsized engine.[779, 780] The IAV engines were modeled and simulated in a midsize non-performance vehicle with an automatic transmission and the same road load technologies, MR0, ROLL0 and AERO0, to isolate for the benefits associated with the specific engine maps.[781] Eng 12, a 1.6L, 4 cylinder, turbocharged, SGDI, DOHC, dual cam VVT, VVL engine was selected as the closest engine configuration to the Honda 1.5L. Eng 22b, a 2.5L, 4 cylinder, VVT Atkinson cycle engine, was selected as the closest engine configuration to the Toyota 2.5L. As discussed before, both the Toyota 2.5L naturally aspirated engine and Honda's 1.5L engine have incorporated a number of fuel saving technologies including improved accessories and engine friction reduction. In order to assure an "apples-to-apples" comparison, both IACC and EFR technologies were applied to the IAV engine maps. IACC technology provides an additional 3.6% incremental improvement and EFR provides an additional 1.4% incremental improvement beyond the IAV engine maps for midsize non-performance vehicles.[782]

The comparison shows effectiveness of the IAV engine maps and effectiveness values for the final rule analysis are in line with the Honda 1.5L and the Toyota 2.5Lbenchmarked engines. Figure VI-17 below shows the effectiveness improvements for the EPA benchmarked engines and the corresponding IAV engine maps incremental to a baseline vehicle. Accordingly, the agencies believe that the methodology used in this analysis, and the engine maps and incremental effectiveness values used, are in line with benchmarking data and are reasonable for the

[782] The NPRM and this final rule analysis allowed the adoption of IACC technologies in the CAFE model that provided an additional 3.6% incremental improvement for the midsize car vehicle class. As discussed in Section The Model Applies Technologies Based on a Least-cost Technology Pathway to Compliance, Given the Framework Above Other Technologies, these benefits are not shown in the IAV engine simulated results, so they were added manually for this comparison.

rulemaking analysis. The agencies believe the approach used in this rulemaking analysis appropriately allows the agencies to account for a wide array of engine technologies that could be adopted during the rulemaking timeframe. Declining to use manufacturer-specific engines allows the agencies to ensure that all effectiveness and cost improvements due to the incremental addition of fuel economy improving technologies are appropriately accounted for.

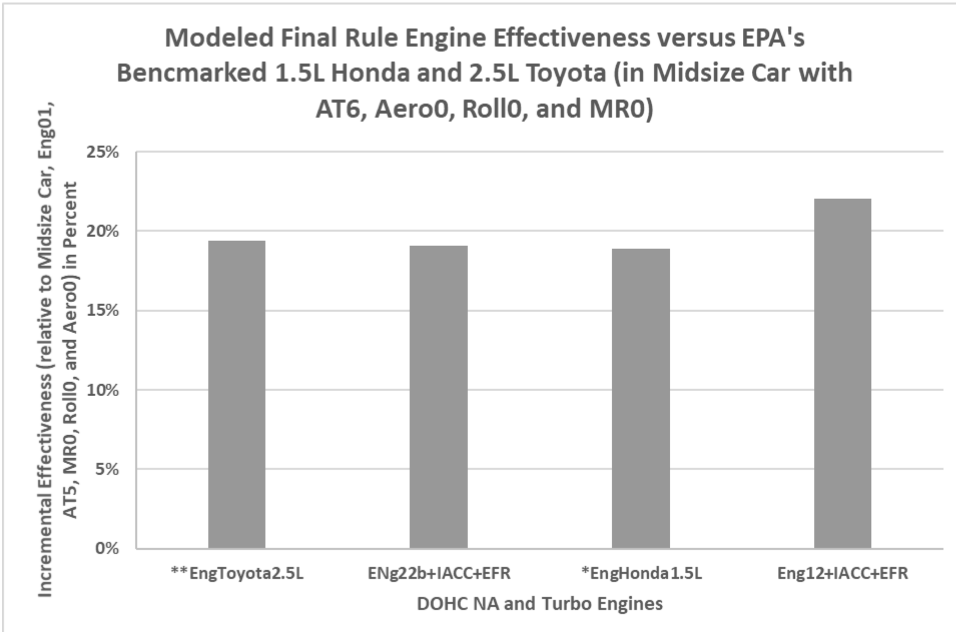

Figure VI-17 – Comparison of Engine Effectiveness used for the Final Rule Analysis versus EPA benchmarked Honda 1.5L Turbo Engine and Toyota 2.5L NA Engine

Next, Roush Industries ("Roush"), writing on behalf of the California Air Resources Board, commented that the NPRM-modeled engines vary in cylinder size, which would significantly alter combustion, heat transfer, knock tolerance, and other important operating parameters.[783] Roush stated that a more accurate simulation, which would improve incremental fuel economy improvement, should maintain a consistent cylinder displacement (500cc) and vary the number of cylinders or expected fuel consumption maps.[784]

The agencies believe that holding cylinder volume constant is the appropriate approach to research seeking to identify the impacts of technological changes on BSFC, torque, power, and other characteristics, when holding cylinder volume constant. However, as explained in Section VI.B.3.a)(2) Maintaining Vehicle Attributes and Section VI.B.3.a)(6) Performance Neutrality, CAFE and CO_2 rulemaking analyses attempt to maintain vehicle attributes, including performance, and hold all of the attributes constant when showing pathways that improve fuel

economy. Therefore, the agencies' analyses require engine maps that attempt to hold *performance* constant—not necessarily cylinder size. Since certain fuel economy improving technologies would *increase* performance if cylinder size is held constant, such as when adding turbocharging technology, the agencies appropriately include changes in displacement and cylinder volume for technologies that have a significant impact on engine torque and power, such as turbocharging. For a number of fuel economy improving technologies that had smaller impacts on engine torque and power, the engine maps were created with cylinder volume held constant. Table VI-40 identifies the engine displacement information for each of the engine maps. For example, the same engine displacement (2.0 L) and cylinder displacement (500 cc) was used for creating engine maps for naturally aspirated engines Eng01, Eng02, Eng03, Eng04, Eng05a, Eng5b, Eng06a, Eng07a, and Eng08a, whereas engine displacement (1.6 L) and cylinder displacement (400 cc) is used for creating the engine map for turbocharged engine Eng12 in order to maintain performance. The agencies have concluded that the approach used for the NPRM and the final rule analysis is the most technically sound approach given the data needs and assessments required for CAFE and CO_2 rulemaking.

Roush also commented as follows:

> [S]everal of the base engine maps used in the 2018 PRIA analysis exhibit maximum thermal efficiency (lowest fuel consumption) at 2000-3000 rpm and at maximum load, which is unrealistic for normal passenger vehicle engines. Such maps will over predict fuel economy for extremely down-sized applications (very small engine in a heavy vehicle). This is because there is no fuel economy penalty for running the engine at a high loads point where, in reality, BSFC is high due to retarding spark timing to prevent knocking and fuel enrichment to reduce exhaust temperatures to protect exhaust valves and turbocharger components.[785]

For example, Roush stated that Eng12 is predicted to have its highest efficiency at very high load and high engine speeds with no degradation in brake specific fuel consumption (BSFC) at engine speeds between 2,000 rpm and 4,500 rpm all the way up to peak load, which is unrealistic because turbocharged engines at high loads require retarded spark timing to prevent knock and fuel enrichment to prevent overheating of the turbocharger and related components.[786] Roush stated that these factors would increase fuel consumption and reduce efficiency under real-world conditions.[787] Roush also stated that another effect of the Eng12 fuel consumption curve would be to predict unreasonably good fuel consumption at very high power levels for downsized turbocharged engines. Roush stated this could bias technology pathways in over-predicting fuel economy benefits for small engines installed in heavier vehicles, causing an

[785] Roush Industries on behalf of California Air Resources Board, Rogers_Final_Final_NPRM_10.26.2018, Docket No. NHTSA-2018-0067-11984, at 11.
[786] Roush Industries on behalf of California Air Resources Board, Rogers_Final_Final_NPRM_10.26.2018, Docket No. NHTSA-2018-0067-11984, at 18.
[787] Roush Industries on behalf of California Air Resources Board, Rogers_Final_Final_NPRM_10.26.2018, Docket No. NHTSA-2018-0067-11984, at 19.

overly optimistic predicted performance of the vehicle with regard to drivability, acceleration, and fuel consumption, which would create unrealistic real-world pathways to compliance.[788]

As discussed in the Argonne model documentation for the final rule analysis, the simulations used to determine incremental effectiveness for the NPRM and final rule analyses were conducted using 2-cycle test procedures, because they are the test procedures used for CAFE and CO_2 compliance.[789] Therefore, the engines maps are intended to represent BSFC accurately under those test conditions and do not need to capture BSFC under every operating condition. During 2-cycle test conditions, engines do not operate for extended periods at the speed and high load conditions noted by Roush. A few vehicle and engine combinations may operate at those speed and load points only briefly during the 2-cycle CAFE and CO_2 tests. Engines are capable of operating for short periods of time under higher exhaust temperature conditions and manufacturers commonly delay fuel enrichment until it is needed to protect engine components (in particular exhaust valves and exhaust manifolds) from excessive temperatures that can impact engine durability. Fuel enrichment can be delayed because it takes a period of time at higher temperature for components to heat up and reach a temperature that would impact durability. Because these high speed and load conditions occur for a relatively short time during the CAFE and CO_2 test cycles, and then return to lower speed and/or load conditions with lower exhaust temperature, engines operate for the entire CAFE and CO_2 test cycles without triggering fuel enrichment. The fuel enrichment delay also enables vehicles to comply with criteria emission regulations and improves real world fuel economy. Therefore, the engine maps used for the NPRM and final rule analysis fully represent how engines operate during CAFE and CO_2 test cycles, and properly do not include fuel enrichment at all 2-cycle operating conditions. Also, a trained knock model was used to develop the engine maps, and the spark timing reflects appropriate levels for engine operation during the delay in fuel enrichment.

Next, regarding developing the NPRM engine maps to account for Tier 3 test fuel, the Alliance and Ford stated that the engine maps using Tier 3 test fuel represented an improvement over prior analyses. The Alliance stated that previous EPA modeling had incorrectly used Tier 2 premium octane fuel to predict the benefits of engine technologies, which overstated fuel economy gains that would be achievable when using regular-grade octane Tier 3 fuel. Ford provided similar comments, and also noted that regular grade octane fuel will be required for compliance after the 2020 model year.[790]

In contrast, ICCT and UCS both commented that the agencies had incorrectly updated the IAV engine maps developed with Tier 2 test fuel to account for Tier 3 fuel.[791] ICCT stated that the update reduced the effectiveness of the turbo technologies and suggested that the fuel update adjustment should not have been done at all, stating manufacturers that label vehicles as

---

[791] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-82; Union of Concerned Scientists, Technical Appendix, Docket No. NHTSA-2018-0067-12039, at p. 15.

“premium fuel recommended” are required to show no emissions changes over all test cycles when using premium octane fuel and therefore reducing effectiveness for fuel differences, as the agencies did with the IAV engine maps, is unrealistic and inappropriate.

UCS also commented more specifically on the impact of the adjustment from Tier 2 to Tier 3 fuel related to the knock threshold for advanced engines, noting that manufacturers consider different approaches to different fuels, and not all of those approaches necessitate reductions in efficiency, as the agencies’ assumption suggests. UCS stated that charge cooling can reduce knock in direct injection engines, resulting in an “effective octane” difference of a six point increase for E10, thus potentially compensating for the difference in octane between Tier 2 (E0 93 AKI) and Tier 3 (E10 87 AKI) fuels. UCS argued that excluding this consideration led the agencies to restrict advanced engines like HCR2 and reduce the effectiveness of turbocharged engines with CEGR. UCS suggested that there would be a reduction in the costs between the baseline and proposed standards if the analysis allowed the application of HCR2 engines and corrected the effectiveness of turbocharged CEGR engines.

Both ICCT and UCS also stated that the adjustment ignored a 2018 EPA study showing that, while fuel consumption increases with the switch from Tier 2 to Tier 3 test fuel, emissions are reduced, meaning that the agencies’ adjustment is wrong “for some technologies because [CO_2]-per-mile emissions can be lower with the switch to higher octane ethanol blends.” UCS also stated that the adjustment factor applied is wrong for two reasons, first because converting solely with energy density would assume a 3.7 percent increase in fuel consumption compared to the observed 2.7 percent increase, and second because the adjustment goes in the wrong direction when applied to CO_2 emissions, which show a reduction of 1.4 percent on the test cycle. UCS stated that the Autonomie model accordingly overstates CO_2 emissions on Tier 3 fuel by 4.2 percent. UCS argued that the adjustment to account for Tier 3 test fuel therefore double counts any penalty in fuel economy and ignores CO_2 tailpipe reductions, which would result in an improvement on the test cycle. Because the CAFE test procedure already has an adjustment in place to correct for fuel properties relative to 1975 test fuel, but carbon-related exhaust emissions do not, UCS stated that the fuel adjustment could lead to drastically conservative fuel economy and CO_2 curves.

ICCT stated that the agencies could fix this issue by relying on EPA’s engine maps, where EPA had accounted for cost and effectiveness of technology used to protect operation on regular octane fuel by increasing costs and reducing effectiveness.

Some of these comments can be addressed with a simple clarification: the NPRM contained text that was inconsistent regarding how the analysis accounted for the engine maps (which were based on Tier 3 fuel). The separate model documentation correctly described that, for the NPRM analysis, the agencies developed fuel maps for Tier 3 fuel and did not adjust the final Autonomie outputs.[792] The NPRM text, however, incorrectly stated that “(a)n adjustment factor was applied to the Autonomie simulation results to adjust them to reflect Tier 2 certification fuel. Argonne adjusted the vehicle fuel economy results to present certification fuel

[792] NHTSA-2018-0067-0007 at 177-178 and 191.

by using the ratio of the lower heating values to the rest and certification fuels." In fact, no adjustments were made to the NPRM Autonomie simulation outputs, as the modeled engine maps were appropriately modeled using Tier 3 fuel.

As discussed in detail in VI.C.1.a) Fuel Octane, engine specifications used to create the engine maps for the NPRM and the final rule were developed using Tier 3 fuel. Tier 3 fuel was used to ensure the engines were capable of operating on real world regular octane (87 pump octane = (R+M/2)). This capability is in line with what manufacturers must do to ensure engines have acceptable noise, vibration, harshness, drivability and performance levels, and will not fail prematurely when operated on regular octane fuel. If the agencies developed engine maps based on Tier 2 fuel alone, the engine maps would reflect the engines' ability to have higher compression ratios and to operate with greater levels of spark advance than could be implemented by manufacturers, who must take into account operation on regular octane fuels used by a majority of U.S. consumers.[793] Not considering regular octane fuel operation by manufacturers would lead to engine durability, and engine noise, vibration, harshness, and drivability issues. Manufacturers have told the agencies that even for vehicles designed to operate on high octane fuel, the engines and controls must be designed to operate on every fuel octane level available in the U.S. to avoid these issues.[794] Thus, developing engine maps based on Tier 2 fuel alone would incorrectly overstate the BSFC improvements achievable in the real world.

Based on these comments and considerations, the agencies determined the engine maps developed for the NPRM appropriately account for fuel octane, and better approximate BSFC achieved by the majority of engines used in the U.S. vehicle fleet. The agencies believe ICCT's and other commenters' assertions that the engine maps should reflect Tier 2 fuel and not be updated for Tier 3 fuel would ignore these important considerations, and would provide engine maps that could not be achieved by engines in the real world. The agencies determined that engine maps developed for the Draft TAR and EPA Proposed Determination that were based on Tier 2 fuel should not be used for the NPRM and final rule analyses for these reasons.

EPA is addressing the impact of Tier 3 fuel on fuel economy and CO_2 emissions compliance test results as part of a separate rulemaking. The separate rulemaking may establish an adjustment to account for the impacts of the change in test fuel. Those impacts are beyond the scope of this rulemaking. The analysis for this rule uses fuel economy and CO_2 emissions of the vehicles in the MY 2017 analysis fleet as the reference for absolute fuel economy and CO_2 emissions. The analysis starts with absolute compliance data from MY 2017 and adopts technologies incrementally to determine future compliance. Because MY 2017 absolute compliance values are based on Tier 2 fuel, and standards are based on the use of Tier 2 fuel,

---

[793] Tamm, D. C., Devenish, G.N. Finelt, D. N.. Kalt, L. K. "Analysis of Gasoline Octane Costs" Baiker and O'brien, Inc. Prepared for EIA. October 18, 2018. https://www.eia.gov/analysis/octanestudy/pdf/phase1.pdf at 11-13.
[794] Ford Motor Company. NHTSA-2016-0068-0048 at 3.
Auto Alliance comments for 2016 draft TAR. Attachment 7 Limitations of Ricardo Fuel Economy Analysis of Downsizing. NHTSA-2016-0068-0070.

there is no need to make any adjustments for the differences in energy content and carbon content of Tier 2 and Tier 3 fuel.[795]

The agencies considered ICCT's statement that manufacturers that label vehicles as "premium fuel recommended" are required to show no emissions changes over all test cycles when using regular octane fuel, and therefore reducing effectiveness for fuel differences as the agencies did with the IAV engine maps is unrealistic and inappropriate. The agencies believe these conclusions are technically incorrect. The existence of an EPA compliance regulation does not impact the laws of nature, which govern issues associated with the impact of fuel octane on the ability to improve engine BSFC and on engine durability, noise, vibration, harshness, and drivability. It is widely recognized and accepted that higher octane fuels allow engines to be designed with higher compression ratios, faster combustion rates, and more optimal spark advance, which improve BSFC. Section VI.C.1.a) discusses comments advocating for increasing the minimum fuel octane specification to enable these improvements. The engine maps developed by IAV and used for the Draft TAR and NPRM were consistent with these trends and showed that BSFC is better with Tier 2 (higher octane) fuel than Tier 3 (lower octane) fuel.[796] ICCT did not provide any data supporting the concept that there is no shift in BSFC, fuel economy, or CO_2 emissions when engines are optimized with different octane fuels, or between Tier 2 and Tier 3 fuel. It is appropriate to note that the EPA regulation does provide a tolerance which in practice allows a small level of shift in emissions.[797]

Regarding comments that certain combinations of technologies can enable BSFC improvements while controlling spark knock, the agencies in fact considered a very broad array of engine technology combinations for the analysis, including several added technologies as discussed further below. The agencies believe the rigorous methodology used to develop the engine maps resulted in engine maps representing the maximum improvement in BSFC for each engine configuration, while also addressing real world constraints. Engine maps for the new technologies were presented in PRIA Chapter 6.3.2.2.16.4. The PRIA also discussed that IAV maps were developed considering a very comprehensive list of combustion operating parameters as part of the IAV GT-Power engine modeling. IAV's GT-Power engine modeling included sub-models to account for heat release through a predictive combustion model, knock characteristic through a kinetic fit knock model, physics-based heat flow model physics based friction model, and IAV's proprietary Optimization Tool Box.[798] These independent models were run

[795] During the 1980s, the U.S. Environmental Protection Agency (EPA) incorporated the R factor into fuel economy calculations in order to address concerns about the impacts of test fuel property variations on corporate average fuel economy (CAFE) compliance, which is determined using the Federal Test Procedure (FTP) and Highway Fuel Economy Test (HFET) cycles. The R factor is defined as the ratio of the percent change in fuel economy to the percent change in volumetric heating value for tests conducted using two differing fuels.
[796] *See* BSFC difference between engines modeled with Tier 3 fuel versus high octane fuel by IAV in PRIA 6.3.2.2.20.9 at 288 to PRIA 6.3.2.20.11 at 292.
[797] 40 CFR 1066.210 (b) Accuracy and Precision.
[798] IAV's Optimization Tool Box is a module of IAV Engine. IAV Engine, as the basic platform for designing engine mechanics, provides a large number of tools that have proven their worth across the globe in several decades of automotive development work at IAV. The modules help designers, computation engineers and simulation

concurrently to make sure engine design requirements were met for each engine configuration that was modeled.

Finally, in response to the agencies' request for comment on including the additional engine maps presented in the NPRM as potential technological pathways, several commenters stated that the agencies should include those technologies, in addition to other emerging engine technologies.[799] After considering these comments, the agencies added several engine technologies and technology combinations to the final rule analysis. The additions included a basic high compression ratio Atkinson mode engine (HCR0), a variable compression ratio engine (VCR), a variable turbo geometry engine (VTG), and a variable turbo geometry with electric assist engine (VTGe). The agencies also added advanced cylinder deactivation technology (TURBOAD) to Eng12 (TURBOD) in the Autonomie modeling for the final rule analysis. Like with ADEAC, the agencies did not have IAV engine maps for TURBOAD, so the agencies took the effectiveness values as predicted by full vehicle simulations of a TURBOD and added 1.5 percent or 3 percent respectively for I-4 engines and V-6 or V-8 engines, as explained in more detail further below. The agencies also included more iterations of existing technologies, like diesel engines with cylinder deactivation, diesel engines paired with manual transmissions, and diesel engines paired with 12-volt start stop technology, in addition to more combinations of hybrid technologies that are discussed further in Section VI.C.3, below.

The following sections list and describe the comprehensive set of engine technologies and combinations of engine technologies that have been included in the analysis. The agencies also discuss the additional engine technologies added for the final rule, and reasons for excluding a small number of technologies proffered by commenters. The agencies believe the wide array of engine technologies included in the final rule analysis and the methodology used to develop the engine maps to measure the effectiveness of those technologies reasonably represents the scope of technologies that should be considered during the rulemaking timeframe.

c) Engine Modeling in the CAFE Model

(1) Sources of Engine Effectiveness Data

This analysis used engine data from a wide range of sources to update engine effectiveness for this assessment -

- Newly available public data (e.g., peer-reviewed journals, peer-reviewed technical papers, conference proceedings);
- Data directly acquired by EPA via engine dynamometer testing at EPA-NVFEL or at contract laboratories;
- Benchmarking and simulation modeling of current and future engine configurations;
- EPA's benchmarking and simulation modeling of current transmission configuration;

---

specialists in designing mechanical engine components—for example, in laying out valvetrains and timing gears as well as crankshafts.

799 ICCT Docket # NHTSA-2018-0067-11741 at I-19 – I-22; CARB Docket # NHTSA-2018-0067-11873 at 107-108.

- Confidential data from OEMs, Tier 1 suppliers, and major automotive engineering services firms;
- NHTSA benchmarking of production vehicles with advanced engine and transmission technologies;
- Data from the U.S. Department of Energy Vehicle Technologies Program; and
- Sources of engine effectiveness data used in the analysis supporting the light-duty CAFE and CO_2 rule covering MYs 2017 and beyond

Data gleaned from each source is discussed in turn, below.

(a) Publicly Available Literature

A considerable amount of brake-specific fuel consumption (BSFC), brake-thermal efficiency (BTE) and chassis-dynamometer drive cycle fuel consumption data for advanced powertrains has been published in journals, technical papers and conference proceedings since the 2012 final rule. In some cases, published data includes detailed engine maps of BSFC and/or BTE over a wide area of engine operation. In addition, these publications provide a great deal of information regarding the specific design changes made to an engine which allow the engine to operate at an improved BSFC and vehicles to operate with improved fuel consumption. These design details often include changes to engine friction, changes to valvetrain and valve control, combustion chamber design and combustion control, boosting components and boosting control, and exhaust system modifications. This information provides an indication of which technologies to investigate in more detail and offer the opportunity to correlate testing and simulation results against currently available and future designs.

Literature is referenced throughout this RIA and Preamble. Additionally, CAFE model documentation and Autonomie model documentation also provide individual references for individual technologies. Many of these papers are published and publicly available from organization like Society of Automotive Engineers (SAE), American Society of Mechanical Engineers (ASME), International Wiener Motor Symposium, and others.

(b) Engine and Chassis Dynamometer Testing

Since 2012, many examples of advanced engine technologies have gone into production for the U.S., European and Japanese markets. EPA has acquired many vehicles for chassis dynamometer testing and has developed a methodology for conducting detailed engine dynamometer testing of engines and engine/transmission combinations. Engine dynamometer testing was conducted both at the EPA-NVFEL facility in Ann Arbor, MI and at other test facilities under contract with EPA. Engine dynamometer testing of production engines outside of the vehicle chassis required the use of a vehicle-to-engine (or vehicle-to-engine/transmission) wiring tether and simulated vehicle feedback signals in order to allow use of the vehicle manufacturer's engine management system and trained control parameters.

NHTSA conducted engine dynamometer testing of light-duty truck engines at Southwest Research Institute and vehicle testing at ANL Advanced Powertrain Research Facility (APRF). In addition to measuring fuel consumption and regulated emissions, many of the engines were also instrumented with piezo-electric cylinder pressure transducers and crankshaft position sensors to allow calculation of the apparent rate of heat release and combustion phasing. Engines with camshaft-phasing were also equipped with camshaft position sensors to allow monitoring of the timing of valve events. Engine dynamometer testing also incorporated hardware-in-the-loop simulation of drive cycles so that vehicle packages with varying transmission configurations and road-loads could be evaluated.

(c) Confidential Business Information

While the confidential data provided by vehicle manufacturers, suppliers, and engineering firms cannot be published in the NPRM, these sources of data were important as they allowed the agency to perform quality and rationality checks against the data that we are making publicly available. In each case where a specific technology was benchmarked, the agencies met with the vehicle manufacturers.

In cases where expected combinations of future engine technologies were not available for testing from current production vehicles, a combination of proof-of-concept engine dynamometer testing and engine and vehicle Computer Aided Engineering (CAE) simulations were used to determine drive cycle effectiveness.

(d) Benchmark Data

NHTSA worked with ANL and IAV to develop the engine maps used for this analysis. IAV is one the world's leading engineering services partners to the global automotive industry and has extensive experience in testing and modeling engines and combustion. NHTSA updated the list of engine technologies included in the NPRM analysis based on consultations with EPA, CARB, ANL and IAV. The technology list builds on the technologies that were considered in the 2012 final rule and includes new technologies that are being implemented or that are under development and to be feasible in that timeframe.

IAV used benchmark production engine test data to develop a 1-D GT-POWER engine model for the baseline engine technology configuration. Technologies were incrementally added to the baseline model to assess the impacts of the various technologies on fuel consumption. Assumptions and inputs to the modeling and validation of results leveraged IAV's global engine database that included benchmarking data, engine test data, single cylinder test data and prior modeling studies, and also technical publications and information presented in conferences.

The rulemaking analysis uses the incremental impact of technologies on fuel economy and CO_2 emissions and applies those incremental impacts to the fuel economy and emissions of each model in the MY 2016 analysis fleet. Using a single engine model as the reference for engine technologies provides a common base for all of the incremental technologies and anchors the incremental effectiveness values to a common reference.

The potential future MY fuel economy of each individual vehicle model is based on the vehicle model's MY 2016 actual fuel economy and the incremental effectiveness of the combination of technologies that the CAFE model applies. Because each vehicle model in the analysis fleet has a unique technology configuration and fuel economy value, applying the same incremental set of technologies to two different vehicle models produces different fuel economy impacts results between the vehicles modeled.

(e) IAV Process to Develop Engine Maps

For the Draft TAR analysis, all NHTSA engine models were derived from a single parent naturally aspirated engine and from a single parent turbocharged engine. The naturally aspirated and turbocharged engines were trained using engine test data in fixed ambient conditions of 25 degrees Celsius and 990 millibar.[800] In the original modeling of the turbocharged engines, IAV had utilized 93 octane fuel to develop the fuel maps. As discussed above, for this analysis the fuel maps have been updated for 87 AKI fuel to reflect the fuel that manufacturers specify for the majority of vehicles. Figure VI-18 shows the overview of the engine models utilized by IAV to develop engine maps for the Draft TAR and this NPRM analysis. In addition of use of GT-POWER, many other hardware models and computational fluid dynamic models were utilized to convert test data for use in the submodels shown below.

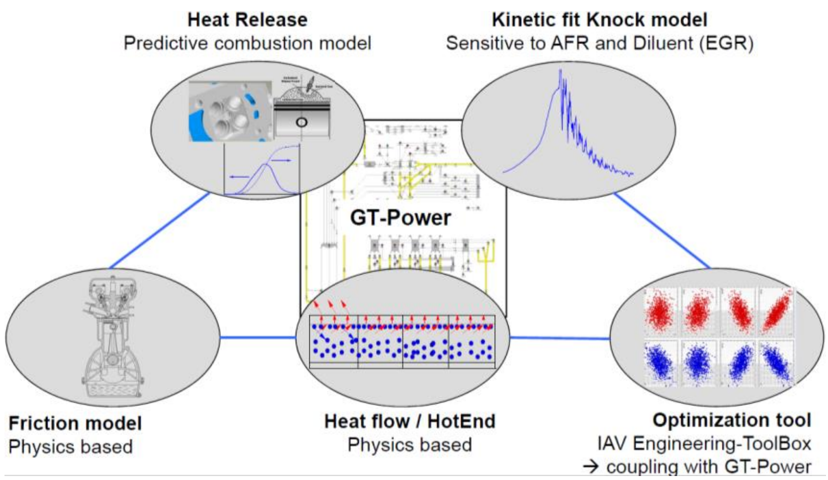

Figure VI-18 – Overview of the Engine Model Development

Figure VI-19 below shows the first step in setup and calibration of the engine model. The first steps of the modeling involve defining the different characteristics of the geometries of an engine and correlating the model results with test data for gas exchange. This process has been automated in IAV's analysis for this final rule to minimize development time of each individual engine configuration. With the definition of geometries of any engine defined, the friction model is also trained based on combination of physics and empirical data.

[800] Within this PRIA, the term "normal-temperature operating conditions" refers to conditions specified in 40 CFR Part 86 control of emissions from new and in-use highway vehicles and engines, which specifies operation with fixed ambient conditions of 25 degrees Celsius and 990 millibar.

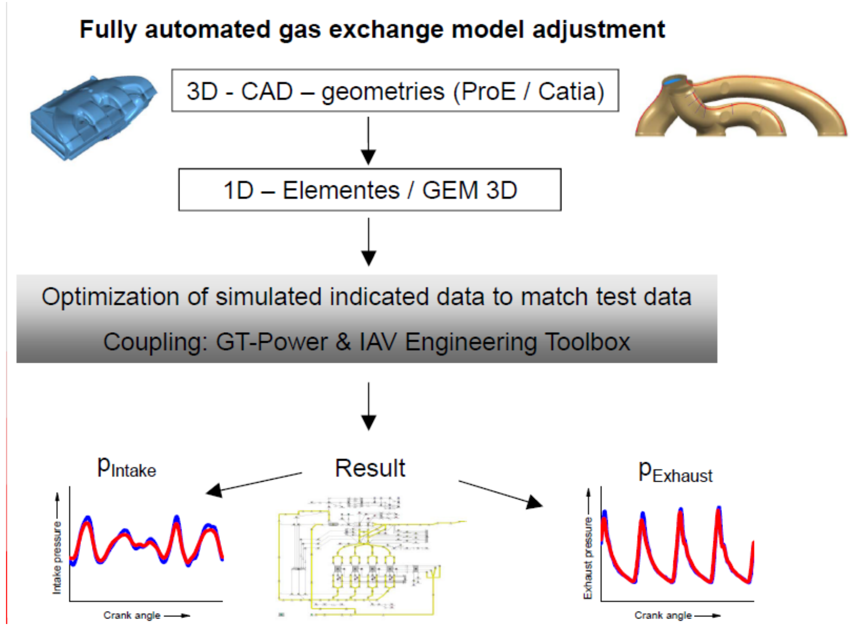

Figure VI-19 – shows the Gas Exchange Setup and Calibration

The predictive combustion model is then used to calculate the premixed combustion in gasoline engines. This step involves modeling turbulence and flame propagation of the combustion based on the consideration of the geometrical characteristics of the combustion chamber.

The final and most important part of the engine modeling is the knock model. GT Kinetics Fit knock model, a modification of the Arrhenius function, was used to develop the maps based on the fuel properties defined in Section VI.C.1.a). The model is further developed with test data to predict knocking behavior due to lean combustion process and cooled EGR. Knock modeling remains an important step in understanding the performance constraints of an engine, especially if the engine is aggressively down-sized in vehicle application or in simulation.

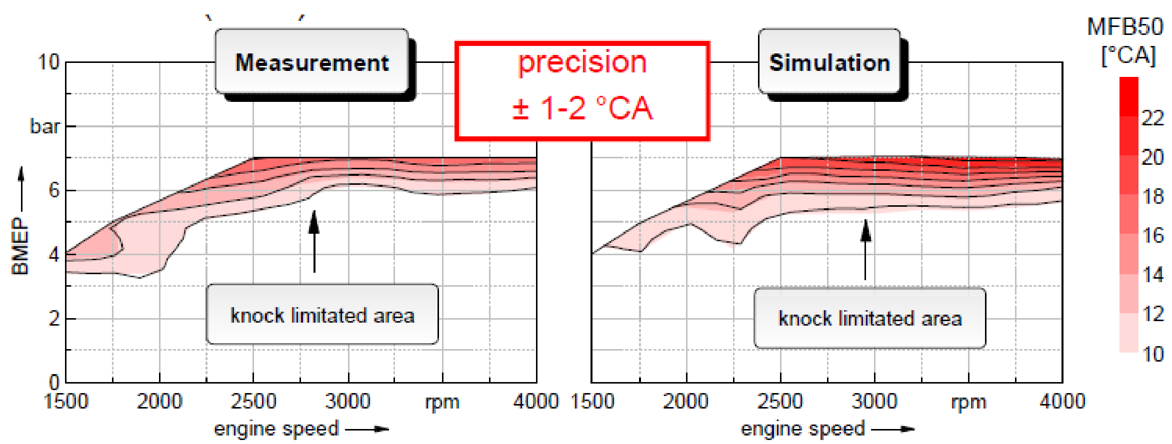

Figure VI-20 – Example of advanced calculation of knock tendency due to cylinder deactivation.

(2) Basic Engines

The NPRM described that there are a number of engine technologies that manufacturers can use to improve fuel economy and CO_2 emissions. Some engine technologies can be incorporated into existing engines with minor or moderate changes to the engines, but many engine technologies require an entirely new engine architecture. The terms “basic engine technologies” and “advanced engine technologies” are used only to define how the CAFE model applies a specific engine technology and handles incremental costs and effectiveness improvements. “Basic engine technologies” refer to technologies that, in many cases, can be adapted to an existing engine with minor or moderate changes to the engine, compared to “advanced engine technologies” that generally require significant changes or an entirely new engine architecture.

In the CAFE model, basic engine technologies may be applied in combination with other basic engine technologies; advanced engine technologies (defined by an engine map) stand alone as an exclusive engine technology. The words “basic” and “advanced” are not meant to confer any information about the level of sophistication of the technology. Also, many advanced engine technology definitions include some basic engine technologies, but these basic technologies are already accounted for in the costs and effectiveness values of the advance engine. The “basic engine technologies” need not be (and are not) applied in addition to the “advanced engine technologies” in the CAFE model.

(a) DOHC

In the NPRM analysis, the agencies characterized dual overhead cam (DOHC) engine technology as “basic.” DOHC engine configurations have two camshafts per cylinder head, one operating the intake valves and one operating the exhaust valves. Four basic engine technologies—variable valve timing (VVT), variable valve lift (VVL), stoichiometric gasoline direction injection (SGDI), and basic cylinder deactivation (DEAC)—were considered for DOHC engines. Implementing these technologies involves changes to the cylinder head of the engine, but the engine block, crankshaft, pistons, and connecting rods require few, if any, changes.

Variable valve timing (VVT) is a family of valve-train designs that dynamically adjusts the timing of the intake valves, exhaust valves, or both, in relation to piston position. VVT can reduce pumping losses, provide increased engine torque and horsepower over a broad engine operating range, and allow unique operating modes, such as Atkinson cycle operation, to further enhance efficiency. VVT is nearly universally used in the MY 2017 fleet.[801] In the NPRM analysis, the VVT technology modeled by IAV was based on dual (independent) cam phasing. This was a more advanced VVT technology that allowed controlling of valve overlap, which can be used to control internal EGR to minimize fuel consumption at low engine loads.[802] VVT

---

[801] 98.1 percent of MY2017 vehicles are equipped with VVT. EPA Report. *The 2018 EPA Automotive Trends Report*. https://nepis.epa.gov/Exe/ZyPDF.cgi/P100W5C2.PDF?Dockey=P100W5C2.PDF at Table 4.1 Production Share by Engine technology.
[802] 2015 NAS at p. 32.

enables control of many aspects of air flow, exhaust scavenging, and combustion relative to fixed valve timing engines. Engine parameters such as volumetric efficiency, effective compression ratio, and internal exhaust gas recirculation (iEGR) can all be enabled and accurately controlled by a VVT system.

Valvetratins with Intake Cam Phasing (ICP) modify the timing of the opening and closing of cylinder inlet valves.

Coupled cam phasing (CCP) results from applying cam phasing to an engine architecture that has only one camshaft actuating both intake and exhaust valves. Coupled cam phasing dynamically adjusts the angular position of the camshaft in relation to the crankshaft which affects the timing of both the intake exhaust valve timing equally. CCP is the only VVT implementation option available and requires only one cam phaser, and can be more cost effective than two cam phasers depending on the application. However, its limited availability could outweigh its reduced cost and complexity.

The most flexible VVT design is dual (independent) cam phasing, where the intake and exhaust valve opening and closing events are controlled independently. This option allows the option of controlling valve overlap, which can be used as an internal EGR strategy. At low engine loads, DCP creates a reduction in pumping losses, resulting in improved fuel consumption. Increased internal EGR also results in lower engine-out NO_X emissions. The amount by which fuel consumption is improved and CO_2 emissions are reduced depends on the residual tolerance of the combustion system and on the combustion phasing achieved. Additional improvements are observed at idle, where low valve overlap could result in improved combustion stability, potentially reducing idle fuel consumption.

Variable valve lift (VVL) dynamically adjusts the distance a valve travels from the valve seat optimizing airflow over a broad range of engine operating conditions. The technology can increase effectiveness by reducing pumping losses and may improve efficiency by affecting in-cylinder charge (fuel and air mixture), motion, and combustion. VVL is less common in the 2017 fleet than VVT. Some manufacturers have implemented a limited, discrete approach to VVL where just two valve lift profiles are available versus a full-range, continuously variable implementation.

DVVL systems allow the selection between two or three discrete cam profiles by means of a hydraulically-actuated mechanical system. By optimizing the cam profile for specific engine operating regions, the pumping losses can be reduced by reducing the amount of throttling required to produce the desired engine power output. This increases the efficiency of the engine. These cam profiles may consist of a low and a high-lift lobe or other combinations of cam profiles, and may also include an inert or blank lobe to incorporate cylinder deactivation (in the case of a 3-step DVVL system). DVVL is normally applied together with VVT control. DVVL is a mature technology with low technical risk.

In CVVL systems, valve lift is varied by means of a mechanical linkage or hydraulic actuators, driven by an actuator controlled by the engine control unit. The valve opening and phasing vary as the lift is changed and the relation depends on the geometry of the mechanical system. BMW has considerable production experience with CVVL systems and has versions of its "Valvetronic" CVVL system since 2001. CVVL allows the airflow into the engine to be regulated by means of intake valve opening reduction, which improves engine efficiency by reducing pumping losses from throttling the intake system further upstream as with a conventionally throttled engine. CVVL provides greater effectiveness than DVVL, because it can be fully optimized for all engine speeds and loads, and is not limited to a two or three step compromise. There may also be a small reduction in valvetrain friction when operating at low valve lift, resulting in improved low load fuel consumption for cam phase control with variable valve lift as compared to cam phase control only. Most of the fuel economy effectiveness is achieved with variable valve lift on the intake valves only; for example, FCA's Multiair electrohydraulic system is implemented on the intake valves only. CVVL is only applicable to double overhead cam (DOHC) engines.

Stoichiometric gasoline direct injection (SGDI) sprays fuel at high pressure directly into the combustion chamber, which provides cooling of the in-cylinder charge via in-cylinder fuel vaporization to improve spark knock tolerance and enable an increase in compression ratio and/or more optimal spark timing for improved efficiency. SGDI appears in about half of basic engines produced in MY 2017, and the technology is used in many advanced engines as well.[803]

From MY 2012 to MY 2016, the penetration rate of SGDI has increased from 23% to 48% in both car and truck segments. Nearly all vehicles using turbocharged spark-ignition engines also used GDI to improve suppression of knocking combustion. GDI provides direct cooling of the in-cylinder charge via in-cylinder fuel vaporization.[804] Use of GDI allows an increase of compression ratio of approximately 0.5 to 1.5 points relative to naturally aspirated or turbocharged engines using port-fuel-injection (e.g., an increase from 9.9:1 for the 5.3L PFI GM Vortec 5300 to 11:1 for the 5.3L GDI GM Ecotec3 with similar 87 AKI gasoline octane requirements).

Toyota's D-4S system combines GDI and PFI systems, with two injectors per cylinder (one directly in-cylinder and one immediately upstream of the intake port).[805,806,807] As of 2015, all Toyota vehicles in the U.S. with GDI appear to be using a variation of the D-4S dual GDI/PFI fuel injection system. This system increases peak BMEP, provides additional flexibility with respect to calibration of the EMS for improved cold-start emissions and offers an efficiency improvement over GDI alone.

---

[803] 49.7 percent of MY2017 vehicles are equipped with SGDI. EPA Report. The 2018 EPA Automotive Trends Report. https://nepis.epa.gov/Exe/ZyPDF.cgi/P100W5C2.PDF?Dockey=P100W5C2.PDF at Table 4.1 Production Share by Engine technology.

The recently redesigned Ford turbocharged 3.5L "EcoBoostTM" engine in the 2017 Ford F150 also uses a dual GDI/PFI injection system to increase power, reduce emissions, and improve efficiency,[808] but other engines in Ford's EcoBoost lineup use GDI. In MY 2015, Ford offered a version of the EcoBoost turbocharged GDI engines as standard or optional engines in nearly all of models of light-duty cars and trucks. Ford's world-wide production of EcoBoost engines exceeded 200,000 units per month during CY 2015.[809] Figure VI-21 below shows NHTSA's test data for the operation of dual fuel injection system of 2017 Ford F150 3.5L EcoboostTM on UDDS, HWFET, and US06 test cycles. The figure shows the split of operation of DI and PFI system on the 2017 Ford F150 3.5L engine with outline of varies test cycles. It shows that combination of PFI and DI are required in standard federal 2-cycle tests. The PFI system provides the fuel to the engine when the absolute engine load is below 40 percent. The DI system is quickly blended in above 40 percent absolute engine load. Between 60 percent to 140 percent absolute load, 70 percent to 80 percent of the fuel is delivered through the DI system. At absolute engine loads above 140 percent the PFI system provides an increase proportion of the fuel up to 40 percent.

as though it were a smaller engine, which reduces pumping losses and improves efficiency. In the MY 2017 fleet, manufacturers used DEAC on V6, V8, V10, and V12 engines in OHV, SOHC, and DOHC engine configurations. With some engine configurations in some operating conditions, DEAC creates noise-vibration-and-harshness (NVH) challenges. NVH challenges are significant for V6 and I4 DEAC configurations, and limit the operating range where DEAC can operate. For I4 engine configurations with smaller displacements, there are fewer operating conditions where engine load is low enough to use DEAC, which limits effectiveness. No manufacturers produced I4 DEAC engines in MY 2017. Typically, the smaller the engine displacement, the less opportunity DEAC provides to improve fuel consumption.

In MY 2013, Volkswagen introduced their 1.4L TSI EA 211 turbocharged GDI engine with "active cylinder management" in Europe.[811] This engine is the first production application of cylinder deactivation to an I4 engine and can deactivate 2 cylinders via cam-shifting under light load conditions. VW recently introduced a Miller Cycle variant of the same EA211 engine family with cylinder deactivation, providing indication the system has been accepted in the European marketplace, thus far, and will continue to be offered.[812]

Additionally, a system developed by Schaeffler employs a dynamic cylinder deactivation for I3 and I5 engines. The system alternates or "rolls" the deactivated cylinders allowing all cylinders to be deactivated after every ignition cycle and reactivated during the next cycle. Cylinder deactivation thus alternates within a single deactivation phase and not each time a new deactivation mode is introduced. The net result is that engines with an odd number of cylinders can operate, on average, with half their cylinder displacement (for example, a 3-cylinder engine could drop down to "1.5" cylinders on average or an I5 can drop to "2.5" cylinders on average). Ford and Schaeffler investigated both rolling cylinder deactivation and a system to deactivate one cylinder with Ford's EcoBoost 1.0L I3 engine and found that, with appropriate vibrational dampening, either strategy could be implemented with no NVH deterioration and with 3 percent or greater improvement in both real-world and EU drive cycle fuel economy.[813] Finally, Tula Technology has demonstrated a system, termed "Dynamic Skip Fire", with the capability of deactivating any cylinder.[814, 815]

The agencies provided engine fuel maps for each of the eight DOHC engines (Eng01, Eng02, Eng03, Eng04, Eng18, Eng19, Eng20, and Eng21) used for the NPRM analysis. Each of

these engines incrementally added technology to Eng01, a basic VVT engine, while holding all other factors constant like ambient temperature, ambient pressure, and fuel type.

For the NPRM analysis, the agencies estimated the effectiveness of DEAC using full vehicle modeling and simulation. In the NPRM PRIA 6.2.1.2, the agencies discussed how Autonomie uses a specific control logic for cylinder deactivation for naturally aspirated engines that takes into consideration for noise, vibration, and harshness.[816] For the final rule analysis, the agencies took steps to use full vehicle modeling and simulation to apply DEAC to both naturally aspirated and turbocharged engines. The same control logic was applied to the turbocharged engine cylinder deactivation (TURBOD) for the final rule analysis.

The agencies used the same assumptions for advanced cylinder deactivation (ADEAC) in the final rule analysis. In the NPRM the agencies stated engine maps were not available at the time of the analysis, and said that ADEAC was estimated to improve a basic engine with VVL, VVT, SGDO, and DEAC by three percent (for 4 cylinder engines) and six percent (for engines with more than 4 cylinders).[817] The new technology combination for turbocharged advanced cylinder deactivation (TURBOAD) uses a similar approach for determining effectiveness. The agencies have applied a one-and-a-half percent effectiveness improvement estimate for 4-cylinder or smaller engines and a three percent effectiveness estimate for 6-cylinder or larger engines relative to TURBOD.

For the final rule analysis the basic engine path for DOHCs are shown in Figure VI-22 and the high-level engine specifications are shown in Table VI-42. The baseline basic DOHC engine, Eng01, was the starting point and other engine technologies were incrementally adopted to determine effectiveness. Adoption of DEAC technology for turbocharged engines is discussed in Section VI.C.1.e)(2). Similarly, ADEAC technology is discussed in Section VI.C.1.e)(4).

Eng21	DOHC VVT + SGDI + DEAC	Cylinder deactivation added to Eng18	113

(b) SOHC

Similar to DOHC engines, SOHC engines were characterized as "Basic" engine technologies in the NPRM analysis. They are characterized by having a single camshaft in the cylinder head operating both the intake and exhaust valves. Four basic engine technologies, VVT, VVL, SGDI, and DEAC were considered for SOHC engines. Implementing these technologies involves changes to the cylinder head of the engine, but the engine block, crankshaft, pistons, and connecting rods require few, if any, changes.

The agencies provided engine fuel maps for each of these types of SOHC engines and requested comments. Engine maps 5b, 6a, 7a, and 8a were modeled SOHC engines. The SOHC engine models used engine 5a, which was based on Eng01 as a reference, by removing one camshaft. Eng5a was included for the Draft TAR, but not included for the NPRM analysis due to high BSFC from higher friction that was inherited from the DOHC engine design. A level 0.1 bar of friction reduction over the entire operating range for engine maps 5b, 6a, 7a, and 8a was applied to represent improvements over existing engine designs. The addition of friction reduction to these engines was a result of consideration of deliberative interagency comments received during the Draft TAR review process noting higher fuel consumption on the baseline SOHC engine 5a relative to other modern SOHC engines.

Meszler on behalf of NRDC commented that "[a]lthough variable valve timing (VVT) technology is identified as an available refresh technology, the NPRM CAFE model (unlike the version used for the 2016 TAR analysis) actually assumes that all baseline vehicles include VVT technology. As a result, the approximately 9 percent of model year 2016 sales that do not actually include VVT are not credited with any efficiency benefit for adoption of the technology….”[818]

We agree with this comment, and for the final rule analysis updated the CAFE model to add a non-VVT level engine in the 2017 analysis fleet and to allow those vehicles to adopt VVT technologies at a refresh or redesign. However, the agencies did not have engine maps for the non-VVT engines, so the agencies applied a fixed-value effectiveness estimate from similar VVT engine maps to represent the effectiveness for non-VVT engines. The agencies used the effectiveness of a similar configuration technology package of another engine to represent non-VVT engines. Non-VVT SOHC engines may add any combination of VVL with SGDI and DEAC. The agencies believe that the estimated effectiveness used for VVT engines was appropriate because the effectiveness offset is in line with 2015 NAS estimates for VVT engines with respect to VVL engines.[819, 820]

The basic engine path for SOHC engines used in this final rule is shown in Figure VI-23 and the specifications are shown in Table VI-43. Note, that Eng5a is only a reference used to build the rest of the SOHC engines.

Table VI-43 – Specifications for SOHC Basic Engine Technologies Modeled by Autonomie for the Final Rule Analysis

Engines	Technologies	Notes	Engine Reference Peak Power (kW)
Eng5a	SOHC VVT+PFI	Eng01 converted to SOHC (gasoline, 2.0L, 4cyl, NA, PFI, single cam VVT)	Reference only
Eng5b	SOHC VVT (level 1 Red. Friction)	Eng5a with valvetrain friction reduction (small friction reduction)	109
Eng6a	SOHC VVT+VVL (level 1 Red. Friction)	Eng02 with valvetrain friction reduction (small friction reduction)	109
Eng7a	SOHC VVT+VVL+SGDI (level 1 Red. Friction)	Eng03 with valvetrain friction reduction (small friction reduction), addition of VVL and SGDI	114
Eng8a	SOHC VVT+VVL+SGDI+DEAC (level 1 Red. Friction)	Eng04 with valvetrain friction reduction (small friction reduction), addition of DEAC	114

(3) Turbocharged Downsized Engines

Turbocharging increases the engine airflow and specific power output, allowing engine displacement reductions while maintaining a desired level of performance. As a result, friction and pumping losses are reduced at lighter loads relative to a larger, naturally aspirated engine. Recent turbocharger improvements have included use of lower-mass, lower inertia components and lower friction ball bearings to reduce turbocharger lag and enable higher peak rotational speeds. Improvements have also been made to turbocharger compressor designs to improve compressor efficiency and to expand the limits of compressor operation by improving surge characteristics.

Turbochargers with variable nozzle turbines (VNT) or variable geometry turbocharger (VGT) use moveable vanes within the turbocharger to allow adjustment of the effective exhaust turbine aspect ratio, allowing the operation of the turbocharger to be better matched across the entire speed and load range of an engine. VNT turbochargers are commonly used in modern light-duty and heavy-duty diesel engines.

The use of head-integrated exhaust manifolds (IEM) and split-coolant loops within the engine and the use of cooled EGR can reduce peak exhaust temperatures sufficiently to allow lower cost implementation of VNT turbochargers in spark ignition engines. There are also synergies between the application of VNT to Miller cycle operating engines, where increased low-speed torque, improved torque response are possible.[821]

A comparison of the same 2.4L PFI engine with a more recent, MY 2017 Honda 1.5L Turbocharged GDI engine with IEM.[822,823] The torque characteristics of the Honda engine are a closer match to the 2.4L PFI engine and the Honda engine represents approximately 37 percent downsizing relative to the 2.4L PFI engine due to turbocharging and includes other improvements (friction reduction, dual cam phasing, higher rates of internal EGR). The Honda 1.5L turbocharged GDI engine has significantly improved efficiency when comparing BTE across 20 speed and load points of significance for the regulatory drive cycles (1500 -2500 rpm and 2-bar to 8-bar BMEP as referenced to the 2.4l ENGINE). The BTE of the Honda 1.5L turbocharged engine showed an incremental effectiveness of 6 percent to 30 percent across this entire range of operation. The difference was more pronounced at lighter loads. Incremental effectiveness was 16% to 30% below 6-bar BMEP relative to the 2.4L engine.

Exhaust gas recirculation (EGR) is a broad term used for systems that control and vary the amount of inert, residual exhaust gases left in cylinder during combustion. EGR can improve efficiency at part-load by reducing pumping losses due to engine throttling. EGR also reduces combustion temperatures and thus reduces NO_x formation. The use of cooled EGR (cEGR) can reduce knocking combustion, thus allowing compression ratio and/or turbocharger boost pressure to be increased or spark timing to be advanced. EGR also slows the rate of combustion, so its use is often accompanied by other changes to the engine (e.g., inducing charge motion and turbulent combustion) to shorten combustion duration and allow improved combustion phasing. Internal EGR uses changes in independent cam-phasing to vary the overlap between intake and exhaust valve timing events, thus changing the amount of residual gases trapped in cylinder after cylinder scavenging. External EGR recirculates exhaust gases downstream of the exhaust valve back into the air induction system.

With turbocharged engines, there are variants of external EGR that use a low pressure loop, a high pressure loop or combinations of the two system. External EGR systems can also incorporate a heat-exchanger to lower the temperature of the recirculated exhaust gases (e.g., cooled EGR or cEGR), improving both volumetric efficiency and enabling higher rates of EGR.

[823] Nakano, K., Wada, Y., Jono, M., Narihiro, S. "New In-Line 4-Cylinder Gasoline Direct Injection Turbocharged Downsizing Engine." *Honda R&D Technical Review*, April 2016, pp 139-146.

Nearly all light-duty diesel engines are equipped with cEGR as part of their NO_x emission control system. Some diesel applications also use relatively large amounts (>25%) of cEGR at light- to part-load conditions to enable dilute low-temperature combustion. Research is also underway to apply similar forms of low-temperature combustion using high EGR rates to gasoline engine applications[824]

The use of cEGR technology was analyzed for post-2017 light-duty vehicles with engines at 24-bar BMEP, primarily as a means to prevent pre-ignition at the high turbocharger boost levels needed at 24-bar BMEP and above. The analysis did take into account efficiency benefits from the use of cEGR with turbocharged engines due primarily to part-load reductions in pumping losses and the reduction or elimination of commanded fuel enrichment under high-load conditions.

Prior to 2012, there were no examples of production vehicles equipped with turbocharged GDI engines using cEGR. The PSA 1.2L EB PureTech Turbo engine was launched in the MY 2014 Peugeot 308 in Europe as the first high-volume production application of cEGR on a turbocharged GDI engine. This engine has over 24-bar BMEP and also operates using Miller Cycle. The MY 2016 Mazda CX-9 2.5L SKYACTIV Turbo engine similarly combines the use of Miller Cycle with cEGR.[825] In another variant, Chrysler has implemented liquid-cooled cEGR on the 2016 3.6L Pentastar V-6 with natural aspiration and PFI.[826]

Engine maps 12, 13, and 14 modeled turbocharged downsized engines. Turbocharged downsized engines are characterized by technology that can create greater-than-atmospheric pressure in the engine intake manifold when higher output is needed. The raised pressure results in an increased volume of airflow into the cylinder supporting combustion, increasing the specific power of the engine. An increased specific power means the engine can generate more power per unit of volume, which allows engine volume to be reduced while maintaining performance, thereby increasing fuel efficiency. IAV Eng12 was the base engine for all simulated turbocharged engines and was validated using engine dynamometer test data.[827]

One notable change that the agencies made for the NPRM analysis based on stakeholder comments to the Draft TAR was to update the turbo family engine maps to assume operation on regular octane fuel (Tier 3, or 87 AKI), instead of premium fuel (Tier 2, or 93 AKI), to assure the maps accounted for real world constraints that impact durability and drivability, and noise, vibration, and harshness. Using regular octane fuel is consistent with the fuel octane that manufacturers specify be used in the majority of vehicles (manufacturers generally only specify premium fuel is required for higher performance models, although that is not always the case), and enables the modeling to account for important design and calibration issues associated with

regular octane fuel. The agencies noted in the NPRM that using the updated engine maps addressed over-estimation of potential fuel economy improvements and ensured that the analysis reflected real-world constraints faced by manufacturers to assure engine durability and acceptable drivability. Importantly, assuming no change in fuel octane required to operate a vehicle ensures that the agencies are modeling technology pathways that can improve fuel economy while maintaining vehicle performance, capability, and other attributes.

Compared with the NHTSA analysis in the Draft TAR, the turbocharged and downsized engine maps adjusted at high torque and low speed operation, and at high speed operation to account for knock limitations when using regular octane fuel. The knock model used to develop the turbocharged engines was trained on production and development engines tested at IAV to quantify the effects of different octane fuels.[828] Below the knock threshold, there is no change to the fuel consumption maps. The agencies noted that with the fuel octane change there are generally two major effects in the regions where the engine is knock-limited: first, spark timing is retarded causing a reduction in combustion efficiency and hence an increase in BSFC, and second, an increase in combustion and exhaust temperatures requiring fuel enrichment to cool those temperatures for engine component protection and resulting in increased BSFC.[829, 830]

The agencies also noted that for Eng14, the turbocharged downsized engine with cooled exhaust gas recirculation (cEGR), cEGR was added at the higher speeds where further reduction in combustion temperature was required. The higher specific heat capacity of cEGR reduced the need for fuel enrichment by lowering combustion temperatures and limiting the amount of spark retardation necessary to manage spark knock. With increasing load, cEGR is also used to lower combustion temperatures to reduce NOx emissions. The agencies explained that because IAV's models are not trained for emissions, cEGR was only considered for areas that are knock-limited and/or to reduce combustion temperatures. Because cEGR has the impact of slowing down burn rates, the amount of cEGR that could be utilized was balanced to maintain efficient combustion. Combustion stability was also evaluated to assure cEGR rates did not cause excessive cycle-to-cycle combustion variations, which adversely impact drivability.[831]

Some commenters criticized these downsized turbocharged IAV maps, referencing deliberative EPA comments docketed pursuant to the Clean Air Act procedural requirements at 42 USC 7607, which stated that the assumptions for Eng12's fuel octane, heating value, and carbon content were not representative of certification fuel and did not appear to be consistently used for the various engine maps, concluding that the resultant engine maps were not representative of CO_2 performance of turbocharged engines over the certification cycle. ICCT

---

[828] Knock models are based on Gamma Technology's kinetic fit model per the technical paper titled, "A combustion model for IC engine combustion simulations with multi-component fuels," by YoungChul Ra, Rolf D. Reitz – Engine Research Center, University of Wisconsin-Madison.

[829] Fuel enrichment is extra fuel is injected at the intake manifold port or directly into the cylinder. Fuel vaporization and the fuel's thermal mass reduces combustion and exhaust temperatures. Changes to the air/fuel ratio also impact combustion speed which impacts the knock limit.

[830] Singh, E. and Dibble, R., "Effectiveness of Fuel Enrichment on Knock Suppression in a Gasoline Spark-Ignited Engine," SAE Technical Paper 2018-01-1665, 2018, https://doi.org/10.4271/2018-01-1665.

[831] Heywood. B. J, Internal Combustion Engine Fundamentals, at 413-37, McGraw-Hill (1988).

stated it appeared these concerns had not been addressed for the NPRM, and that "this problem essentially affect[ed] all engines on the turbocharged engine pathway."[832]

The agencies disagree with ICCT's comments relating both to whether fuel specifications were used consistently and whether the fuel specifications for fuel octane, heating value and carbon content were representative of the same fuel. First, the EPA deliberative comments were resolved in the deliberative process through the clarification that a single fuel specification was used to develop all of the engines and engine maps. Therefore, the engine maps are internally consistent. The fuel specification was presented in the NPRM section PRIA Chapter 6.3.2.2.17. Second, the agencies considered future fuel and emissions standards by using regular octane fuel for this analysis. The assumptions for the fuel used in this analysis align with the EPA's Tier 3 standards that went into effect January 1, 2017.[833] For the reasons discussed further above, the agencies believe it is important to use Tier 3 fuel for engine maps used for rulemaking analysis.

Roush claimed that the turbocharged engine maps used in the analysis were responsible for an overly-conservative estimate of underlying combustion engine efficiencies, arguing that many production engines available today use the same technology packages identified in the PRIA but with significantly higher efficiencies.[834] Roush noted that the base turbocharged engine map used in the PRIA, Eng12, is assumed to have variable valve lift (VVL), but with a turbocharged engine the benefit of VVL over dual variable valve timing (VVT) is limited.[835] Roush argued that almost all vehicle manufacturers use lower-cost dual VVT systems in their turbocharged engines, and that the agencies' base turbocharged engine assumption is unrealistic with a correspondingly high cost.[836]

Roush contrasted its critique of Eng12 with an EPA ALPHA run of a 2016 Honda Civic 1.5L turbocharged engine (L15B7) with continuously variable intake and exhaust camshaft phasing (CVVT), which is less expensive than the CVVL, arguing that it showed greater efficiency over more of the engine map at a lower cost than Eng12. Roush further argued that since the L15B7 engine is the first generation of the new Honda turbocharged engine, "even further fuel consumption improvement is highly likely in the period through MY2025."[837]

As the agencies explained further above, from a technical perspective there is no reason why the 2016 Honda Civic 1.5 L Turbo should have an engine map that is the same as Eng12,

Eng13, or Eng14. The turbocharged engine technologies represented by Eng12, Eng13 and Eng14 are not representative of any specific engine from any one manufacturer. Honda's 1.5L turbocharged engine incorporates a unique combination of technologies including electric wastegate, sodium-filled exhaust valves, light weight internal components, friction reduction technologies, 2-stage oil pump, low viscosity oil (0W-20), and a unique exhaust system.[838]

While there are an enormous number of different technology combinations that manufacturers could apply on their engines, the agencies' analysis must select a reasonable number of configurations—in fact, the agencies analyze thousands of unique make/model/powertrain combinations and apply them to over one hundred thousand unique technology combinations for each of ten classes for this rulemaking. See Section VI.B.3.a)(6) and Section VI.B.3 for more details. For turbocharged engines, the agencies selected eight combinations which represent a wide range of technologies, combinations of technologies, and effectiveness improvements for the rulemaking analysis, as listed in Table VI-41. Three of the combinations were added based on commenter's recommendations. While it is possible to identify other combinations, such as the unique technologies Honda chose for its 1.5L Turbo engine, agencies do not believe it would be appropriate to select all of the technologies on one specific manufacturer's engine for the rulemaking analysis. Doing so would, appropriately, raise questions about the availability of proprietary designs and controls to other manufacturers, among other considerations.

The agencies also believe that the engine maps for Eng12, Eng13 and Eng14 show reasonable differences in BSFC maps that characterize the impact of each of these technology combinations, and differences relative to naturally aspirated engines. As discussed further above, incremental differences in BSFC are used for the rulemaking analysis. Roush's comments center on the comparison of absolute effectiveness values for a specific production vehicle, and do not address incremental effectiveness among a range of technologies, nor the appropriate baseline reference for the Honda 1.5L Turbo for technology content and for effectiveness. The ALPHA simulation for the 2016 Honda Civic 1.5L turbocharged engine provides absolute test data and has no baseline for assessing incremental effectiveness. Because there is no baseline, there is no basis for identifying which specific technologies have changed, nor any basis for determining the incremental effectiveness of each individual technology.

Regarding Roush's comment that that further fuel consumption improvement for the Honda L15B7 is highly likely in the period through MY 2025, Roush provided no information or data on what specific technologies would further improve the fuel consumption of that engine. With no defined new technology to consider, there is no basis for estimating the costs, nor for estimating the effectiveness of Roush's assertion. Without further information, the agencies can only point to the additional engine technologies considered for this final rule, discussed further below.

---

[838] Honda Press Release. "2016 Honda Civic Sedan Press Kit – Powertrain" October 18, 2015. https://hondanews.com/en-US/releases/2016-honda-civic-sedan-press-kit-overview?page=178. Last accessed Feb. 12, 2020.

ICCT also stated that IAV's handling of cooled EGR (cEGR) in the engine maps was inappropriate, as IAV analyzed cEGR as a knock-abatement technology instead of a fuel efficiency technology. ICCT stated that this is reason that the NPRM analysis showed no benefit to cEGR, and if the agencies had used EPA's properly modeled cEGR effectiveness based on validated data, the effectiveness of cEGR would have been more realistic.

Similarly, Roush commented that cEGR application in the modeled turbocharged engines is excluded in engine operating modes that highly influence vehicle fuel economy. Roush contrasted Eng13, a turbocharged engine with VVT, direct injection, and cEGR, with the Mazda 2.5L SkyActiv Turbo engine available in the 2016 Mazda CX-9, which also employs cEGR.

The agencies believe Eng14 was created and modeled using a sound technical methodology, using constraints that the industry uses to ensure the engines would meet durability and customer acceptability criteria. IAV turbocharged engines adopted VVT and VVL to maximize volumetric efficiency and improve the combustion process. Engines with VVT control intake and exhaust valve timing to recycle burned exhaust gas into the combustion chamber. The recycling of exhaust gases using VVT is commonly called internal EGR. Cooled EGR (cEGR) is a *second* method for diluting the incoming air that takes exhaust gases, passes them through a cooler to reduce their temperature, and then mixes them with incoming air in the intake manifold. Diluting the incoming air with inert exhaust gas reduces pumping losses, thereby improving BSFC. The dilution also reduces combustion rates, temperatures, and pressures, which mitigates spark knock and reduces the need for fuel enrichment at higher loads to control exhaust temperature for component durability (typically, exhaust valves and exhaust manifold). Not only does this exhaust gas displace some incoming air, but it also heats the incoming air and lowers its density. Both interactions lower the volumetric efficiency of the engine.[839] Cooled EGR is a more effective way of reducing combustion temperature in higher load and higher speed engines like turbocharged engines.

As mentioned above, IAV developed engine specifications, including the rate of internal EGR and cEGR, using variation in combustion criteria used by industry to ensure the engines would meet durability and customer acceptability criteria. In addition to reducing pumping losses, EGR slows the combustion rate and causes combustion to be less consistent cycle-to-cycle as the concentration increases. Industry and researchers use a measurement known as coefficient of variation of indicated mean effective pressure (COV of IMEP) to evaluate combustion stability. Industry commonly recognizes values greater than 3.0 percent as unacceptable because above those levels, the combustion instability creates a noticeable and objectionable drivability problem for vehicle occupants, referred to as "surge." Surge is perceived as the vehicle accelerating and decelerating erratically, instead of running smoothly. IAV set EGR rates at each of the engine operating conditions at the highest level that did not exceed 3.0 percent COV of IMEP. Therefore, the IAV engine maps *did* maximize efficiency within real-world constraints, similar to how manufacturers develop their engines. At the lower

[839] Volumetric efficiency (VE) in internal combustion engine engineering is defined as the ratio of the mass density of the air-fuel mixture drawn into the cylinder at atmospheric pressure (during the intake stroke) to the mass density of the same volume of air in the intake manifold. Ideally, you want this to be high as possible to maximize thermal efficiency during the power stroke (combustion phase).

speed and load conditions of the 2-cycle tests, the COV of IMEP threshold was reached using internal EGR alone, so additional cEGR was not applied. At higher load conditions, such as the US06 cycle, cEGR was applied.

ICCT's statement that the engine maps were only developed considering knock-abatement is inaccurate. In the PRIA Chapter 6.3.2.2.11, the agencies discussed the application of internal EGR in combination with cEGR for Eng14. VVT technology, with which Eng14 is equipped, maximizes EGR usage first in areas where the engine primarily operates, such as low load and low speed area like city cycle and highway cycle tests used in CAFE compliance testing. Cooled EGR is applied at higher speed and higher load conditions, such as the US06 test cycle.

Using EPA's modeled cEGR would have resulted in infeasible engine maps because they were developed assuming the exclusive use of high octane Tier 2 fuel, and using a COV of IMEP threshold of 5 percent, which is beyond the level that is deemed acceptable to consumers in the real world.[840] The use of these criteria results in engine maps with BSFC levels that cannot be achieved by manufacturers that must ensure their engines are durable and are acceptable to customers with fuels that are used and available. The reference engine for EPA's cEGR concept was a 2010 Ricardo prototype V6 engine that used 98 RON fuel (93AKI or premium fuel) to determine effectiveness.[841] The problems associated with using high octane Tier 2 to develop engine maps are discussed in detail in Section VI.C.1.a). The issues associated with excessive cEGR rates and COV of IMEP, are discussed immediately above. In addition, the cEGR engine maps that EPA used were never evaluated with regular octane Tier 3 fuel to assess the further degradation in BSFC and COV of IMEP that would occur where spark advance would need to be decreased to address spark knock, as decreasing spark advance directionally makes both BSFC and COV of IMEP worse.[842] Also, because some models are still under development, ALPHA effectiveness estimates in the Draft TAR and derived for the Proposed Determination do not provide the best available basis for assessing effectiveness impacts.[843] Therefore, the assumptions used for the EPA Draft TAR and Proposed Determination engine maps overstate feasible improvements and therefore do not provide meaningful comparisons to the engine maps used for the NPRM and final rule analyses.

Finally, with regards to Roush's comparison of Eng13 to the 2016 Mazda SkyActiv-G 2.5L Turbo, the agencies believe these engines use technologies that are sufficiently different so as to render a comparison not useful, even for a very rough validation of Eng13. Most fundamentally, as discussed in PRIA Chapter 6.3.2.2.11 and 6.3.2.2.13, the Mazda 2.5L Turbo is

a Miller cycle engine, whereas Eng13 is an Otto cycle engine. Also, the Mazda 2.5L Turbo has cEGR, whereas Eng13 does not.[844] On a more detailed level, as described in PRIA Chapter 6.3.2.2.20.10, Eng13 has a BSFC of 238 g/kwh, whereas Roush refers to an engine having a BSFC of 250 g/kwh.[845] The agencies therefore believe comparing the 2016 Mazda SkyActiv-G 2.5L Turbo to Eng13 is not a useful or relevant comparison. In the PRIA, the agencies included an engine map for a Miller cycle engine and requested comments on whether it should be included in the final rule analysis. Based on the comments, as discussed further below, the agencies added a Miller cycle engine to the final rule analysis.

(4) Non-HEV Atkinson Mode Engines

Manufacturers use a variety of designs and technologies to obtain an engine's highest thermal efficiency while maintaining drivability and performance. While the Otto cycle has historically been used by the vast majority of gasoline based engines, one way to improve thermal efficiency is by using alternative combustion cycles. One such alternative combustion cycle that can be used in place of the Otto cycle to achieve a higher maximum thermal efficiency is the Atkinson cycle. Atkinson cycle operation is achieved by modifying the Otto cycle engines' crank and valvetrain mechanics to maintain compression ratio while increasing expansion ratio.[846,847,848] Specifically, in Otto cycle operation, the exhaust valve is opened near the end of the power stroke, allowing exhaust gases out of the cylinder. The pressure in the cylinder is still about three to five atmospheres.[849] Currently, there are two common approaches to achieving Atkinson Cycle operation: either the exhaust valve timing or the intake valve timing are modified. In the first instance, the exhaust valve is not opened until enough expansion has occurred for the cylinder pressure to be equivalent to atmospheric pressure. The energy that typically is lost when the exhaust valve opens in Otto cycle is captured in the Atkinson cycle, leading to higher thermal efficiency. Modifying the intake valve timing, the most common way to achieve Atkinson cycle operation, involves allowing the intake valve to stay open during some portion of compression stroke. As a result, some of the fresh charge is driven back into the intake manifold by the raising piston so the cylinder is never completely filled with air, allowing optimized capture of combustion-created pressure.

While Atkinson cycle engines have higher theoretical thermal efficiency compared to Otto cycle engines, the Atkinson cycle engine delivers that higher efficiency at the cost of power

845 NHTSA-2018-0067-11984 at p. 20 of 37 Figure 8.

846 Otto cycle is a four-stroke cycle that has four piston movements over two engine revolutions for each cycle. First stroke: intake or induction; seconds stroke: compression; third stroke: expansion or power stroke; and finally, fourth stroke: exhaust.

847 Compression ratio is the ratio of the maximum to minimum volume in the cylinder of an internal combustion engine.

848 Expansion ratio is the ratio of maximum to minimum volume in the cylinder of an IC engine when the valves are closed (*i.e.* the piston is traveling from top to bottom to produce work).

849 Pulkrabek. W. W. "Engineering Fundamentals of the Internal Combustion Engine." 2nd edition. Pearson Prentice Hall, at p. 118.

density.[850] The reduced power density is because of lower operation pressures in the cylinder than in a typical Otto cycle engine. Accordingly, Atkinson cycle engines have been ideal for hybrid vehicles because their electric motor can make up for lost power density.

As vehicle technologies have become more sophisticated, descriptions of Atkinson cycle engines and Atkinson mode engine technologies have been used interchangeably, and often incorrectly, in association with high compression ratio (HCR) engines by the agencies and stakeholders. Although they both achieve an overall higher thermal efficiency than Otto cycle-only engines, they differ in execution depending on engine load. For the following discussion, Atkinson technologies considered in the analysis can be categorized into three groups: (1) Atkinson engines, (2) Atkinson-mode engines, and (3) Atkinson-enabled engines, which are variable valve timing engines with late intake closing that enables the Atkinson cycle mode. As discussed earlier, because power density is traded for efficiency, there is a limit to where Atkinson technology can be applied. While any vehicle could, theoretically, adopt an Atkinson-mode engine or an engine that enables operating in Atkinson cycle mode, the difference in vehicle application (high-performance versus standard-performance vehicles, towing requirements, trucks) leads to different effectiveness levels. The range of effectiveness appeared to create confusion among stakeholders regarding how the technology is applied to vehicles for compliance modeling and simulation.

Atkinson engines are engines that operate full-time in the Atkinson cycle. As mentioned above, the most common method of operation used by Atkinson engines currently is late intake closing. This approach allows backflow from the combustion chamber into the intake manifold, reducing the dynamic compression ratio, but providing a higher expansion ratio. This improves thermal efficiency but reduces power density. As a result of limited engine operation, these engines tend to have lower specific power.[851] The lower specific power tends to relegate these engines to hybrid vehicles applications, as coupling the engines to electric motors can compensate for the lower specific power. The Toyota Prius is an example of a vehicle that uses an Atkinson engine. Typically, vehicles that use an Atkinson cycle engine incorporate various fuel-efficient technologies like aerodynamic improvements, advanced continuously variable transmissions, mass reduction, and many other technologies to minimize engine load and attain high thermal efficiency.[852] The 2017 Toyota Prius achieved a peak thermal efficiency of 40 percent.[853]

Atkinson-mode engines are engines that use both the Otto cycle and Atkinson cycle during operation, switching between the modes of operation based on engine loads. During high loads the engine will operate in the power-dense Otto cycle mode, while at low loads the engine will operate in the higher-efficiency Atkinson cycle mode. The magnitude of efficiency improvement experienced by a vehicle using this technology is directly related to how much of

---

[850] Power density is the engine power per unit of displacement (= [Engine Power]/[Engine Displacement]).
[851] Specific power is the maximum power produced per displacement typically in units of hp/L or kw/l.
[852] Toyota. "Under the Hood of the All-new Toyota Prius." Oct. 13, 2015. Available at https://global.toyota/en/detail/9827044. Last accessed Nov. 22, 2019.
[853] Matsuo, S., Ikeda, E., Ito, Y., and Nishiura, H., "The New Toyota Inline 4 Cylinder 1.8L ESTEC 2ZR-FXE Gasoline Engine for Hybrid Car," SAE Technical Paper 2016-01-0684, 2016, https://doi.org/10.4271/2016-01-0684.

the vehicle's operation time is spent in Atkinson mode. This means vehicles that typically operate at a high load, like a truck towing a trailer, will spend more time in the Otto mode and less time in the Atkinson cycle mode, and will achieve a lower overall efficiency improvement over a traditional Atkinson engine that operates full-time in the Atkinson cycle. As a result, manufacturers will try to use this type of engine in conjunction with other technologies that reduce engine load, which allows the engine to operate more frequently in Atkinson cycle mode. For example, manufacturers could reduce parasitic losses by incorporating more efficient accessory technologies, or reducing overall vehicle mass and aerodynamic drag. These technologies are enablers for Atkinson-mode engines. When these types of technologies are adopted, it reduces the parasitic losses and, in turn, reduces the time the engine is in high load region. An example of an Atkinson-mode engine is the MY 2017 Mazda 3.

The last type of Atkinson-type engine, the Atkinson-enabled engine, can be characterized by primarily running the Otto cycle, but can achieve Atkinson-mode using variable valve timing (VVT) technology. Some engines use changes in VVT on the intake side to enable Atkinson cycle operation in low load, low speed operation, like city driving. These types of engines are typically used in applications that generally require higher specific power such that it would be infeasible to use Atkinson-mode engines or Atkinson engines. These vehicles tend to have higher load demands due to towing requirements, payload requirements, greater aerodynamic drag from larger frontal areas, greater tire rolling resistance from larger tires and higher driveline losses from four-wheel drive or all-wheel drive (*e.g.*, SUVs and pickup trucks). These higher load demands tend to push these engines more frequently to the less efficient region of the engine map and limit the amount of Atkinson operation. An example of the Atkinson-enabled engine is the Toyota MY 2017 Tacoma 3.5L 6-cylinder engine.

EPA developed two engine maps representing non-hybrid Atkinson engines to support the 2016 Draft TAR, Proposed Determination, and first Final Determination.[854] Referred to as ATK and ATK2, the engines represented a current non-hybrid Atkinson cycle engine based on the 2.0L 2014 Mazda SkyActiv-G (ATK) engine, and a future Atkinson engine concept based on the Mazda engines, but adding cooled EGR, cylinder deactivation, and an increased compression ratio (14:1) developed for full vehicle modeling and simulation (ATK2). For the 2016 Draft TAR, the agencies adopted EPA's high compression ratio (HCR) engine maps as Eng24 and Eng25, which corresponded to HCR1 and HCR2 in the CAFE modeling.

The Alliance had provided significant comments on the 2016 Draft TAR regarding the engine maps for HCR engines.[855] The Alliance detailed concerns regarding the feasibility and

[855] Alliance of Automobile Manufacturers, Alliance of Automobile Manufacturers Comments on Draft Technical Assessment Report: Midterm Evaluation of Light-Duty Greenhouse Gas Emission Standards and Corporate Average

effectiveness of Eng24 (HCR1) and Eng25 (HCR2). Many of the comments on the 2016 Draft TAR noted that the modeling projected an implausible rapid fleet penetration for these technologies, and overestimated effectiveness. Commenters stated the overestimation was due largely to modeling with use of high-octane fuel and the addition of other technologies like cEGR and cylinder deactivation (DEAC) using theoretical assumptions that exceed the bounds of operation of components. In contrast, other commenters had stated that EPA's work on the future Atkinson concept "has shown this pathway to be a promising alternative way to match the levels of improvement from a 27-bar BMEP turbocharged engine," and that "it is prudent to assume that the robust body of evidence EPA is putting together based on benchmarking and modeling data is a reasonable assessment of the technology's potential."[856]

For the NPRM analysis, the agencies included EPA's engine maps. The agencies allowed HCR1 to be applied only for a few manufacturers that indicated they would pursue this technology pathway versus alternative pathways, such as downsized turbocharged engines. The agencies were also careful to maintain vehicle performance and utility attributes when considering the application of Atkinson-type technologies. Current Atkinson capable engines have incorporated other technologies to reduce load in order to maximize time in Atkinson operation and to offset the power loss partially. This includes improved accessories, addition of friction reduction technologies, and other technologies that reduce engine load. Although modern improvements to engines have allowed Atkinson operation to occur more often (because of lower engine loads) for passenger cars, larger vehicles capable of carrying more cargo and occupants, and towing larger and heavier trailers, have more limited potential Atkinson operation. Those adoption features are discussed further in Section VI.C.1.e) Adoption Features, below.

As stated in the NPRM, the agencies excluded the HCR2 concept engine from the central analysis for several reasons. First, the concept was not subjected to validation to assess its technical feasibility. The concept was only modeled with high octane Tier 2 fuel. The HCR2's capability to operate on regular octane Tier 3 fuel was assessed using non-cycle specific operation, necessitating adjustments to the final results to account for Tier 3 fuel properties from Tier 2 operation, instead of simply operating the engine on Tier 3 to generate effectiveness estimates.[857] As discussed further above and in Section VI.C.1.a), fuel octane affects engine durability, performance, drivability, and noise, vibration and harshness. Assumptions about compression ratio, EGR rates, and use of cylinder deactivation were not adequately validated. PRIA Chapter 6.3.2.2.20.18 discussed many questions about HCR2 technology's practicability as specified, especially in high load, low engine speed operating conditions. There also has been no observable physical demonstration of the technology assumptions. Many manufacturer engine experts questioned its technical feasibility and commercial practicability during the model

[857] EPA PD TSD at 2-210.

years covered by the rulemaking. Stakeholders like the Alliance had previously asked for the engine to be removed from the rulemaking analyses until the performance could be validated with engine hardware.[858] For these reasons, the agencies considered the HCR2 engine too speculative to include in the NPRM central analysis. However, the agencies did provide a sensitivity analysis that included the HCR2 engine.

Comments on HCR1 and HCR2 varied, with commenters split on issues like whether HCR2 was speculative or real, whether there was technology in the fleet that could adequately be represented by HCR2, and the effectiveness of HCR2 in the analysis.

The Alliance commented in support of the decision to exclude HCR2 from the analysis, citing previous comments to the Draft TAR and proposed determination "detailing concerns of feasibility and effectiveness of the non-hybrid Atkinson engine technology packages, including cooled exhaust gas recirculation ("CEGR") and cylinder deactivation."[859] Specifically, the Alliance's comments "noted that the modeling projected an implausibly rapid fleet penetration of this complex engine technology and overestimated its effectiveness, due largely to modeling with high-octane fuel and the theoretical addition of CEGR plus cylinder deactivation." The Alliance concluded that "the inexplicably high benefits ascribed to this theoretical combination of technologies has not been validated by physical testing." Ford commented that previous assessments had "over-estimated both the effectiveness and near-term penetration of advanced Atkinson technology powertrains," stating that "[t]he effectiveness of the 'futured' Atkinson package (HCR2) that includes cooled exhaust gas recirculation (CEGR) and cylinder deactivation (DEAC) is excessively high, primarily due to overly-optimistic efficiencies in the base engine map, insufficient accounting of CEGR and DEAC integration losses, and no accounting of the impact of 91RON Tier 3 test fuel. Given the speculative and optimistic modeling of this technology combination, Ford supports limiting the use of HCR2 technology to reference only, as described in the Proposed Rule."[860] Separately, in support of its overarching comments that the NPRM modeling better reflected reality over prior regulatory assessments, Toyota commented that the effectiveness estimates for Atkinson cycle engine technology in the NPRM may still have been overstated.[861]

In contrast, CARB, ICCT, Meszler Engineering Services, UCS, and other stakeholders commented in different respects, with the broad themes being: (1) that the change in approach towards HCR engines from the Draft TAR and Proposed Determination to the NPRM was not justified, was inadequately justified, or was based on justification from the industry and not the agencies' own independent judgment; (2) that HCR2 as defined by EPA does exist and therefore should be used in the analysis; and (3) that even if HCR2 technology does not exist exactly as EPA defined it, other technologies in the fleet provide the same level of efficiency improvement as HCR2 and therefore it should be used in the analysis. Many of these commenters stated that if HCR2 had been allowed in the compliance analysis, as shown in the NPRM sensitivity analysis

[861] NHTSA-2018-0067-12150.

allowing HCR2 to be applied, compliance costs would have been reduced dramatically, "on par with NHTSA and EPA estimates in the TAR."[862,863]

Specifically, ICCT, CARB, and UCS took issue with the agencies' description of HCR2 technology as speculative, stating that description contrasted with how EPA described the technology in prior documents. ICCT commented that "in the Draft TAR and Final Determination, EPA observed the real-world advances toward production vehicles using HCR2 technology, and determined that that technology could be adopted by automakers during the compliance period."[864] ICCT stated that in the NPRM, "without rational explanation, the agencies now describe this technology as 'speculative' and have omitted the technology from their primary compliance scenarios altogether." CARB similarly commented that "[t]he fact that the Agencies, especially EPA, make [a statement that HCR2 is entirely speculative] is genuinely impossible to credit."[865] In support, all three commenters referenced EPA's hardware testing of a European Mazda engine,[866] with ICCT stating that HCR2 was dismissed as entirely speculative "despite the careful benchmarking of improved HCR engines by EPA," while CARB and UCS similarly cited this hardware testing to rebut the Alliance's assertion that the effectiveness values for HCR2 was "seriously overestimated."

ICCT also took issue with the NPRM statements that "many engine experts questioned [HCR2's] technical feasibility and near-term commercial practicability,"[867] and that "[s]takeholders asked for the engine to be removed from compliance simulations until the performance could be validated with engine hardware," with references to comments from Fiat-Chrysler (stating "Remove ATK2 from OMEGA model until the performance is validated" and "ATK2 – High Compression engines coupled with Cylinder Deactivation and Cooled EGR are unlikely to deliver modeled results, meet customer needs, or be ready for commercial application."),[868] and comments from the Alliance of Automobile Manufacturers, stating that "[There] is no current example of combined Atkinson, plus cooled EGR, plus cylinder deactivation technology in the present fleet to verify EPA's modeled benefits and … EPA could not provide physical test results replicating its modeled benefits of these combined technologies."[869] ICCT stated that the agencies did not identify any such comments or evidence from engine experts, or agency analysis of them. ICCT stated that "it is clear that NHTSA is deferring to stakeholders, and that EPA has been forced to defer to NHTSA."

ICCT also cited interagency review documents where EPA stated "[t]here are Atkinson engine vehicles on the road today (2018 [Toyota] Camry and Corolla with cooled EGR and the

2019 Mazda CX5 and Mazda6 with cylinder deac) that use high geometric compression ratio Atkinson cycle technology that is improved from the first generation, MY2012 vintage "HCR1" technology. While it is true that no production vehicle has both cooled EGR and cylinder deac, as the EPA "HCR2" engine did, nonetheless, these existing engines demonstrate better efficiency than estimated by EPA. Therefore, it would be appropriate to continue to use EPA's cooled EGR + deac engine map to represent "HCR2" engines."[870]

More specifically regarding the technical specifications of the HCR2 engine, ICCT and others stated that EPA had already addressed concerns brought by the Alliance[871] on (1) the base engine fuel consumption maps used as the foundation of the HCR2 engine map;[872] (2) practical limitations for cEGR to limit engine knock;[873] (3) the reliance on the availability of cylinder deactivation at unrealistic speed and load operating points; (4) the impact of 91 RON market and certification test fuels; and (5) the ability to implement HCR2 technology in existing vehicle architectures.[874]

CARB, UCS, and ICCT all stated, in different terms, that even if HCR2 technology does not exist exactly as EPA defined it, other technologies that exist in the fleet provide the same level of efficiency improvement as HCR2, specifically referencing the MY 2018 Toyota Camry engine and various Mazda engines, and claiming that HCR2 should therefore be used in the analysis. Specifically, CARB stated that these engines "are already achieving similar efficiency as the modeled HCR2 package even though they don't have the full complement of technologies

[871] EPA-HQ-OAR-2015-0827-4089; EPA-HQ-OAR-2015-0827-6156.

[872] NHTSA-2018-0067-11741 ("EPA showed how its "difference" engine maps validly represented performance of the ATK2 [HCR2] packages including on different fuels (pp. 301-02); and that the difference maps submitted in the industry comment "provided no information to compare vintage or application of the actual engine or engines tested, and did not state whether or not testing was conducted," lacking any information on "test and/or analytical methods, assumptions, fuel properties, environment test conditions, how the engine was controlled or how control was modeled, the number of data points gathered to generate the AAM 'difference map' to assure that identical testing and a sufficient fit of data was performed" (p. 301). In addition, EPA showed that concerns about knock due to use of cooled exhaust gas recirculation had been considered and resolved by ignition improvements (p. 302).").

[873] NHTSA-2018-0067-12039 ("The agencies appear to have relied upon the differences between anti-knock properties of Tier 2 and Tier 3 fuels, mistakenly focusing solely on octane while ignoring ethanol content. … this fails to acknowledge the anti-knock benefit of charge cooling related to ethanol, which more than compensates for the change in octane. HCR2 therefore should not be omitted out of concerns around knock.").

[874] NHTSA-2018-0067-11741. ICCT stated that EPA had previously concluded that existing engine architectures were "well adapted for [HCR] technology, and well adapted for the emerging next level HCR2 package of technologies, since the foundational technologies of gasoline direct injection, increased valve phasing authority, higher compression ratios, and cooled exhaust gas recirculation are already in widespread use." ICCT also commented that "EPA correctly observed that there was sufficient lead time to adopt the HCR2 technology before MY2022 and that it could be incorporated without requiring major vehicle redesigns."

(i.e., CEGR and DEAC) used in the HCR2 package."[875] CARB stated that these engines' "existence as production engines today certainly speaks to the feasibility of this technology for modeling that goes out to 2030MY."[876] Similarly, UCS stated that while the 2018 Toyota Camry engine "does not have all of the features of the HCR2 package constructed by EPA, it achieves similar levels of performance, thus rendering the agencies' rationale for excluding HCR2 moot—this is a production vehicle using Tier 3 fuel which achieves performance equivalent to HCR2."[877] Similarly, ICCT cited their own analysis of the 2018 Toyota Camry for the propositions that the package of technologies on the Camry exceeds the efficiency gains projected by EPA's OMEGA model, meaning that EPA's projections for the HCR2 engine might understate its effectiveness, and the early problems with low-end torque losses associated with Atkinson cycle engines have been completely solved.[878] ICCT stated that "[t]his evaluation of a real world vehicle that comes close to meeting all of the elements of an HCR2 engine makes it clear that HCR2 engines are far from a speculative technology."

ICCT and CARB also took issue with the agencies' justification for not using the HCR2 engine map as a simulation proxy for other new engine technology, specifically the statement that:

> It is important to conduct a thorough evaluation of the actual new production engines to measure the brake specific fuel consumption and to characterize the improvements attributable to friction and thermal efficiency before drawing conclusions. Using vehicle level data may misrepresent or conflate complex interactions between a high thermal efficiency engine, engine friction reduction, accessory load improvements, transmission technologies, mass reduction, aerodynamics, rolling resistance, and other vehicle technologies.[879]

Both commenters also took issue with the agencies' statement that existing technologies in the NPRM version of the CAFE model could work together appropriately to represent an HCR1 engine with additional efficiency improvements.[880]

ICCT stated that the complexity associated with the package of improvements in the Camry engine was common to all of the technology packages included in either OMEGA or CAFE modeling, and was neither a new issue nor an issue that precludes making reasonable engineering judgments. ICCT stated that the agencies projected efficiency estimates for other technology packages without engine maps from a production engine, citing the agencies' approach to modeling ADEAC technology, and concluded that the purpose of full vehicle simulation modeling is to project the efficiency impact when several different parts of the vehicle are simultaneously upgraded. ICCT stated that "[i]f reasonable estimates could be made for

ADEAC without fully validated engine maps, there is no reason to exclude other technologies on these grounds, especially considering the deep expertise by the agencies and their state-of-the-art technology simulation capabilities with the ALPHA modeling." Similarly, HDS noted that in contrast to the agencies' exclusion of HCR2 due to unresolved issues associated with knock mitigation and cylinder deactivation, "the 2018 analysis included Advanced Cylinder De-activation (ADEAC) which has recently come to market readiness."[881]

Merriam-Webster's dictionary defines speculative as "involving, based on, or constituting intellectual speculation," and also, "theoretical rather than demonstrable."[882] To be clear, most engines maps used in this analysis—IAV engine maps included—are theoretical, although they are built based on benchmarked engine data, and additional fuel-economy-improving technologies are added through modeling and simulation. But that does not mean that these engines are speculative. Although the IAV engine maps are not meant to model any manufacturer's particular engine, many, if not all, technology combinations have been implemented in real-world engines.

The agencies qualified the HCR2 engine as speculative because "no production engine as outlined in the EPA SAE paper has ever been commercially produced or even produced as a prototype in a lab setting. Furthermore, the engine map has not been validated with hardware and bench data, even on a prototype level (as no such engine exists to test to validate the engine map)."[883] It is important to distinguish theoretical engines maps with technology combinations that have been proven through real-world testing and operation, from the HCR2 engine map, that was created using a combination of validated individual component models, but the resulting engine system model and generated engine map were not fully validated against actual hardware.

The Alliance and individual automakers have repeatedly provided comments on agency actions with their assessment of the feasibility of the HCR2 engine, including comments ICCT referenced, stating the EPA had addressed concerns brought by the Alliance in the Proposed Determination Technical Support Document.[884] The agencies agree with ICCT that EPA provided responses to comments about HCR2 assumptions and engine maps in the Technical Support Document, the Proposed Determination, and the 2017 Final Determination. However, the agencies considered the matter further after receiving extensive comments on HCR2 for the NPRM. The agencies have concluded responses did not directly and fully address the technical concerns raised by the Alliance. Further, new data and information has become available since the Proposed and Final Determination that is directly relevant to the use of EPA's engine maps in this analysis.

[881] NHTSA-2018-0067-11985.
[882] Definition of "speculative," https://www.merriam-webster.com/dictionary/speculative.
[883] 83 FR 43038.
[884] Also important to note regarding ICCT's comment, the Alliance comment cited in the NPRM came from a section of the Alliance's comments titled, "EPA's Response to Alliance Comments Regarding Atkinson Cycle Engine Technology Benefits is Inadequate," which seems to suggest that EPA did not address concerns brought by the Alliance in the Proposed Determination Technical Support Document.

First, it is important to provide background information about ICCT's comments referencing previous discussions from the TAR, Proposed Determination and Final Determination. For the 2016 Draft TAR, EPA initially created the ATK1 and ATK2 engine maps based on the MY 2014 Mazda 2.0L SKYACTIV-G engine. The EPA benchmarked the Mazda engine, then modeled increasing the efficiency of the Mazda engine map by simulating the application of additional technologies using GT-Power models. The Alliance and FCA commented on the 2016 Draft TAR suggesting the EPA's development of the ATK1 and ATK2 engine maps were flawed because the maps were developed based on optimistic baseline engine characterization of the Mazda engine. The Alliance provided evidence of the flaws in EPA's characterization by comparing EPA's published base engine data, developed using Tier 2 certification gasoline, to engine data benchmarked by USCAR. USCAR benchmarked their own Mazda Skyactiv engine map using a 91 RON fuel. The comparison resulted in the creation of a "difference map" that showed where the two data sets diverged. The "difference map" implied there were areas of significant divergence, calling into question the data upon which the ATK1 and ATK2 models are based. The EPA responded stating "[the Alliance] did not provide data or other information to substantiate its claim that EPA's engine dynamometer fuel consumption measurements using a MY2014 Mazda OEM production 2.0L SKYACTIV-G, upon which the ATK2 packages from the TAR analysis are based, were in any way unrepresentative of this engine's actual performance."[885] ICCT cited in their NPRM comments that the EPA's discussion of these "difference maps" supported their statement that "[i]n fact, in the Technical Support Document for EPA's Proposed and 2017 Final Determination, EPA addressed all these concerns brought forth by the Alliance [regarding HCR2] (including the costs and effectiveness impacts of using regular octane fuel instead of premium fuel)."

It is understandable why ICCT may have thought this discussion addressed concerns raised about the HCR2 map; however, review of the Alliance's original Draft TAR comments makes it clear the Alliance's initial comments addressed the *benchmarking* of the MY 2014 Mazda 13:1 SKYACTIV-G engine itself. The Alliance's original comments, expressed concern over the modeled effectiveness of the advanced Atkinson technology packages because of the baseline engine data used. The Alliance suggested the effectiveness is likely overestimated due to multiple flaws in the benchmarking and modeling approaches taken by EPA. Only the benchmarking is addressed by EPA's response to the "difference maps," not the concerns about modeling approach.

The Alliance's concerns about modeling included the accuracy of the base engine fuel consumption maps (to the extent the baseline engine maps were overly optimistic, the modeled ATK maps were optimistic), limitations for cEGR to mitigate engine knock, limitations of cylinder deactivation, and the impact of fuels.[886] After further review, the agencies determined the Alliance's concerns were not fully addressed, resulting in a closer review of the ATK model development process.

---

[885] EPA PD TSD at 2-299.
[886] EPA-HQ-OAR-2015-0827-4089.

Review of the engine model development showed the engine map was generated assuming the use of high octane fuel, and the follow-up engine dynamometer validation testing also used high octane fuel.[887] The characterization of the baseline Mazda Skyactiv engine showed 1-3 percent increase in thermal efficiency across a large portion of the engine map when operated on Tier 2 fuel versus lower octane fuel.[888,889] The increase in engine thermal efficiency, caused by the higher octane fuel, is anticipated to be amplified when applying ATK technologies. ATK technologies increase efficiency by increasing the pressure in cylinder during combustion; however, at the same time the increased pressure increases risk of knock. For more discussion on engine knock, see Section VI.C.1.a). Ultimately, it is expected that the ATK1 and ATK2 engines would show a larger improvement in thermal efficiency as a result of being developed assuming a high-octane fuel versus the 1-3 percent improvement observed on the baseline Mazda Skyactiv engine.

A further limitation was revealed during the agencies review of the ATK model development. The limitation was in how COV of IMEP, an important indicator of combustion stability, was not accounted for directly in the model. The 0-D/1-D models used for investigating cEGR effectiveness could not adequately simulate changes to COV of IMEP. To compensate for the lack of an appropriate model, limits on cEGR were based on literature values for unrelated engine technologies.[890] As a result, there was no direct evaluation of combustion stability while evaluating the feasibility of the engine concept.

In contrast, for the NPRM and final rule analysis, IAV engines were optimized using Tier 3 fuel, to balance performance and fuel consumption. The majority of baseline vehicles are specified to operate on 87 AKI fuel, therefore lower octane fuel was used to maintain baseline functionality. The IAV engine maps were all derived from a consistent baseline engine and were also optimized using a validated kinetic knock model, and using a COV of IMEP threshold of 3 percent.

These differences in model construction caused an inconsistency that resulted in unrealistic improvements in fuel economy and CO_2 emissions for the HCR engine technologies, whereas the IAV engine maps reflect more realistic accounting for the improvements. The use

[887] Ellies, B., Schenk, C., and Dekraker, P., "Benchmarking and Hardware-in-the-Loop Operation of a 2014 MAZDA SkyActiv 2.0L 13:1 Compression Ratio Engine," SAE Technical Paper 2016-01-1007, 2016, doi:10.4271/2016-01-1007.

[888] The engine was first run on LEVIII-compliant certification fuel which has a 7 psi vapor pressure and 88aki. This fuel is similar to Tier 3 fuel with exception of the vapor pressure which is required to be 9 psi to meet Tier 3 certification. It was then tested on Tier 2 certification fuel (93aki) to assess effects of higher octane fuel on engine operation and efficiency.

[890] Schenk, C. and Dekraker, P., "Potential Fuel Economy Improvements from the Implementation of cEGR and CDA on an Atkinson Cycle Engine," SAE Technical Paper 2017-01-1016, 2017, doi:10.4271/2017-01-1016.

of high octane fuel and lack of combustion stability modeling are complimentary issues that have compounded effects when combined. For example, the use of high octane fuel allows more advanced spark timing which both increases efficiency and improves combustion stability, allowing higher cEGR rates before reaching acceptable limits for drivability. The compound effect is greater than the simply adding together individual effects, causing a potentially further unrealistic increase in effectiveness. At a minimum, it is uncertain how using Tier 3 fuel in the HCR2 engine would impact the BSFC of the engine, as there was no direct evaluation of the feasibility of the engine concept's ability to operate on regular octane fuel. The cost for the effectiveness of the HCR2 technology also is inconsistent with the cost of the effectiveness improvement values for the technologies in the 2015 NAS report.[891] In considering all of this information, the agencies, believe the HCR2 engine map overstates the capabilities of the technology and decided not to use that engine map for the final rule analysis.

However, the agencies believe the HCR1 engine map does reflect improvements that are representative of the technology in the rulemaking timeframe. For the final rule, to reflect better the incremental effectiveness for a low-cost version of HCR technology, the agencies added the HCR0 engine for the analysis. The specification of this engine was provided in the NPRM PRIA as Eng22b. Using this engine improves the estimated incremental effectiveness because the incremental engine changes from were directly specified for the modeling. HCR0 is the first engine in the HCR path that a manufacturer could adopt. Accordingly, the non-HEV Atkinson engine maps used for the NPRM and final rule central analysis fit into the three defined categories as follows: (1) Eng26 is an HEV Atkinson Cycle engine; (2) in the NPRM analysis, Atkinson-mode engines were characterized by Eng24 (HCR1), and for the final rule analysis, Atkinson-mode engines are characterized by Eng22b (HCR0) and Eng24 (HCR1); and (3) Atkinson-enabled engines are characterized by the different VVT engine technologies identified earlier in basic engine discussions and shown on Table VI-42 and Table VI-43.

Regarding the ability of manufacturers to adapt the engine architecture to practical use, the agencies see merit in observations from both manufacturers and other groups. ICCT is correct in their observation that some production engines have integrated combinations of the technologies, including SGDI, VVT and cEGR. Furthermore, the agencies agree with ICCT that an engine could be built integrating all the technologies represented in the HCR2 engine model. However, the agencies also agree with the Alliance's comments to the 2016 Draft TAR that applying all the technologies to an engine that only has some of the technologies would require a significant redesign of the powertrain package. The redesign would need to accommodate the new hardware integration, controls and emissions calibration, OBD development and other major efforts. As discussed further in Section VI.C.1.e), the agencies believe these considerations impact how quickly and widely the technology could be implemented in the rulemaking timeframe.

The agencies also disagree with commenters that the HCR2 engine map should be used as a proxy for other vehicles in the fleet that achieve high thermal efficiency. None of the existing vehicles that commenters cited, like the 2019 Toyota Camry and Corolla with cEGR or

---

[891] 2015 NAS at p. 90 and 91.

the 2019 Mazda CX5 and Mazda 6 with cylinder deactivation, include the same combination of technologies as the HCR2 engine. Unlike other engine technologies in the NPRM and the final rule analysis, no engines in the market or in prototype stages exist that have the combined technology specifications of the HCR2. Accordingly, there is no production vehicle that demonstrates the combination of technologies as applied in the HCR2 engine that (1) is feasible, and (2) can achieve the same effectiveness as the modeled HCR2 engine. The NPRM highlighted concerns about using the HCR2 engine map as a proxy for new engine technologies that achieve high thermal efficiency, specifically that:

> It is important to conduct a thorough evaluation of the actual new production engines to measure the brake specific fuel consumption and to characterize the improvements attributable to friction and thermal efficiency before drawing conclusions. Using vehicle level data may misrepresent or conflate complex interactions between a high thermal efficiency engine, engine friction reduction, accessory load improvements, transmission technologies, mass reduction, aerodynamics, rolling resistance, and other vehicle technologies.[892]

The agencies continue to believe this is true, and Toyota's comments that the Camry improvements were due to more than just the engine improvements, as discussed further below, provide further support to this conclusion.

Several commenters cited EPA's SAE paper discussing the use of the HCR2 engine model and comparing it to the benchmarking of a 2018 Toyota Camry 2.5L engine.[893,894] The commenters cited the HCR2 engine's similarities to the Toyota Camry engine as a reason to employ the technology model broadly across the entire vehicle fleet, including applying it to pickup trucks such as the Toyota Tacoma. In the paper, EPA benchmarked a 2018 Toyota Camry 2.5L Atkinson cycle engine equipped with cEGR. EPA created a full vehicle model (the exemplar vehicle) based on the benchmarked data for use in the ALPHA modeling tool. The full vehicle simulation was used to compare the HCR2 engine to the Camry's 2.5L engine, and showed some similarities. The paper implied that it is possible to adopt more technologies to the MY 2018 Camry, like cylinder deactivation, to meet future standards.

This paper, and the comments relying on it—specifically that it shows that additional technologies can be added to the MY 2018 Camry engine to meet future standards—were the subject of considerable debate in the rulemaking docket. Toyota provided supplemental comments regarding issues Toyota had with the modeling and simulation. These included a detailed discussion on why HCR2 is not a reasonable model of the 2018 Toyota Camry engine. Toyota identified other technologies that contributed to the overall thermal efficiency of the 2018

[893] Kargul, J., Stuhldreher, M., Barba, D., Schenk, C. et al., "Benchmarking a 2018 Toyota Camry 2.5-Liter Atkinson Cycle Engine with Cooled-EGR," SAE Int. J. Adv. & Curr. Prac. in Mobility 1(2):601-638, 2019, https://doi.org/10.4271/2019-01-0249.

[894] Duleep, K.G., "Review of the Technology Costs and Effectiveness Utilizing in the Proposed SAFE Rule," Final Report, H-D Systems, October 2018, at p. 37.

Camry compared to previous generation.[895] Toyota stated that the 2018 Toyota Camry employed numerous technologies like SGDI, cEGR, optimized intake system, optimized exhaust system, optimized piston design, laser-cladded valve seats, VVT, engine friction reduction, variable oil pump, and electric coolant pump, that all contributed to the engine's improved efficiency over the previous version.[896]

In addition, Toyota stated:

> [T]he 2018 Exemplar Vehicle that is based on the baseline 2018 Toyota Camry was equipped with engine start stop that doesn't exist on the production vehicle. Cylinder deactivation was added to the 2025 exemplar vehicle as a protentional enhancement. We acknowledged that adding cylinder deactivation to the Atkinson-cycle engines is technically possible and would provide some fuel economy benefits. However, the primary function of cylinder deactivation is to reduce engine pumping losses which the Atkinson cycle and EGR already accomplish. The diminishing return on the cylinder deactivation, Atkinson cycle and EGR are further exaggerated by smaller 4-cylinder engines.

This assessment aligns with the 2015 NAS committee report that estimated a 0.7 percent fuel consumption improvement for adoption of cylinder deactivation for DOHC and SOHC V6 and V8 engines.[897] The agencies agree with Toyota and the NAS assessment that applying cylinder deactivation in small cylinder count engines is subject to diminishing returns.

The agencies agree with Toyota that the presence of the advanced technologies, in addition to the HCR technology, contributed to the performance of the Camry. The analysis already provides benefits for the other advanced technologies individually, and risks, if not ensures, double counting these benefits if the HCR2 model is used (as discussed above and in Section VI.B). Likely double counting of technology effectiveness further supported the agencies' choice not to use the HCR2 model for the final rule analysis.

The agencies disagree that the approach taken to modeling ADEAC technology should similarly apply to modeling the HCR2 engine, or that because ADEAC just recently entered the market and was employed in the modeling, HCR2 should be as well. As discussed further below, the effectiveness estimates for ADEAC were based on extensive discussions with suppliers and manufacturers that provided CBI data, and technical publications.[898] The effectiveness estimates provided for ADEAC represented the effects of applying a single technology, and not a combined estimate for several technologies applied at once. Moreover, as commenters noted, ADEAC had recently "come to market readiness,"[899] compared to the HCR2

[899] NHTSA-2018-0067-11985.

technology which cannot be found, as modeled, in the market, or even in prototype form. As discussed throughout this document, the preferred approach for the NPRM and final rule was to isolate the effectiveness improvement attributable to specific technologies and apply those through full vehicle simulations to capture technology synergies and dis-synergies appropriately.

The agencies also disagree with ICCT's comment that the agencies were simply deferring to stakeholders, or that EPA was simply deferring to NHTSA regarding the feasibility of the HCR2 engine. It is reasonable to assume that the automobile manufacturers that belong to the Alliance employ some engine experts that are qualified to speak on the feasibility of an engine. Not just one or two manufacturers objected to the HCR2 engine; the Alliance commented on behalf of its members in support of the exclusion of the engine from the analysis,[900] and this exclusion was further supported by comments from individual automakers as well. Toyota, the automaker cited by several commenters as closest to implementing HCR2 technology stated in supplemental comments that (1) the HCR2 is not representative of its engine technology;[901] and (2) Toyota believes there are diminishing returns for implementing the HCR2 technologies.[902] The agencies received no comments from stakeholders that manufacture engines in support of the HCR2 technology's feasibility and potential future adoption.

For HCR technology, the agencies carefully considered comments to the NPRM and the available data, and concluded it is appropriate to include HCR0 and HCR1 engine models for the final rule analysis. The engine maps for those technologies provide the best estimates for the effectiveness of HCR technology relative to the engine maps for the other engine technologies used for the analysis. The agencies have reconsidered issues associated with the HCR2 engine models and maps. The agencies find that significant technical questions and issues remain and the engine maps very likely overstate the feasible amount of effectiveness that could be achieved by the represented technologies. Therefore, HCR2 technology is not included for the final rule analysis.

(5) HEV Atkinson Cycle Engines

Three types of Atkinson technology were discussed in the previous section. HEV Atkinson cycle engines fall in the first category, operating solely or primarily in Atkinson mode, supported by an electric drive.

Engine map 26 (Eng26) is the model of the HEV/PHEV Atkinson cycle engine used for the NPRM and final rule analysis. The engine was based on Argonne's Advanced Mobility Technology Laboratory (AMTL) 2010 Toyota Prius test data and published literature.[903]

[901] Comment from Toyota NHTSA-2018-0067-12376 ("While the agencies' definitions for the different levels of Atkinson technology seem to have evolved, the 2018 Camry is clearly not equipped with HCR2 technology.").

[902] Comment from Toyota NHTSA-2018-0067-12376 ("advanced cylinder deactivation has not yet been established when packaged with an Atkinson-cycle engine. Both technologies play similar roles in reducing engine pumping losses which can led to diminishing returns when combined.").

[903] "2010 Toyota Prius." http://www.anl.gov/energy-systems/group/downloadable-dynamometer-database/hybrid-electric-vehicles/2010-toyota-prius. Last accessed April, 2018.

Argonne's AMTL is continuously involved in research and testing of advanced technologies, especially in areas of electrification, and has a large existing database of test data from advanced technology vehicles.[904] As a result of Argonne's continued research, a 2017 Toyota Prius was characterized for an independent project. Argonne updated the HEV Atkinson cycle engine using the new Prius data to reflect the 41 percent thermal efficiency of the new 2017 system.[905] The electrification technology groups that used Eng26 include powersplit hybrid vehicles (SHEVPS) and plug-in powersplit hybrid vehicles (PHEV20/50).

(6) Advanced Cylinder Deactivation Technologies

Advanced cylinder deactivation (ADEAC) systems, also known as rolling or dynamic cylinder deactivation systems, allow a further degree of cylinder deactivation than the base DEAC. ADEAC allows the engine to vary the percentage of cylinders deactivated and the sequence in which cylinders are deactivated, essentially providing "displacement on demand" for low load operations.

ADEAC systems may be integrated into the valvetrains with moderate modifications on OHV engines. However, while the ADEAC operating concept remains the same on DOHC engines, the valvetrain hardware configuration is very different, and application on DOHC engines is projected to be more costly per cylinder due to the valvetrain differences.

The agencies discussed assumptions and effectiveness for the ADEAC package in the NPRM preamble.[906] The initial review of this technology was based on a technical publication that used a MY 2010 engine design that had incorporated a SOHC VVT basic engine.[907] Other preproduction 8-cylinder OHV prototype vehicles with ADEAC were briefly evaluated for this analysis, but no production versions of the technology have been studied.[908] For ADEAC fuel consumption effectiveness values, no engine map was available at the time of the NPRM analysis. Accordingly, the agencies took the effectiveness values as predicted by full vehicle simulations of a DEAC engine with SGDI, VVL, and VVT, and added 3 percent or 6 percent respectively for I-4 engines and V-6 or V-8 engines, and cross-referenced CBI data to quality check this approach.

[908] EPA, 2018. "Benchmarking and Characterization of a Full Continuous Cylinder Deactivation System." Presented at the SAE World Congress, April 10-12, 2018. Retrieved from https://www.regulations.gov/document?D=EPA-HQOAR-2018-0283-0029.

The agencies noted two potential approaches to including advanced cylinder deactivation in the full-scale Argonne simulation modeling analysis for the final rule. First, the agencies proposed using IAV Eng25a, which was developed to capture the maximum benefits of advanced cylinder deactivation with several constraints that could include emissions, cold start, NVH, and durability. Second, the agencies proposed using a technique developed by Argonne in coordination with NHTSA to split the overall engine data into individual cylinder data and compute overall torque and the fuel consumption rate by accounting for whether each cylinder is active or inactive. The agencies sought comment on using either approach in the final rule analysis to capture best the benefits of advanced cylinder deactivation.

CARB, ICCT, Meszler Engineering Services, HDS, and UCS provided a mixed set of comments on numerous aspects of ADEAC in the NPRM analysis.[909] Broadly, HDS commented on a need to describe ADEAC technology better: "The 2018 analysis also utilized Advanced Cylinder Deactivation in its analysis but the package components were not completely explained in the PRIA."[910] Other stakeholders provided comments on ADEAC adoption features, effectiveness, and cost, which are discussed below.

The agencies discussed assumptions and effectiveness for the ADEAC package in the NPRM preamble.[911] The initial review of this technology was based on a technical publication that used a MY 2010 engine design incorporating SOHC and VVT.[912] After determining the MY2010 engine design was not representative of the analysis fleet, the agencies used effectiveness values based on CBI data. The MY2017 baseline fleet reflects technology updates such as SGDI and DEAC that could adopt ADEAC incrementally in the final rule analysis. The cost and effectiveness for ADEAC reflects the baseline engine. The 2015 NAS Committee estimated an 0.7 percent fuel consumption improvement for adoption of cylinder deactivation for V6s and V8s engines.[913,914]

The agencies requested comments on alternative methods to estimate ADEAC effectiveness but received no comments regarding either approach mentioned in the NPRM. For the final rule analysis, the agencies used effectiveness values as predicted by full vehicle simulations of a DEAC engine with SGDI, VVL, and VVT, and added 3 percent or 6 percent respectively for I-4 engines and V-6 or V-8 engines for the naturally aspirated engines. Effectiveness for turbocharged engines used 1.5 percent and 3 percent values, as predicted by full vehicle simulation of a TURBOD engine for I4 and V6/V8, respectively. Without sufficient

[913] Applied after VVT and VVL.

[914] Applied before VVT and VVL.

data to simulate ADEAC, both the IAV and Argonne methodologies described in the NPRM provided questionable estimates for ADEAC. These errors would have propagated across other technology combinations in the analysis. The estimates used for ADEAC and TURBOD for the final rule analysis are also in line with EPA estimates discussed in their SAE technical publications.[915]

For the final rule analysis, the agencies used the same effectiveness values for ADEAC applied to naturally aspirated engines as in the NPRM, and incorporated estimated effectiveness values for TURBOAD to represent ADEAC on downsized turbocharged engines.

(7) Miller Cycle Engines

Like Atkinson Cycle, Miller Cycle engines use changes in valve timing to reduce the effective compression ratio while maintaining the expansion ratio. Automakers have investigated both early intake valve closing (EIVC) and LIVC variants. There is some disagreement over the application of the terms Atkinson or Miller Cycle to EIVC and LIVC valve event timing and sometimes the terms are used interchangeably. For the purpose of this analysis, Miller Cycle is a variant of Atkinson cycle with intake manifold pressure boosted by either a turbocharger and/or a mechanically or electrically driven supercharger. More simply, it is an extension of Atkinson Cycle to boosted engines. The first production vehicle offered using Miller Cycle was the MY 1995 Mazda Millenia S, which used the KJ-ZEM 2.3L PFI engine with a crankshaft-driven Lysholm compressor for supercharging. Until recently, no Miller Cycle gasoline SI engines were in mass production after 2003, and Miller Cycle was not evaluated as a potential gasoline engine technology as part of the rulemaking for MYs 2017-2025.

As with Atkinson Cycle engines, the use of GDI and camshaft-phasing with a high degree of authority have significant synergies with Miller Cycle. Modern turbocharger and aftercooler systems allow Miller Cycle engines to attain BMEP levels approaching those of other modern, downsized, turbocharged GDI engines. The 1.2L I3 PSA “EB PureTech Turbo” Miller engine recently launched in Europe, N. Africa and S. America in the MY 2014 Peugeot 308.916 In addition to Miller Cycle, the engine also uses cEGR. This engine has a maximum BMEP of 24-bar and is similar in many respects to the Ford 1.0L I3 EcoBoost but achieves 35% BTE.

In MY 2016, VW launched a Miller Cycle variant of the 2.0L EA888 turbocharged GDI engine in the U.S. The VW implementation of Miller Cycle has a second Miller Cycle cam profile and uses camshaft lobe switching on the intake cam to go into and out of an EIVC version of Miller Cycle.917,918 The peak BTE of 37 percent is higher than that of the PSA Miller cycle

engine, in part due to a higher expansion ratio (11.7:1 for the VW engine vs. 10.5:1 for the PSA engine). Like the PSA engine, the VW uses high-pressure cEGR. Peak BTE is comparable to the Mazda SKYACTIV-G engines but is available over a broader range of speed and load conditions. Both Atkinson and Miller Cycle engines show broad areas of operation at greater than 32% BTE. Light-duty Diesel Engines

In the proposed rule, the agencies provided two engine maps representative of Miller cycle and Eboost engines with 48V battery systems. The Miller cycle engine (Eng23b) and Miller cycle engine with Eboost (Eng23c) specifications were provided in the PRIA but were not used in the NPRM analysis,[919] although the agencies sought comment on the specifications used for the modeling.

Roush on behalf of CARB, ICCT, Meszler Engineering on behalf NRDC, HDS, and UCS, commented that the agencies did not consider the combination of turbocharging and Miller cycle.[920] Specifically, Roush argued that the agencies' omission of an engine that utilizes a combination of turbocharging and Miller cycle was unreasonable because it is already in production, specifically on the VW 2.0L EA888 Gen3B – DI. Roush stated this omission would limit the effectiveness for turbocharged engines and cause the adoption of more expensive solutions, thereby overstating the cost to achieve target fuel economy levels. Similarly, Roush pointed to the omission of an engine that uses a variable geometry turbocharger as an error in the agencies' vehicle modeling; Roush pointed to VW's EA211 TSI Evo engine available in Europe in 2017 as an example of an engine in production that enables cost-effective Miller cycle applications.

In response to these comments, the agencies added and used both Miller cycle-type engines and Miller cycle engines with electric assist for the final rule analysis. Discussed earlier in this section, the agencies developed engine maps for additional combinations of technologies for the final rule, including engine maps that became available after the NPRM analysis was completed but before the NPRM was published. For the final rule analysis, the agencies have included a Miller cycle engine, Eng23b (VTG), as another available engine technology. The specification of this engine was discussed in PRIA Chapter 6.3.2.2.20.20.2.2 and the costs are based on the 2015 NAS estimates for this technology.

(8) Variable Compression Ratio Engines

Variable compression ratio (VCR) engines work by changing the length of the piston stroke of the engine to operate at a more optimal compression ratio and improve thermal efficiency over the full range of engine operating conditions. Engines using VCR technology are currently in production, but appear to be targeted primarily towards limited production, high performance and very high BMEP (27-30 bar) applications.

A few manufacturers and suppliers provided information about VCR technologies, and several design concepts were reviewed that could achieve a similar functional outcome. In

---

919 NPRM PRIA at p. 307-09.
920 NHTSA-2018-0067-11985. HD systems at p, 34; ICCT at p. 102; NRDC Attachment 2 at p.16.

addition to design concept differences, intellectual property ownership complicates the ability of the agencies to define a VCR hardware system that could be widely adopted across the industry.

For the NPRM analysis, the agencies provided specifications of a VCR engine (Eng26a) in the PRIA for review and comment.[921] However the VCR engine was not used in the NPRM analysis.

The Alliance commented in support of the exclusion of variable compression ratio engines from the analysis, stating that the technology is still in early development, and too speculative to be included at this time. The Alliance also stated that the technology is unlikely to attain significant penetration in the MY 2026 timeframe due to intellectual property protection associated with early implementations and its likely application primarily to high-performance vehicles. The Alliance also cited the technology's price as a potential barrier to adoption.[922] Similarly, Ford commented that:

> [VCR technology] is likely to be adopted only for premium / limited-market vehicles in the near future. We also agree that intellectual property protections on early implementations will further inhibit significant fleet penetration. Incorporation of VCR requires a new or highly modified engine architecture, necessitating major investment from both the engineering and manufacturing standpoints. Sharing / commonality across engine families would be greatly limited."[923,924]

Similarly, other automakers commented on a confidential basis that several main hurdles prevented them from employing VCR engines, including the complexity of VCR engines and the associated cost of those complex parts.

UCS commented that the agencies did not consider VCR engine technologies in the NPRM analysis.[925] They stated that the technology was not modeled, nor was it incorporated into the CAFE model. UCS argued that Nissan's VC-Turbo engine is part of a strategy to improve fuel efficiency for Nissan's luxury vehicles by 30-35 percent over previous models, which would be enough to exceed the vehicle's regulatory targets without any credits. UCS concluded that given VCR technology is being put into production in a high-volume vehicle, there is no reason for the agencies to exclude its adoption.

The agencies agreed with comments to include VCR engine technologies in the final rule analysis and on further technical consideration, the agencies have added a VCR engine to the engine technologies list manufacturers could adopt. However, the agencies limited the adoption of the VCR engine technology to Nissan only. VCR engines are complex, costly by design, and synergetic with mainstream technologies like downsize turbocharging, making it unlikely that a

manufacturer that has already started down an incongruent technology path would adopt VCR technology.

(9) Diesel Engines

For many years, engine developers, researchers, manufacturers have explored ways to achieve the inherent efficiency of a diesel engine while maintaining the operating characteristics of a gasoline engine. Diesel engines have several characteristics that result in superior fuel efficiency over traditional gasoline engines, including reduced pumping losses due to lack of (or greatly reduced) throttling, high pressure direct injection of fuel, a combustion cycle that operates at a higher compression ratio, and a very lean air/fuel mixture relative to an equivalent-performance gasoline engine.[926] However, diesel technologies requires additional enablers, such as a NO_x adsorption catalyst system or a urea/ammonia selective catalytic reduction system, for control of NO_x emissions.

Gasoline powered engines have used an electric spark to ignite a fuel and air mixture to produce power since their invention. A fuel and air mixture is drawn into an engine cylinder and ignited at a defined, precise moment releasing energy as a controlled explosion.[927] The energy released during this explosion is translated to the engine crankshaft and then out of the engine to perform whatever work the engine is tasked to do.

Diesel fueled engines ignite the fuel and air mixture without an electric spark. They rely on the heat generated by squeezing the fuel and air mixture until it ignites; this is commonly referred to auto-ignition. Diesel engines utilize very high compression ratios to achieve auto-ignition and, therefore, produce more power per unit of energy. Aside from efficiency, however, gasoline and diesel fueled engines maintain very distinct characteristics such as the rates (time) power is achieved, emissions, component weight, and more.

Diesel engines have characteristics that differ from gasoline spark ignition (SI) engines and allow improved fuel efficiency, particularly at part-load conditions. These include reduced pumping losses due to lack of (or greatly reduced) throttling, and a combustion cycle that operates at a higher compression ratio and at very lean air/fuel ratio when compared with an equivalent-performance gasoline engine. Operating with a lean-of-stoichiometric air/fuel ratio poses challenges with respect to NO_x control, requiring either a NO_x adsorption catalyst (NAC), urea or ammonia-based selective catalytic reduction (SCR) or some combination of NAC and SCR in order to meet Federal Tier 3 and California LEV III NO_x emissions standards. Beginning with Federal Tier 2 emission standards, it has also been necessary to equip light-duty diesels with catalyzed diesel particulate filters (CDPFs) in order to comply with light duty PM emission standards.

---

[926] Diesel cycle is also a four-stroke cycle like the Otto Cycle, except in the Intake stroke no fuel is injected and fuel is injected late in the compression stroke at higher pressure and temperature.
[927] A spark is required because the air to fuel mixture contains too much gasoline ("rich") to ignite without it but cannot be made lean enough to reliably, precisely and controllably ignite on its own.

Detailed analysis of the vehicle simulation results used within the 2012 FRM uncovered some shortcomings within the MSC EASY5 vehicle simulations used as light-duty diesel vehicle GHG effectiveness inputs into the Ricardo Surface Response Model. The modeled light-duty diesel technology packages did not operate in the most efficient regions of engine operation. This may have been in part due to inconsistencies in the application of the optimized shift strategy and in part due to an oversight that resulted in the apparent oversizing of light-duty diesel engine displacements. For example, plotting the average engine speed and load operating points over the regulatory drive cycles for the MSC EASY5 diesel simulations on top of the diesel engine maps showed that there was significant potential for improvement in the choice of selected gear. These issues were addressed for the Draft TAR CAFE analysis, and for the CO_2 and CAFE analyses for this NPRM through the use of the Autonomie shift schedules and control models described in this chapter.

Light-duty diesel engines have also evolved considerably over the last five years, particularly in Europe. Modern light-duty diesel engine designs appear to be following similar trends to those of turbocharged GDI engines and, in some cases, heavy-duty diesel engine designs, including:

1) Engine downsizing (increased peak BMEP)
2) Engine down-speeding
3) Advanced friction reduction measures
4) Reduced parasitic
5) Improved thermal management
6) Use of a combination of both low- and high-pressure-loop cooled EGR
7) Advanced turbocharging, including the use of VNT and sequential turbocharging
8) Incorporation of highly-integrated exhaust catalyst systems with high NO_x and PM removal efficiencies
9) Adoption of high-pressure common rail fuel injection systems with higher injection pressures and increased capability (i.e., multiple injections per firing cycle)

The highest BMEP engines currently in mass-production for high-volume light-duty vehicle applications are all diesel engines. MY 2016-2017 light-duty diesel engines are available from Honda, BMW and Mercedes Benz in the EU with approximately 26-bar to 29-bar BMEP and peak cylinder pressures at or above 200-bar, [928, 929, 930]. The light-duty diesel technology packages used in the 2012 FRM analyses relied on engine data with peak BMEP in the range of 18-20 bar. These were engine configurations using single-stage turbocharging with electronic wastegate control, high-pressure or low-pressure (single-loop) cooled EGR, and common-rail

fuel injection with an 1800 bar peak pressure. The cost analysis in the 2012 FRM for advanced light-duty diesel vehicles assumed use of using a DOC+DPF+SCR system for meeting emissions standards for criteria pollutants.

For the NPRM, the agencies modeled one diesel engine, represented by Eng17,[931] which was termed "ADSL" in the CAFE modeling. DSLI, a more advanced diesel engine, represented a 4.5 percent effectiveness improvements over ADSL.

Diesel engines have several characteristics that result in superior fuel efficiency over traditional gasoline engines, including reduced pumping losses due to lack of (or greatly reduced) throttling, high pressure direct injection of fuel, a combustion cycle that operates at a higher compression ratio, and a very lean air/fuel mixture relative to an equivalent-performance gasoline engine.[932] However, diesel technologies requires additional enablers, such as a NO_x adsorption catalyst system or a urea/ammonia selective catalytic reduction system, for control of NO_x emissions.

For the NPRM, the agencies modeled one diesel engine, represented by Eng17,[933] which was termed "ADSL" in the CAFE modeling. DSLI, a more advanced diesel engine, was modeled using a 4.5 percent fixed effectiveness improvements over ADSL.

CARB commented that diesel technologies are essentially locked out of being selected in the CAFE model because of the high cost.[934] They state that diesel technology is only selected in rare instances.

The agencies agree that diesel technology is rarely selected. The technologies required to meet diesel emissions standards are costlier compared to gasoline technologies, particularly in the rulemaking timeframe. For example, the 2015 NAS report determined that in the current market, "vehicles with diesel engines are priced an average of more than $4,000 more than comparably equipped gasoline vehicles."[935] Furthermore, the NAS report stated that the "Carbon Penalty" makes it harder for manufactures to meet CO_2 standards because of the higher carbon density in the diesel fuel compared to gasoline that results in higher CO_2 per gallon.[936] In addition, the market for diesel vehicles has stagnated at around 1 percent for many years after it peaked at 5.9 percent in 1981, according to the EPA Trends Report.[937] The agencies believe that

the modeled cost of diesel engines appropriately prevents their widespread adoption in the analysis.

UCS commented that the agencies restricted cylinder deactivation technologies to only naturally aspirated gasoline engines.[938] In response to this and other comments, the agencies have allowed diesel engines to adopt ADEAC for this final rule analysis. These engines were designated as DSLIAD to represent diesel engines with ADEAC, and were modeled using a 7.5 percent fixed effectiveness improvement on top of DSLI. This effectiveness improvement of ADEAC on diesel engines is based on the review of technical publications discussed earlier in Section VI.C.1.c)(6).

(10) Alternative Fuel Engines

CNG engines use compressed natural gas as a fuel source. The fuel storage and supply systems for these engines differ tremendously from gasoline, diesel, and flex fuel vehicles. CNG engines were a baseline-only technology and were not applied to any vehicle that was not already CNG-based in NHTSA's analysis, per EPCA/EISA's restrictions on considering dedicated alternative fueled vehicles to set fuel economy standards.[939,940] However, for the EPA program the agencies allowed any vehicle to adopt CNG engines. The NPRM MY 2016 analysis fleet did not include any dedicated CNG vehicles to simulate in the CAFE Model.

In addition, for the NPRM and this final rule analysis, NHTSA modified the CAFE model to include the specific provisions related to AFVs under the CO_2 standards. In particular, the CAFE model now carries a full representation of the production multipliers related to electric vehicles, fuel cell vehicles, plug-in hybrids, and CNG vehicles, all of which vary by year through MY 2021.

(11) Emerging Gasoline Engine Technologies

Manufacturers, suppliers, and researchers continue to create a diverse set of fuel economy technologies, some of which are still in the early stages of the development and commercialization process. Due to uncertainties in the cost and capabilities of emerging technologies, some new and pre- production technologies are not a part of the CAFE model simulation. As discussed throughout this section and in VI.B.3, the agencies declined to include technologies in the analysis where the agencies did not believe those technologies would be feasible in the rulemaking timeframe, or the agencies did not have appropriate data upon which to generate an estimate of how effective the technology is that could be applied across the ten

[938] Docket ID NHTSA-2018-0067-12039, at p. 3.
[939] NHTSA's provisions for dedicated alternative fuel vehicles in 49 U.S.C. 32905(a) state that the fuel economy of any dedicated automobile manufactured after 1992 shall be measured based on the fuel content of the alternative fuel used to operate the automobile. A gallon of liquid alternative fuel used to operate a dedicated automobile is deemed to contain 0.15 gallon of fuel. Under EPCA, for dedicated alternative fuel vehicles, there are no limits or phase-out for this special fuel economy calculation, unlike for duel-fueled vehicles, as discussed below.
[940] EPA's provisions for dedicated alternative fuel vehicles that are able to run on compressed natural gas (CNG) currently are eligible for an advanced technology multiplier credit for MYs 2017-2021.

vehicle classes. Evaluating and benchmarking promising fuel economy technologies as they enter production-intent stages of development continues to be a priority as commercial development matures.

UCS and ICCT commented that the agencies should consider novel engine designs.[941] Specifically, ICCT stated that the agencies should consider a more advanced HCR technology called HCCI (similar to Mazda's Skyactiv-X) by estimating efficiency and cost to EPA's process that assigned effectiveness estimates using LPM. They stated that "the agencies developed estimates for ADEAC in the NPRM and the associated modeling even without conclusive and independently verifiable effectiveness."

In response to comments, a number of technologies were added for the final rule analysis, and adoption features were refined accordingly, as discussed further in Section VI.C.1.e). New engine technologies and combinations include Atkinson engine technology allowed with P2 HEV, new high compression ratio engine (HCR0), variable compression ratio engine, variable geometry turbo engine, variable geometry turbo with electric assist engine, diesel with advanced cylinder deactivation engine, turbo with cylinder deactivation engine, diesel with manual transmission, diesel with start-stop, and PHEV-turbo with 20 mile range, and PHEV-turbo with 50 mile range.

The agencies also disagree with ICCT's comment that because ADEAC was developed without "conclusive and independently verifiable effectiveness" estimates, and as such the agencies should allow HCCI technology as well. First, conclusive estimates for ADEAC effectiveness were based on CBI data from both manufacturers and suppliers, technical publications, and engineering judgement. The references can be reviewed in the previous Section VI.C.1.c)(6) Advanced Cylinder Deactivation Technologies. In addition, the agencies benchmarked the first prototype vehicle equipped with skip-fire, and discussed potential application of it for other engines. A similar level of data has not been made available for HCCI engine technologies.

The agencies also believe that the technology associated with Mazda SkyActiv-X has been mischaracterized by ICCT and other commenters, and declined to include a specific representation of the SkyActiv-X family of technologies in the analysis for two reasons. The engine known as Skyactiv-X is characterized by Mazda as a unique spark plug controlled compression ignition (SPCCI) technology, 2-liter displacement, 4-cylinder engine with mechanical compression ratio of 16.3:1 operating on 95 RON fuel (91 AKI) with a mild hybrid system.[942] The NPRM and this final rule analysis may not have the exact technology combination associated with this vehicle, but the analysis does include technologies that are

UCS, Comment. Docket No. NHTSA-2018-0067-12039, at pp. 6 & 7.
[942] Mazda Press Release. "Revolutionary Mazda Skyactiv-x engine details confirmed sales start." May 6, 2019. https://www.mazda-press.com/eu/news/2019/revolutionary-mazda-skyactiv-x-engine-details-confirmed-as-sales-start/. Last accessed Dec, 11, 2019.

representative of them, that could enable the benefits employed by the Mazda engine. A mild hybrid system is available for adoption in both the NPRM and this final rule analysis.

Also, the effectiveness associated with this engine was from European test cycles and cannot be compared for U.S. application. European compliance tests are significantly different than those in the U.S., especially when it comes to fuel type and test cycles. Any effectiveness data provided for this engine or any non-U.S. engine cannot be used for U.S. vehicle application without an adjustment for fuel and emissions. For example, the higher-octane fuel used in Europe enables engines to operate at higher compression ratios across wider areas of engine operation.

The agencies further believe that with the technology additions for the final rule discussed in previous sections, the analysis reasonably represents the suite of engine technologies that could be available in the rulemaking time frame. Manufacturers, suppliers, and researchers continue to create a diverse set of fuel economy technologies. However, due to the uncertainties in the cost, manufacturing, and intellectual property concerns like those identified by commenters, the agencies did not consider prototype technologies in the final rule analysis.

(12) Engine Lubrication and Friction Reduction Technologies

Manufacturers have already widely adopted both lubrication and friction reduction technologies. Previous agency analysis considered these improvements in combination as Improved Low Friction Lubricants and Engine Friction Reduction (LUBEFR). The NPRM analysis included advanced engine maps that already assume application of low-friction lubricants and engine friction reduction technologies, and therefore additional levels of friction reduction were not considered. Low-friction lubricants including low viscosity and advanced low-friction lubricant oils are now available, and widely used. Manufacturers may make engine changes and conduct durability testing to accommodate the lubricants. The level of low-friction lubricants exceeded 85 percent penetration in the MY 2016 fleet.[943] Reduction of engine friction can be achieved through low-tension piston rings, roller cam followers, improved material coatings, more optimal thermal management, piston surface treatments, and other improvements in the design of engine components and subsystems that improve efficient engine operation.

Meszler Engineering on behalf of NRDC commented that "the NPRM CAFE model no longer considers advanced lubricants and evolutionary friction reduction (LUBEFR) to be adoptable. As a result, no fuel efficiency improvement credits are available. Engine friction reduction is an ongoing evolutionary process that should generate benefits on the order of 5 percent or so increase in fuel economy over a multiyear forecast period, with costs totaling approximately $100. Moreover, the technology is a benefit of ongoing industry research and evolutionary engine improvements so that it is easily 'adoptable' and deployed throughout the fleet. Accordingly, NHTSA should revise the NPRM CAFE model to reinstate the ability to adopt evolutionary friction reduction technology."[944]

---

[944] Meszler Engineering. Docket ID NHTSA-2018-0067-11723, at p. 32.

The agencies disagree with Meszler that a five percent fuel economy improvement attributable to lubricants and evolutionary friction reduction is continuously feasible. The MY 2017 baseline vehicles have incorporated many technologies like low viscosity engine oil, integrated exhaust manifold for faster oil warmup, and internal component friction reduction.[945,946,947] The LUB and EFR technologies are a legacy of the existing rulemaking work going back to the 2010 CAFE and CO_2 rule for MY 2012 to MY 2016.[948] The agencies believe that many of these technologies have been incorporated in many of the engines in the baseline fleet, and therefore the engine maps used for the NPRM and final rule analysis incorporated them as well. Furthermore, manufactures have raised concerns over issues with further decreasing oil viscosity; specifically, manufacturers have articulated concerns that damage caused by low speed pre-ignition (LSPI)[949] can damage an engine.[950,951,952]

In response to the comment that engine friction reduction technology is evolutionary technology, the agencies introduced one level of friction reduction (EFR) for the final rule analysis. The agencies estimated a 1.4 percent effectiveness for this type of technology based on the 2015 NAS report assessment of further improvements in lubrication and friction.[953]

d) How the Agencies Assign Engine Technologies to the Baseline Fleet

Manufacturers have made significant improvements in fuel economy and CO_2 emissions reductions since the MY 2012 rulemaking analysis.[954,955] The agencies expended substantial effort to update the analysis fleet from the MY 2016 representative fleet used for the NPRM to a MY 2017 analysis fleet used for this final rulemaking to capture the technologies manufacturers have used to increase their fleet's fuel economy and CO_2 emissions performance. Detailed discussion of the model year 2017 fleet development and application can be found in VI.B.1. The agencies extensively updated the new MY 2017 fleet engine technologies using available manufacturer final model year CAFE compliance submissions to the agencies, as well as manufacturer press release specifications, agency-sponsored vehicle benchmarking studies, review of available technical publications, and through manufacturer CBI.[956]

The data for each manufacturer was used to determine which platforms shared engines and to establish the leader-follower relationships between vehicles. Within each manufacturer's fleet, engines were assigned unique identification designations based on configuration, and technologies applied, along with other characteristics. The data were also used to identify the most similar engine among the IAV engine maps, as discussed in Section VI.C.1.

Just like the real-world vehicle variants, the CAFE model considers differences between each vehicle like base performance and higher performance levels. For example, the 2017 Ford F150 has many variants with different types of engines like the 2.7L turbocharged V6, 3.3L naturally-aspirated V6, 3.5L turbocharged V6, and 5L naturally-aspirated V8. In contrast to the LPM, the CAFE model rosters each variant level and powertrain application individually. This variation is accounted for as engine technologies are assigned in the analysis fleet.

As a result of new information available since publication of the NPRM and comments received to the NPRM, the agencies included additional engine technologies in the compliance analysis, expanding the total number of engine technologies available from 16 to 23. This expansion is a direct result of comments received to the NPRM and further enables the agencies' capabilities to accurately and, realistically, characterize the technologies present on an engine found in the analysis fleet. This collection of technologies represents the best available information the agencies have, at the time of this action, regarding both currently available engine technologies and engine technologies that could be feasible for application to the U.S. fleet during the rulemaking timeframe. The agencies believe this effort has yielded the most technology-rich and accurate analysis fleet utilized by the CAFE model to date.

[956] NPRM CAFE Market Data file.

In some cases, however, it was necessary for the agencies to substitute an engine map that closely represented an engine technology that were effectively the same, or, based on engineering judgement, were the best available proxy at the time of the analysis. For example, many manufacturers offer their own proprietary VVT engine technologies and so the agencies assigned the same engine map for all of these VVT in the baseline fleet. The CAFE model uses compliance CAFE and CO_2 values for baseline vehicles and so it's not as relevant to have exact technology assignment type as it more important to provide the advanced vehicle have adopted to date. For further discussion of this see section VI.A.3 Fuel-Savings Technologies. This substitution was necessary, in some cases, where an "exact-match" engine map was not available for application to a specific vehicle and/or vehicle specific engine application. The agencies leveraged a series of engine operating characteristic maps developed by industry suppliers and, in some cases, the agencies themselves, to assign the closest baseline engine map for the analysis.

As discussed in Section VI.C.1.b), these engine maps provide operational characteristics such as horsepower, torque, or efficiency at a specified point in an engine's operational range. These operational maps are developed based on a given set of engine characteristics and technologies applied to that engine. Engine maps are closely held by vehicle manufacturers and are typically considered intellectual property. As such, vehicle manufacturers are not typically willing provide the operational maps to the agencies, where it would ultimately be in the purview of competitors. In some instances, manufacturer engine maps are published in media such as technical papers or conference presentation materials. However, these publicly available engine maps are, in nearly all instances, void of critical information that would enable their use for meaningful simulation and modeling.

Therefore, the agencies are generally limited to the catalog of engine maps they have developed through contracts and, where possible, in-house which, in turn, yields the need for sound, engineering judgement-based substitution of an engine map as a proxy for an engine application in the marketplace. Unfortunately, this is necessary as the agencies are unable to fund the development of engines maps for every possible engine and technology combination available for sale. However, it is important to note the agencies do have a substantial catalog of engine maps to leverage and continue to fund the development of new maps as new technologies enter the marketplace. Additional information on the agencies' catalog of engine maps used for this this final rulemaking can be found in Section VI.C.1.b).

Some engine technologies are designated in the CAFE Model as "baseline only" technologies, meaning these are characteristics such as engine configuration, architecture, or a technology that is considered inherent to the fleet for the given model year, an example for the MY 2017 fleet used in this analysis is variable-valve-timing (VVT). Beyond the aforementioned configurations and technology, engine technologies that can be applied to a future engine and, eventually, to a vehicle in the compliance modeling are only available at a vehicle redesign. As such, a vehicle will only adopt a new engine according to the application schedule defined as a CAFE model input.

e) *Engine Adoption Features*

Engine adoption features are defined through mechanisms like technology path logic or the application of selection logic, refresh and redesign cycles, and phase-in capacity limits. Most of the technology adoption features from the NPRM have been carried over for the final rule analysis. However, the final rule analysis also included adoption features for the new technologies incorporated in the final rule analysis. For a detailed discussion of CAFE model path logic for the final rule analysis, including technology supersession logic and technology mutual exclusivity logic, please see Section IV.

Figure VI-24 and Figure VI-25 below show the engine technology paths used for the NPRM and this final rule analysis, respectively. The engine technology paths have increased to incorporate new advanced technologies manufacturers could adopt into their fleet.

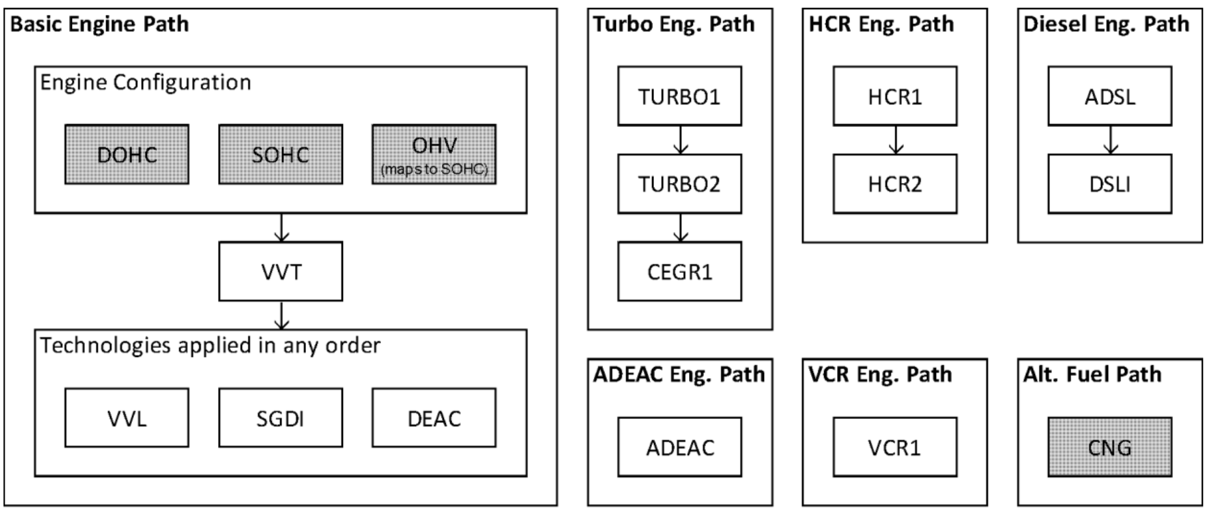

Figure VI-24 – Engine Paths Used for the NPRM Analysis

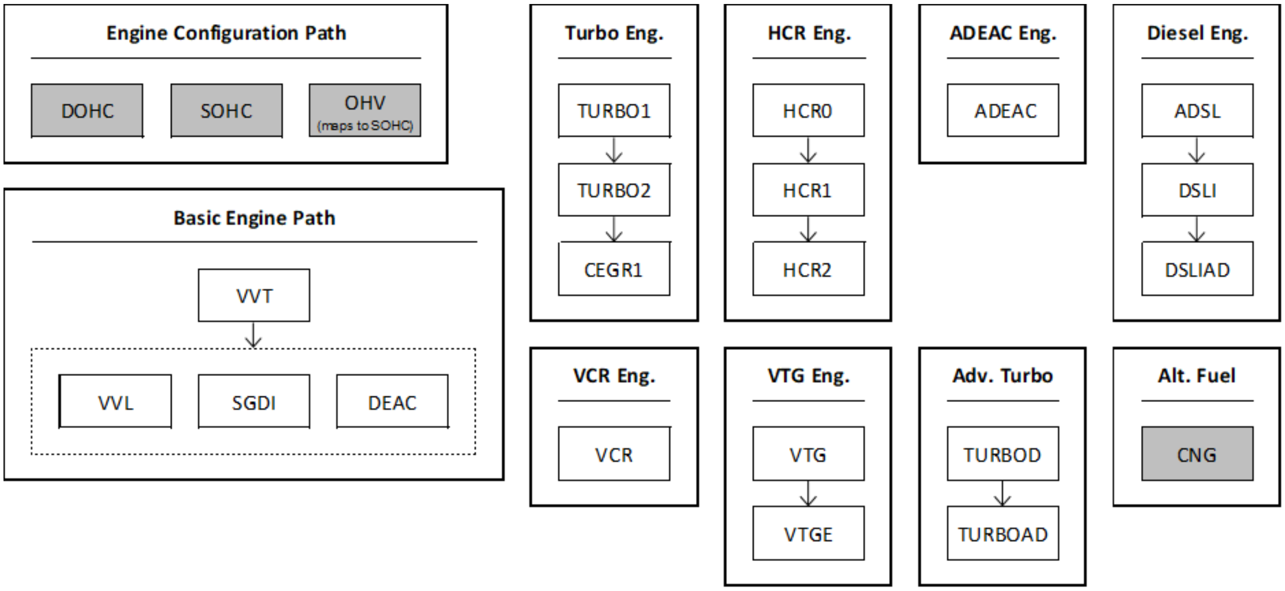

Figure VI-25 – Engine Paths Used for the Final Rule Analysis

Similar to the 2012 final rule for MYs 2017-2025, this final rule analysis also considered real-world limits when the defining the rate at which technologies can be deployed.[957] During the rulemaking timeframe, manufacturers are expected to go through the normal automotive business cycle of redesigning and upgrading their light-duty vehicle products. This allows manufacturers the time needed to incorporate fuel economy improving and CO_2 reducing technologies into their normal business cycle. This is important because it has the potential to avoid the much higher costs that could occur if manufacturers need to add or change technology at times other than their scheduled vehicle redesigns. This time period also provides manufacturers the opportunity to plan for compliance using a multi-year time frame, again consistent with normal business practice.

Section II.G.3.a of the NPRM provided substantial discussion of how an "application schedule" is used by the CAFE model to determine when manufacturers are assumed to be able to apply a given technology to a vehicle. The NPRM application schedule for engine technologies is reproduced in Table VI-44, which shows that all of the engine technologies may only be applied (for the first time) during redesign.

[957] 77 FR 62712.

Table VI-44 – NPRM CAFE Model Engine Technologies Application Schedule

Technology	Application Level	Application Schedule	Description
SOHC	Engine	Baseline Only	Single Overhead Camshaft Engine
DOHC	Engine	Baseline Only	Double Overhead Camshaft Engine
OHV	Engine	Baseline Only	Overhead Valve Engine (maps to SOHC)
VVT	Engine	Baseline Only	Variable Valve Timing
VVL	Engine	Redesign Only	Variable Valve Lift
SGDI	Engine	Redesign Only	Stoichiometric Gasoline Direct Injection
DEAC	Engine	Redesign Only	Cylinder Deactivation
HCR	Engine	Redesign Only	High Compression Ratio Engine
HCR2	Engine	Redesign Only	High Compression Ratio Engine with DEAC and CEGR
TURBO1	Engine	Redesign Only	Turbocharging and Downsizing, Level 1 (18 bar)
TURBO2	Engine	Redesign Only	Turbocharging and Downsizing, Level 2 (24 bar)
CEGR1	Engine	Redesign Only	Cooled Exhaust Gas Recirculation, Level 1 (24 bar)
ADEAC	Engine	Redesign Only	Advanced Cylinder Deactivation
CNG	Engine	Baseline Only	Compressed Natural Gas Engine
ADSL	Engine	Redesign Only	Advanced Diesel Engine
DSLI	Engine	Redesign Only	Diesel engine improvements

For this final rulemaking action, a similar schedule is employed, and has been updated with information gathered since the NPRM and through comments provided to the agencies.

Table VI-45 presents the engine technology application schedule used for the final rule CAFE modeling.

Table VI-45 – Final Rule CAFE Model Engine Technologies Application Schedule

Technology	Application Level	Application Schedule	Description
SOHC	Engine	Baseline Only	Single Overhead Camshaft Engine
DOHC	Engine	Baseline Only	Double Overhead Camshaft Engine
OHV	Engine	Baseline Only	Overhead Valve Engine (maps to SOHC)
EFR	Engine	Redesign Only	Improved Engine Friction Reduction
VVT	Engine	Redesign Only	Variable Valve Timing
VVL	Engine	Redesign Only	Variable Valve Lift
SGDI	Engine	Redesign Only	Stoichiometric Gasoline Direct Injection
DEAC	Engine	Redesign Only	Cylinder Deactivation
TURBO1	Engine	Redesign Only	Turbocharging and Downsizing, Level 1
TURBO2	Engine	Redesign Only	Turbocharging and Downsizing, Level 2
CEGR1	Engine	Redesign Only	Cooled Exhaust Gas Recirculation, Level 1
ADEAC	Engine	Redesign Only	Advanced Cylinder Deactivation
HCR0	Engine	Redesign Only	High Compression Ratio Engine, Level 0
HCR1	Engine	Redesign Only	High Compression Ratio Engine, Level 1
HCR2	Engine	Redesign Only	High Compression Ratio Engine, Level 2

Technology	Application Level	Application Schedule	Description
VCR	Engine	Redesign Only	Variable Compression Ratio Engine
VTG	Engine	Redesign Only	Variable Turbo Geometry
VTGE	Engine	Redesign Only	Variable Turbo Geometry (Electric)
TURBOD	Engine	Redesign Only	Turbocharging and Downsizing with DEAC
TURBOAD	Engine	Redesign Only	Turbocharging and Downsizing with ADEAC
ADSL	Engine	Redesign Only	Advanced Diesel
DSLI	Engine	Redesign Only	Diesel Engine Improvements
DSLIAD	Engine	Redesign Only	Diesel Engine Improvements with ADEAC
CNG	Engine	Baseline Only	Compressed Natural Gas Engine

Fuel economy improving and CO_2 reducing technologies for vehicle applications vary widely in function, cost, effectiveness, and availability. Some of these attributes, like cost and availability, vary from year to year. New technologies often take several years to become available across the entire market. The agencies use phase-in caps to manage the maximum rate that the CAFE model can apply new technologies. Phase-in caps are intended to function as a proxy for a number of real-world limitations in deploying new technologies in the auto industry. These limitations can include but are not limited to, engineering resources at the OEM or supplier level, restrictions on intellectual property that limit deployment, and/or limitations in material or component supply as a market for a new technology develops. Without phase-in caps, the model may apply technologies at rates that are not representative of what the industry is actually capable of producing, which would suggest that more stringent standards might be feasible than actually would be. Table VI-46 and Table VI-47 below shows the phase-in caps between the NPRM and this final rule analysis, respectively.

Most engine technologies are available at a rate of 100 percent in MY2017 for the final rule analysis. Some advanced technologies that have been recently introduced for one or two vehicle models are phased in at lower rates. Technologies such as ADEAC and TURBOD are phase in at rates that represent manufacturers' adoption capability and typically have complementary effectiveness compared to other advanced technologies. These lower phase-in caps also represent intellectual property and functional performance concerns.

Table VI-46 – NPRM CAFE Model Engine Phase-in Caps

Name	Technology Description	Technology Pathway	Phase-in Cap	Phase-in Start Year
VVT	Variable Valve Timing	Basic Engine	100%	2000
VVL	Variable Valve Lift	Basic Engine	100%	2000

Comments received on engine adoption features were mixed, with manufacturers generally supporting the NPRM methodology, and CARB and NGOs opposing it. Several manufacturers commented, both in their public comments or on a CBI basis, that many of the emerging engine technologies had the potential to improve vehicle fuel economy, but were technically complex and addressed many of the same issues as other existing engine technologies.

We agree with manufacturers that broadly, there are technologies that, in theory, present large potential effectiveness improvements like VCR, ADEAC, and others. However, the agencies believe it is important to assure realistic adoption of these technologies into the fleet in the rulemaking time frame, so that the rulemaking analysis accurately represents the costs and benefits of different regulatory alternatives considered. If the agencies were to select stringency based on an assumption that an emerging technology would see widespread adoption, and then it does not, the benefits of that stringency level would not be realized. The agencies have taken steps in the NPRM and this final rule analysis to consider the manufacturability and feasibility of these technologies for different vehicle types and manufacturers. Discussed earlier, the analysis considers these and other concerns by accounting for product cadence, and by implementing phase-in caps and skips, and by designating technology phase-in and phase-out years. Similar to the 2012 final rule, this final rule analysis employed these strategies to reflect better the real-world considerations faced by manufacturers.

EDF commented, referencing EPA's statutory command prescribed in Section 202(a) of the Clean Air Act that:

> EPA's task is thus to identify the major steps necessary for 'development and application of the requisite technology,' and then the respective standard 'shall take effect.' These individual decisions are highly consequential: as noted above, without changing anything else about the agencies' analysis, allowing HCR2 would reduce augural compliance costs by $619—or about 30% of the total difference between the augural and rollback scenarios. The proposal's rejection of these technologies nowhere justifies how the (unfounded and cursorily justified) concerns accord with the agency's limited discretion under Section 202(a)(2) and duty to 'press for the development and application of improved technology rather than be limited by that which exists today.' If the agency is to predict more than the results of merely assembling pre-existing components, it must have some leeway to deduce results that are not represented by present data.[958]

CARB also commented that the CAFE Model prevents manufacturers "from switching between a turbocharged and HCR pathways under the premise that manufacturers either would not develop both or would be committed irreversibly to one path or the other. This assumption is not based in reality and is not reflective of actual industry practice—manufacturers who have pursued turbocharging have also already pursued HCR engines for other vehicles in their line-up. For example, General Motors (GM) utilizes downsized turbocharging in some vehicles, such as the newly designed 2019MY Silverado pick-up and the Malibu sedan which has two different turbocharged engine options. GM also has a third offering in the Malibu sedan which is an HCR naturally aspirated 1.8L equipped with cooled exhaust gas recirculation (CEGR) mated to a hybrid electric system."[959]

CARB's observation was true for the NPRM analysis, however for the final rule analysis the agencies allowed manufacturers to adopt engine technologies from alternate tree paths, when incorporating electrification technology, see Section VI.C.3.c). The agencies still believe that if

---

[958] NHTSA-2018-0067-12108 at 104.
[959] NHTSA-2018-0067-11873 at 109.

manufacturers have invested in one type of engine technology for their vehicles that they would not transition to another technology except in the case of a major vehicle powertrain redesign, such as the inclusion of an HEV system. Additional discussion on this issue is presented in Section VI.B.1.

The following sections discuss adoption features specific to individual engine technologies, including comments received and updates (or not) for the final rule analysis.

(1) Basic Engines

Most vehicles in the MY 2017 analysis fleet that are DOHC or SOHC/OHV spark ignited engines and are not downsized turbocharged engines have any two combinations of VVT, VVL, SGDI or DEAC.[960] For the NPRM, only engines with 6-cylinders or more could adopt DEAC and ADEAC.

HDS on behalf of CARB commented that in the NPRM analysis VVL, which is cost ineffective compared to other conventional technologies, was always included in an adopted technology package.[961] HDS further stated that the "effectiveness of VVL is even smaller when the technology is combined with turbocharged downsized engines." Accordingly, HDS stated that removing VVL from the base pathway would save $314 but reduce fuel economy by only 1.4 percent, according to the LPM.

The agencies did not agree with HDS' assessment of the NPRM analysis. The agencies do not agree VVL was forced to be adopted in the analysis fleet and do not agree with how technology effectiveness values compare to LPM estimates. As discussed earlier in the effectiveness and modeling section, each engine technology was modeled independently and the CAFE model was allowed to adopt the most cost effective technology. Therefore, it is inaccurate to state, a technology is less effective, especially when comparing LPM. Particularly because VVL technologies reduce pumping losses in engines, so it is realistic that other technologies, that also reduce pumping losses, have synergetic effect. This is specifically true for turbocharged engines

ICCT commented that DEAC technology should be available for every engine, and should not be limited to 6-cylinder and higher cylinder count engines. ICCT and CARB also commented that DEAC should be allowed on turbocharged engines. ICCT also commented that ADEAC should be widely available as it can be a viable technology application for various other powertrain technology combinations.[962] Furthermore, CARB commented "automakers will combine technologies like turbocharging, HCR and DEAC as well as more technologies when they have cost-effectiveness synergies."[963]

[962] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-13.
[963] CARB at p. 6.

The agencies agree with ICCT that DEAC and ADEAC could be applied to additional engine types, including turbocharged engines. However, the agencies disagree with ICCT that ADEAC should be widely applied to all powertrain technology combinations in this analysis. The agencies have updated the final rule analysis to allow DEAC and ADEAC for various engine cylinder counts and for turbocharged engines.

For the final rule analysis, both DEAC and ADEAC technologies can be adopted by any naturally aspirated engine. Similarly, any turbocharged engine can also adopt cylinder deactivation technology, as characterized by TURBOD and TURBOAD in the CAFE model. In this final rule analysis, the agencies distinguished cylinder deactivation technologies between naturally aspirated and forced air induction systems.

For the final rule analysis, the agencies allow any combination of VVT, VVL, SGDI and DEAC to be adopted for any engine displacement and cylinder count. Figure VI-24 below shows the basic engine paths a vehicle could traverse for the final rule analysis. Similar to the NPRM, the agencies have not changed the adoption features of the technologies shown in Figure VI-24, with one exception. Vehicles that are SOHC or DOHC configuration that do not have VVT in the baseline can now adopt it.

Finally, the agencies disagree with ICCT and CARB that these DEAC, ADEAC, TURBOD, and TURBOAD should apply beyond these configurations. DEAC's fundamental benefits are driven by reducing pumping losses and by enabling the engine to operate in a more thermal efficient region of the engine fuel map. Conventional spark-ignited engines control airflow into the cylinders via a throttle operated by the driver to provide the level of power that is delivered.[964] In an 8-cylinder engine, when driving in light load conditions such as highway driving, there are lower engine power requirements. In a throttle controlled system, engine pumping losses increase as air flow decreases. A way to reduce pumping loss in an engine is by increasing the airflow into the cylinders. By deactivating a set of cylinders, the same power output can be delivered by a "smaller" engine. Many technologies modeled for this analysis work to reduce pumping losses, but through other mechanisms like VVT, VVL, downsized engines with turbochargers, high compression Atkinson mode cycle, and Miller Cycle.[965] Transmissions with a higher number of gears also provide the opportunity to reduce pumping work of the engine.[966]

As discussed earlier, DEAC can reduce pumping losses, so when combined with other technologies that also reduce pumping losses, like downsized turbocharged engines, the benefits for cylinder deactivation are lower than for naturally aspirated engines because downsized turbocharged engines already have lower pumping losses due to having a downsized engine.[967]

---

[964] A throttle is the mechanism by which fluid flow is managed by constriction or obstruction. An engine's power can be increased or decreased by the restriction of inlet gases, but usually decreased.

[965] 2015 NAS at p. 23.

[966] 2015 NAS at p.173.

[967] 2015 NAS at p. 34.

(2) Turbocharged Downsized Engines

About 23 percent of vehicles in the MY 2017 baseline fleet had turbocharged engines. For the final rule analysis, the agencies allowed any basic engine to adopt turbo engine technology (TURBO1, TURBO2 and CEGR1) from the Turbo path similar to the NPRM analysis. This includes any combination of VVT, VVL, SGDI and DEAC for both SOHC and DOHC configurations. Vehicles that have turbocharged engines in the baseline fleet will stay on the turbo engine path to prevent unrealistic engine technology change in a short timeframe considered in the rulemaking analysis. Turbo path is a mutually exclusive technology in that it cannot be adopted for HCR, diesel, ADEAC, CNG and powersplit PHEVs.

(3) Non-HEV Atkinson Mode Engines

The NPRM analysis allowed limited application of HCR engines (HCR1 and HCR2) to vehicles in the MY 2016 baseline fleet.[968] As discussed above, applying HCR1 or HCR2 technologies to a vehicle resulted in overstated effectiveness values relative to the baseline VVT engine,[969] because of differences in how those maps were developed compared to the IAV engine maps used for the majority of the technology analysis. In an attempt to avoid unrealistic results in the NPRM, adoption of HCR1 (Eng24) technology was limited to only manufacturers that demonstrated existing use of high compression ratio technology. HCR was disallowed for other manufacturers that demonstrated an intent to develop other advanced technologies incompatible with HCR technology. In addition, the agencies disallowed HCR engines from being applied to vehicles with greater performance requirements, like 6- and 8-cylinder vehicles, because the higher load requirements from these vehicles would force the engine to exit the Atkinson mode, where maximum efficiency is achieved.

The Alliance commented in agreement with the application restrictions for HCR1 in the NPRM, listing the following justifications: "Packaging and emission constraints associated with intricate exhaust manifolds needed to mitigate high load/low revolutions per minute knock; Inherent performance limitations of Atkinson cycle engines; and Extensive capital and resources required for manufacturers to shift to HCR from other established technology pathways (e.g. downsized turbocharging)."[970] Ford similarly commented in support of "the more restrained application of HCR1 in the Proposed Rule, an approach that recognizes the investment, packaging, performance and emissions factors that will limit penetration of this technology."[971]

In contrast, CARB stated that the constraint on HCR1 engines was inappropriate and did not reflect reality,[972] and stated that the agencies failed to supply any detailed rationale as to why HCR applications were so constrained in the CAFE Model. Specifically, CARB took issue with the justification that HCR1 is limited in the CAFE model because it is "not suitable for MY 2016

[972] NHTSA-2018-0067-11873.

baseline vehicle models that have 8-cylinder engines and in many cases 6-cylinder engines."[973] CARB stated that "the HCR1 technology is declared not suitable on 207 of the 288 engines cumulatively used by all of industry including over 50 percent of the 4 cylinder engines and nearly 90 percent of the 6 cylinder engines instead of only being restricted from 8 cylinder and 'in many cases 6 cylinder engines.'" CARB also stated that the implied rationale for not allowing HCR1 to be applied to 6- and 8-cylinder engines because trucks or larger vehicles could not utilize it is unreasonable, as the Toyota Tacoma used a 3.5L V6 HCR Atkinson-like engine since MY 2016. CARB stated that the Toyota Tacoma was properly assigned a HCR1 engine in the MY 2016 analysis fleet file, but the engine was disallowed from other Toyota V6 engines utilized in vehicles like the Sienna minivan and 4Runner SUV. CARB commented that "[i]f the intended rationale is that HCR engines will have insufficient low end torque to satisfy truck-like towing demands, it would be inappropriate to restrict the engine from minivan and SUV applications which have a lower tow rating and lower expected towing demands." Finally, CARB stated that the HCR1 package restrictions were inappropriate, as there was no mechanism in the CAFE model to represent appropriately the MY 2019 Dodge Ram 1500 5.7L V8 that uses "a higher compression ratio than earlier versions and using its VVT system to reduce pumping losses via delayed, or late, intake valve closing—resulting in an HCR-like engine with an over-expanded or Atkinson cycle."

Similarly, Meszler Engineering Services, commenting on behalf of NRDC, commented that HCR1 appears as a baseline technology on vehicles representing about 4 percent of the baseline non-hybrid vehicle market, and is subsequently applied to only 23 percent of the market. Meszler stated that the "relative cost effectiveness of the technology is perhaps best illustrated by the fact that the market penetration of HCR technology on non-hybrid vehicles under the augural standard is modeled to be 27 percent of 2032 sales, exactly equal to the baseline penetration of 4 percent and the allowable adoption fraction of 23 percent. In other words, the technology was adopted by every vehicle that was not explicitly prohibited (by NHTSA) from doing so." EDF commented that "NHTSA has further imposed artificial and unreasonable constrains on the use of certain technologies that does not match how automakers are applying them in vehicles today," stating that HCR1 represented a technology that had been in the marketplace for many years and had been applied by several manufacturers, "[y]et, even for MY 2030 vehicles and beyond, NHTSA only allows the use of HCR1 by about 30 percent of the U.S. fleet."[974]

In considering the comments, the agencies agree with commenters that the HCR1 engine application was overly limited for the NPRM analysis. As a result, the agencies have expanded the availability of HCR1 technology for the final rule analysis. The refined adoption features for HCR1 are discussed below. The new adoption features do maintain considerations for performance neutrality. Comments about how the characterization of engine technologies in the analysis fleet impacted HCR technology adoption in subsequent model years are addressed in Section VI.C.1.d) Baseline Fleet Engine Tech.

[973] 83 FR 43038.
[974] NHTSA-2018-0067-12108.

Regarding HCR2, the Alliance commented in support of "the decision to exclude the speculative HCR2 technology from the analysis."[975] The Alliance continued, "[a]s previously documented in Alliance comments, the inexplicably high benefits ascribed to this theoretical combination of technologies has not been validated by physical testing." Similarly, Ford stated that "[t]he effectiveness of the 'futured' Atkinson package (HCR2) that includes cooled exhaust gas recirculation (CEGR) and cylinder deactivation (DEAC) is excessively high, primarily due to overly-optimistic efficiencies in the base engine map, insufficient accounting of CEGR and DEAC integration losses, and no accounting of the impact of 91RON Tier 3 test fuel. Given the speculative and optimistic modeling of this technology combination, Ford supports limiting the use of HCR2 technology to reference only, as described in the Proposed Rule."[976]

In contrast, several commenters disagreed with the agencies' decision to limit the adoption of HCR2 engines, stating that the technology was clearly applicable during the rulemaking timeframe, as the technology was already being applied by manufacturers, and that the technology was cost-effective, as shown by the agencies' own modeling.

ICCT commented that "[i]t is clear that the agencies have artificially excluded a known technology that is applicable in the timeframe of the rulemaking."[977] ICCT commented that "[d]espite the facts that (as discussed above) the agencies have cost and effectiveness data for this technology, many automakers are already deploying the HCR1 technology, and the 2018 Camry has already put most of the HCR2 technologies into production, the agencies did not allow any application of HCR2 by 2025."[978] ICCT concluded that the "only explanations . . . for the agencies' system of omissions and constraints are that the agencies have biased the analysis against including all the viable technologies by inserting their own artificial constraints (either for lack of research, lack of analytical effort, or not fully utilizing all the agencies' best analytical tools and data) or that the auto industry is providing information that erroneously suggests their innovation is far less than what is demonstrated both above and in the agencies' own previous analyses." ICCT stated that "[t]he great lengths the agencies have gone to artificially impose 'skip' constraints for HCR in the CAFE modeling system demonstrates that the agencies have exerted an explicable and apparently deliberate bias towards forcing most of the automaker compliance technology toward higher cost, non-HCR turbocharging paths."[979]

Several commenters also stated that HCR should not have been restricted because it is clearly a cost-effective technology, citing the sensitivity runs conducted that allowed unrestricted HCR application in the analysis. For example, ICCT commented that allowing HCR2 application across the fleet reduced total per-vehicle cost of compliance with the augural standards by $690, which "shows that the agencies intentionally excluded a highly cost-effective technology (by their own analysis) in the rulemaking analysis."[980] Similarly, EDF performed

[975] NHTSA-2018-0067-12073.
[976] NHTSA-2018-0067-11928.
[977] NHTSA-2018-0067-11741.
[978] NHTSA-2018-0067-11741.
[979] NHTSA-2018-0067-11741.
[980] NHTSA-2018-0067-11741.

software modifications of the CAFE model, including allowing the use of both HCR1 and HCR2 technology for all manufacturers by MY 2028. The analysis performed by EDF using their modified version of the CAFE model, showed reductions in the per-vehicle compliance cost projections by nearly $600.[981]

ICCT concluded that "[t]he only reasonable and technically valid assumption is that HCR be allowed for application to all vehicle models' engine redesigns through all the model years of the compliance modeling analysis."[982] ICCT stated that "[f]or the agencies to constrain HCR technology for use by other automakers, they have a responsibility to demonstrate why each of the other automakers cannot adopt this known technology in their fleet."

The agencies agree with commenters' observations about the results of the sensitivity runs performed as part of the NPRM analysis. However, the agencies also believe the adoption features for HCR1 and HCR2 were appropriate for the NPRM analysis. Had the agencies not applied adoption features in that way, the agencies would have shown unrealistic pathways for compliance for manufacturers that would have understated costs and overstated benefits of potential CAFE and CO_2 standards.

The agencies disagree with commenters' statements that HCR has been widely available in the automotive market and that the HCR technology accordingly should not be limited in the CAFE model. For reasons discussed in the NPRM and explained in more detail in Section VI.C.1.c)(4), depending on vehicle type and use, Atkinson cycle operation may be enabled for low and moderate engine demand conditions, whereas Otto cycle operation may be needed for higher load conditions to meet performance needs, such as to move more passengers, cargo, or for towing. In addition, there may be issues on some platforms to package the larger exhaust manifolds needed to enable Atkinson operation, particularly with V6 and V8 engines. Manufacturers have applied Atkinson technologies in unique ways to meet the needs and capabilities of their vehicles to operate using the Atkinson and Otto cycles. The agencies agree with comments from stakeholders, including Toyota, who observed HCR technology is not suitable for all vehicle configurations, and may not meet performance requirements for high-load applications. As discussed earlier, the agencies believe the variation of technologies can be categorized into three different forms of Atkinson engine technologies for this analysis: (1) Atkinson engines, (2) Atkinson-mode engines, and (3) Atkinson-enabled engines using variable valve timing with late intake closing. Manufacturers typically apply one of these technologies and tune that technology for specific applications. Some commenters have consistently conflated the technologies and asserted the capabilities of all three types of Atkinson technologies can be represented by a single engine model. The agencies do not agree with stakeholder assertions that a single HCR engine map should be applied to every technology class or vehicle platform.

To reflect better the incremental effectiveness for a low-cost version of HCR technology, the agencies added the HCR0 engine for the analysis. The specification of this engine was

[981] NHTSA-2018-0067-12108.
[982] NHTSA-2018-0067-11741.

provided in the NPRM PRIA as Eng22b. Using this engine improves the estimated incremental effectiveness because the incremental engine changes were directly specified for the modeling and are relative to the other engine technologies in the analysis.[983] HCR0 is the first engine in the HCR path that a manufacturer could adopt. HCR0 represents technology that could incrementally be adopted to the VVT engine, increasing compression ratio and adding Atkinson cycle capability. The use of the HCR0 technology, applied in the final rule analysis, allowed the agencies to update HCR adoption features. Once a basic engine adopts HCR technology (i.e, HCR0 and HCR1 for the central analysis, or HCR2 for a sensitivity case) the vehicle will not switch to a different engine technology path. For example, if a vehicle had adopted HCR or is equipped with HCR technology it is not allowed to adopt turbocharged engine technologies. The HCR0 technology appropriately captures the benefits of applying transitional Atkinson technologies to conventional basic engine technologies. The agencies note that VVT technology valve control has late intake valve closing under some operating conditions to take some advantage of Atkinson cycle-like operation; however, that operation is not as extensive as HCR technology and is not coupled with a higher compression ratio as is the case for HCR technologies.

The agencies also allowed all 4-cylinder engines on the basic engine path to adopt HCR technology similar to turbocharged technologies. This allowed any small and midsize vehicles, including small and midsize SUVs, that had any combinations of basic engine path technologies to move to the HCR path. However, there are two exceptions to this feature, including: (1) when the vehicle is a pickup including both standard and performance class; and (2) when the base engine is shared with a pickup including both standard and performance class. The agencies discussed earlier in the non-HEV Atkinson section why HCR technology cannot be applied to all vehicle applications.

Finally, engines with advanced engine technology already in the baseline vehicle such as turbocharged engines are not allowed to adopt HCR technology. The agencies continue to believe this constraint is reasonable given the extensive capital resources and stranded capital that would be involved if a manufacturer who focused on and invested heavily in non-HCR advanced technologies were to abandon those technologies abruptly and switch to HCR technologies.[984] For example, Ford has incorporated turbocharged engines across 75 percent to 80 percent of their fleet in MY2017, and these engines are shared across multiple technology classes.[985] The abovementioned modeling, limitation for this analysis assumes that manufacturers will not change advanced engine technology applied to a platform due to the high cost and lead time required for research and development, and for the development and implementation of new manufacturing plants and equipment to implement an entirely new powertrain in the rule making time frame. For further discussion see Section VI.B.1.

In response to ICCT's comment that agencies must discuss the reasoning for allowing and disallowing HCR technology for each individual manufacturer, these updated adoption features now allow more manufacturers to adopt HCR engine technology. The agencies no

[983] PRIA 6.3.2.2.21.20.2.1 IAV Engine 22b - High Compression Atkinson Cycle Engine at p. 307.
[984] 83 FR 43038.
[985] The 2018 EPA Automotive Trends Report figure 4.23. at p.68.

longer apply adoption features based on manufacturer, but now base them on individual platforms. The agencies believe a manufacturer that has already invested in advanced engine technologies for a specific platform would face very high costs and incur significant stranded capital to switch that platform to another advanced technology. And doing so would not be reasonable given the small incremental fuel economy improvement that would be gained, for example, for switching from advanced turbocharging to HCR technologies. Specifically, manufacturers that have invested in turbocharging technology for certain platforms, like Honda, Ford, and the German manufacturers, would incur unreasonable costs to switch to another advanced technology path. However, manufacturers that use turbo technology on one platform are not precluded from implementing HCR technology on another of its platforms. HCR adoption is still limited for all manufacturers based on vehicle performance requirements discussed earlier.

(4) Advanced Cylinder Deactivation Technology

In the NPRM, any basic engine technology could adopt ADEAC. Commenters stated that the agencies restricted ADEAC technologies in the NPRM analysis to naturally aspirated engines.

ICCT provided a broad comment regarding the treatment of advanced technologies, including ADEAC, and criticized how the NPRM "removed many technologies that are viable and being actively deployed by the auto industry." ICCT specifically criticized "cases where viable technology combinations are disallowed" such as "turbocharging and cylinder deactivation (DEAC)."[986]

UCS also commented on how ADEAC technology was applied in the NPRM, stating "While the agencies have acknowledged the existence of dynamic cylinder deactivation, they have not appropriately included it as an available technology, dramatically limiting its availability." UCS specifically disagreed with adoption features of the ADEC, noting the technology "is restricted to naturally aspirated, low-compression ratio engines—it cannot be combined with turbocharged engines, high compression ratio engines, or variable compression ratio engines due to pathway exclusivity in the Volpe model."[987] CARB and Meszler mirrored these concerns.[988]

The agencies agreed with commenters and in response have allowed both naturally aspirated engines and turbocharged engines to adopt ADEAC in the final rule analysis. The new Advanced Turbocharging path includes TURBOD and TURBOAD, while naturally aspirated engines use the same ADEAC engine designation. There is some potential for this type of technology to improve fuel economy and reduce CO_2 emissions, however, the technology provides diminishing returns if it is included with engine downsizing or other technologies that already reduce pumping losses. Accordingly, once a vehicle has adopted ADEAC, TURBOD, or

[986] NHTSA-2018-0067-11741 at p.6.
[987] NHTSA-2018-0067-12039 at p.4
[988] NHTSA-2018-0067-12039 at p.4.

TURBOAD, the agencies did not allow further adoption of other engine technologies that reduce pumping losses such as VCR and VTG.

(5) Miller Cycle Engines

Miller cycle engine technologies (VTG and VTGe) are new for this final rule analysis, and VTG engines could be applied to any basic and turbocharged engine. Discussed earlier, the VTGe technology is enabled by the use of a 48V system that presents an improvement from traditional turbocharged engines, and accordingly VTGe could only be applied with a mild hybrid system.

(6) Variable Compression Ratio Engines

In the NPRM analysis, variable compression ratio (VCR) technology was not available for adoption, but the engine map and specifications were provided for review. For this final rule analysis, VCR engines are included in the analysis and can be applied to basic and turbocharged engines, however the technology is limited to Nissan. VCR technology requires a complete redesign of the engine, and in MY2020, only two of Nissan's models had incorporated this technology. In addition, the technology showed lower fuel savings than expected.[989] The agencies do not believe any other manufacturers will invest to develop and market this technology in their fleet in the rulemaking time frame.

(7) Diesel Engines

Diesel engine adoption and features have been carried from the NPRM analysis for this final rule analysis for ADSL and DSLI. Any basic engine technologies (VVT, VVL, SGDI, and DEAC) can adopt ADSL and DSLI engine technologies. New for the final rule analysis is the adoption of advanced cylinder deactivation for diesel engines (DSLIAD). Any basic engine and diesel engine can adopt this technology in the final rule analysis; however, the agencies have applied a phase in cap and year for this technology at 34 percent and MY 2023, respectively. In the agencies' engineering judgement, the agencies have concluded that this is a rather complex and costly technology to adopt and think that it could take significant investment to develop. For more than a decade, diesel engine technologies have been used in less than one percent of the total light-duty fleet production,[990] and the investment for this cylinder deactivation technologies may not be justifiable.

(8) Alternative Fuel Engines

Adoption features for alternative fueled compressed natural gas (CNG) engines have been carried over from the NPRM for this final rule analysis. Because CNG is considered an alternative fuel under EPCA/EISA, it cannot be adopted during the rulemaking timeframe for

[990] The 2018 EPA Automotive Trends Report Table 4.1 at p. 72.

NHTSA's standard setting analysis. The EPA analysis was modeled separately in the CAFE model without such constraints.

(9) Engine Lubrication and Friction Reduction

Finally, new for this analysis is the addition of EFR. The agencies allow EFR to apply to any engine technology except for DSLI and DSLIAD. DSLI and DSLIAD inherently have incorporated engine friction technologies from ADSL. In addition, friction reduction technologies that apply to gasoline engines cannot necessarily be applied to diesel engines due to the higher temperature and pressure operation in diesel engines.

f) Engine Effectiveness Modeling and Effectiveness Values

(1) Engine 01 – DOHC, VVT, and PFI

Engine 1 is a naturally aspirated PFI 2.0-L gasoline engine with VVT, developed from a MY 2013 vehicle, which is consistent with the timeframe in which the engine technology was commonly used. A brake specific fuel consumption (BSFC) engine map was generated from dynamometer testing of the production engine, which then served as brake specific fuel consumption (i.e., baseline fuel map) for all simulated naturally aspirated engines (Engines 1-8a, 18-21). The engine calibrations were fully optimized for best BSFC and maximum torque.

Each subsequent engine (BSFC map) represents an incremental increase in technology advancement over the previous engine. Engines 2-4 add variable valve lift (VVL), direct injection (DI), and cylinder deactivation (deac) sequentially to the baseline engine. Engine 5a converts Engine 1 from DOHC to SOHC. Engines 5b, 6a, 7a, and 8a add some friction reduction to Engines 5a, 2, 3, and 4.[991] Figure VI-26 below shows the IAV engine 1 BSFC map used for this final rule analysis.

[991] In stage 1, FMEP is reduced by 0.1 bar and in level 2 FMEP is reduced by 25% over the entire operating range.

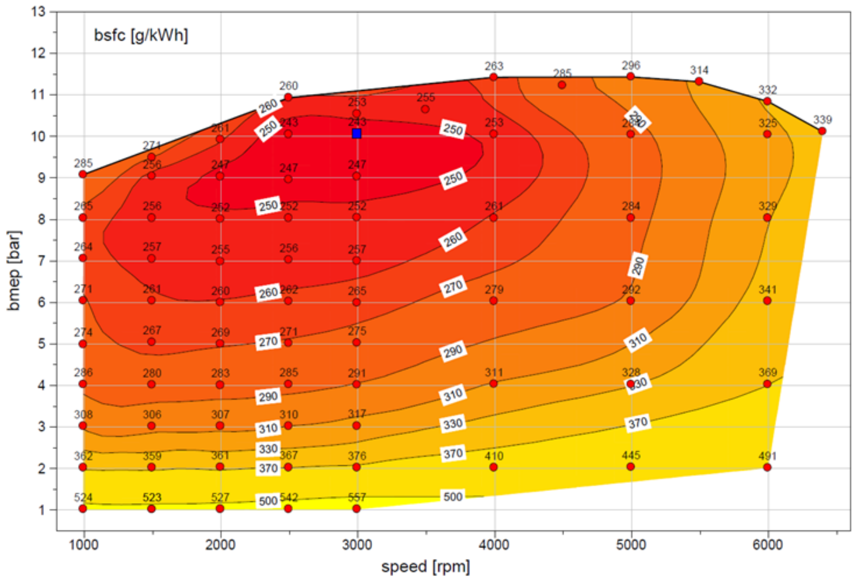

Figure VI-26 – Engine efficiency map for eng01

(2) Engine 02 – DOHC, VVT, VVL, and PFI

For Engine 2, a VVL system was added to the intake valves of Engine 1. Both valve lift and timing were optimized. The compression ratio was raised from 10.2 to 11.0. This engine allows for reduced pumping work at low loads and more torque at low speeds by using reduced intake duration and lift. Figure VI-27 below shows the IAV engine 2 BSFC map used for this final rule analysis.

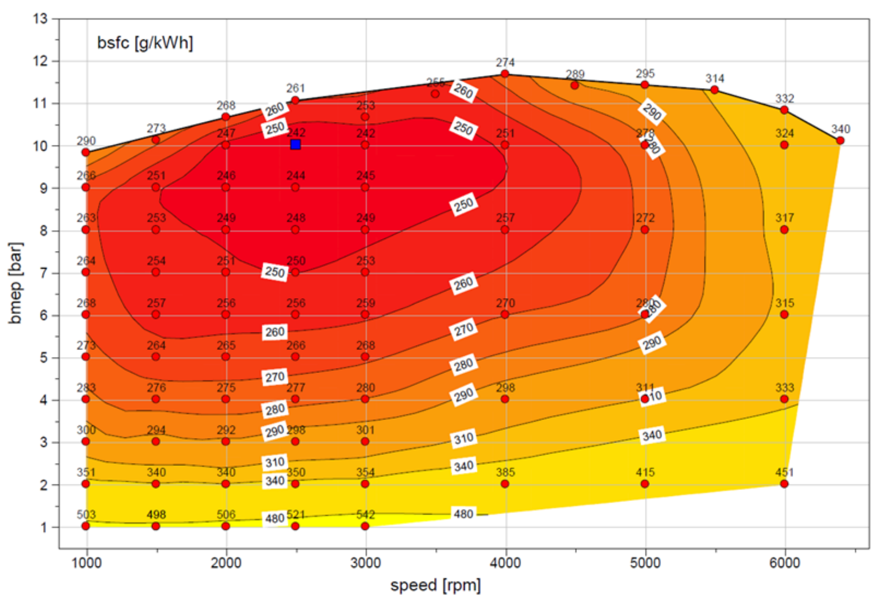

Figure VI-27 – Engine efficiency map for eng02

Figure VI-28 shows the incremental difference BSFC and thermal efficiency between IAV engine 1 versus engine 2.

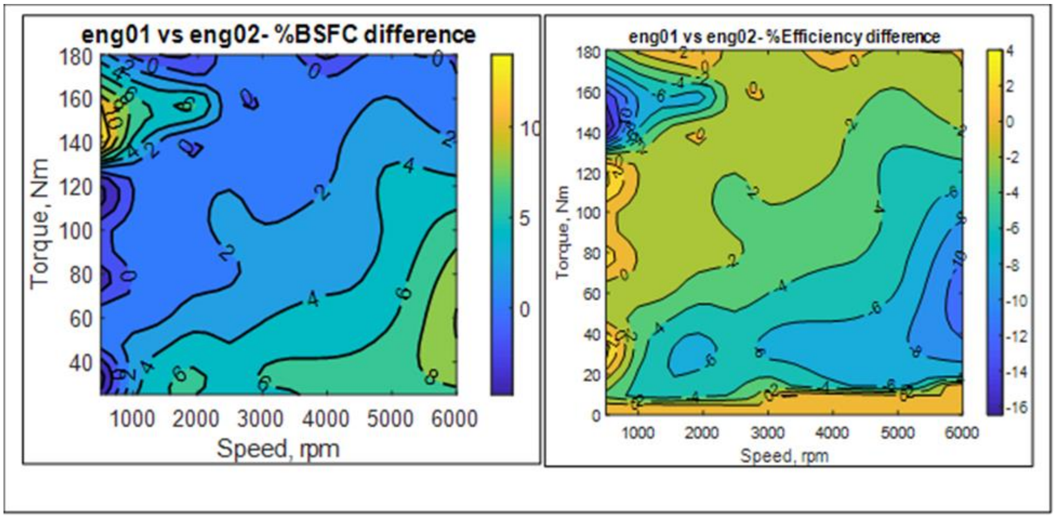

Figure VI-28 – incremental BSFC and thermal efficiency difference between eng01 versus eng02

(3) Engine 03 – DOHC, VVT, VVL, and DI

PFI Engine 2 was converted to direct injection to model engine 3. The compression ratio was raised from 10.2 to 11.0 and injection timing optimized. Direct injection provides greater knock tolerance, allowing higher compression ratio and increased efficiency over the entire operating range (map). Figure VI-29 below shows the IAV engine 3 BSFC map used for this final rule analysis.

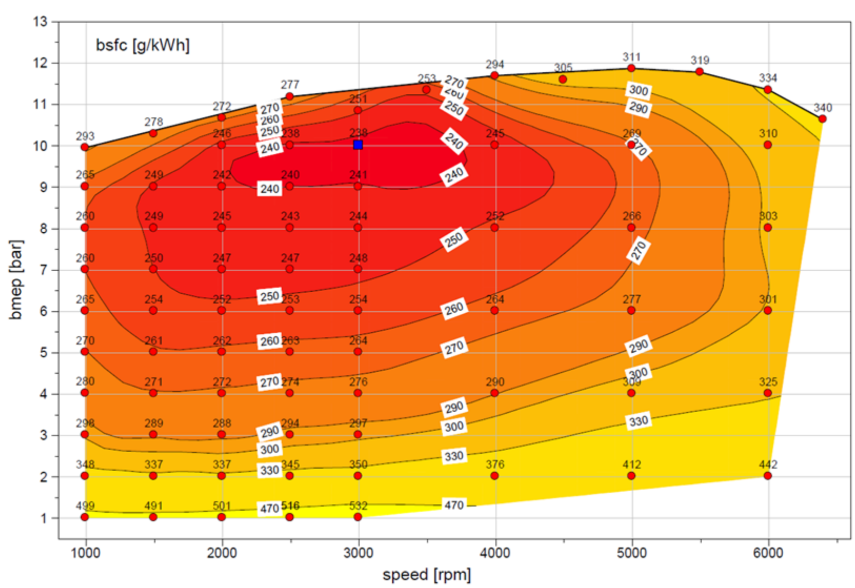

Figure VI-29 – Engine Efficiency Map for Eng03

Figure VI-30 shows the incremental difference BSFC and thermal efficiency between IAV engine 2 versus engine 3.

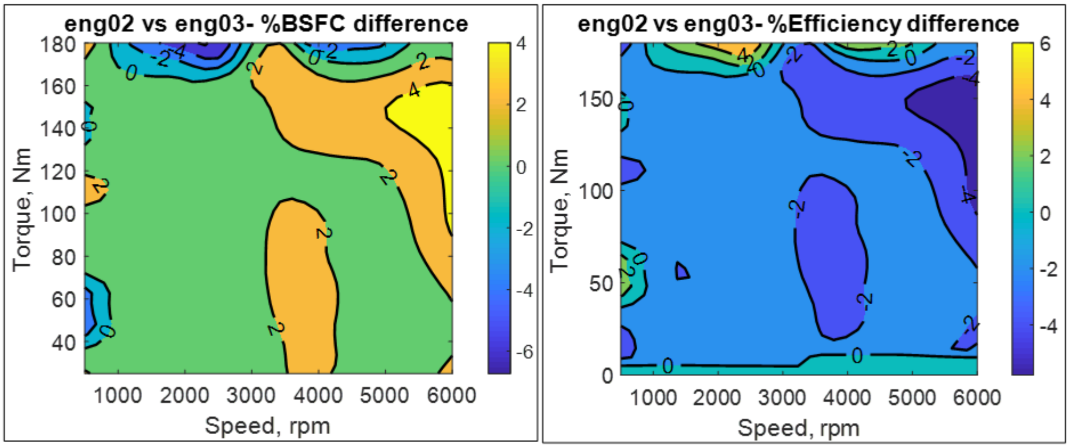

Figure VI-30 – incremental BSFC and thermal efficiency difference between eng02 versus eng03

(4) Engine 04 – DOHC, VVT, VVL, DI, and DEAC

Cylinder deactivation was added to engine 3 to model engine 4. Cylinder deactivation deactivates the intake and exhaust valves and prevents fuel injection into the deactivated cylinders during light-load operation. The engine runs temporarily as though it were a smaller displacement engine which substantially reduces pumping losses. For 4 cylinder applications, the engine fires only 2 cylinders at low loads and speeds below 3000 RPM and less than 5 bar BMEP by deactivating valves on 2 cylinders. The main benefit is that the effective load is doubled on 2 cylinders reducing pumping work and increasing efficiency. Figure VI-31 below shows the IAV engine 4 BSFC map used for this final rule analysis.

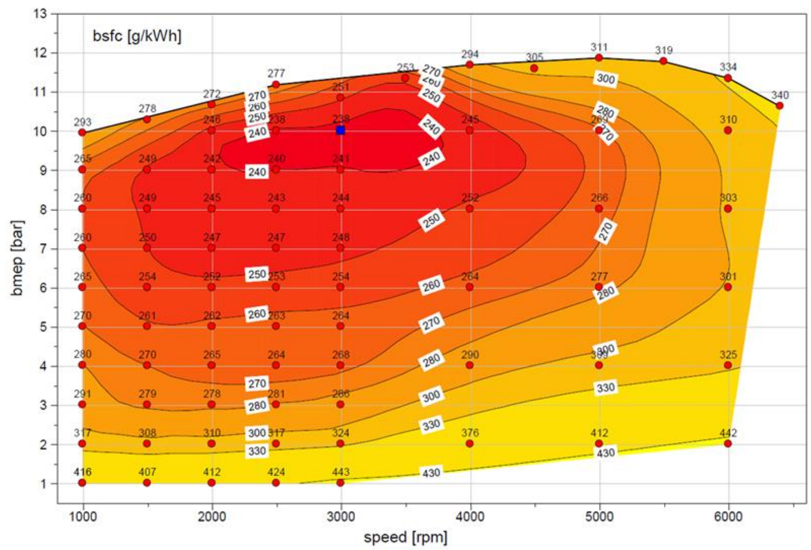

Figure VI-31 – Engine Efficiency Map for Eng04

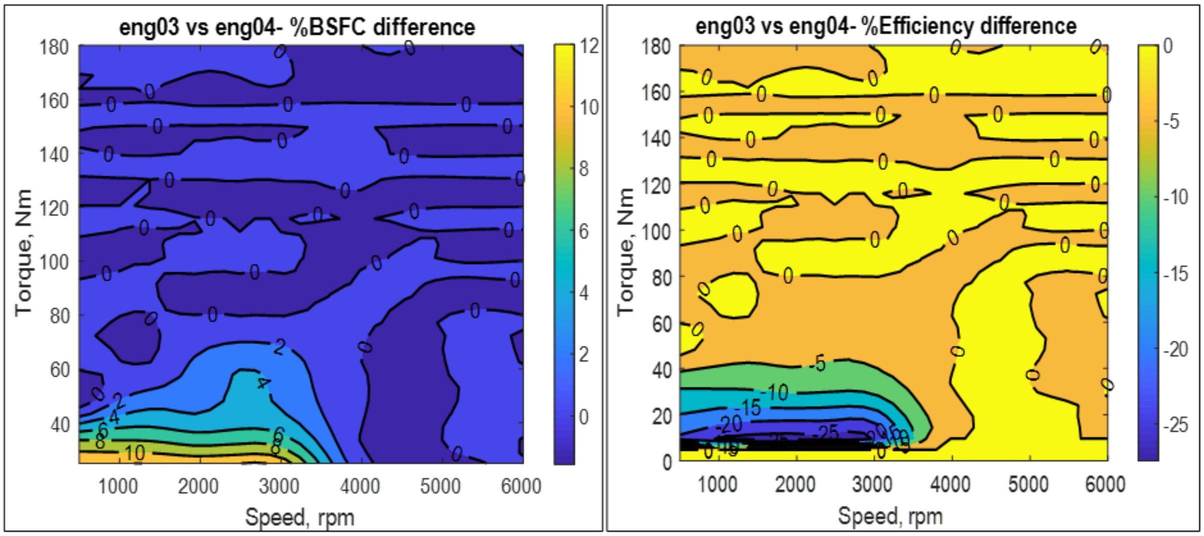

Figure VI-32 – Incremental BSFC and Thermal Efficiency difference between eng03 versus eng04

(5) Engine 5b – SOHC, VVT, and PFI

Engine 5b has reduced friction. Reduction in engine friction can be achieved through low-tension piston rings, roller cam followers, improved material coatings, more optimal thermal management, piston surface treatments, cylinder wall treatments and other improvements in the design of engine components and subsystems that reduce parasitic losses. A SOHC engine with VVT was used as the base and its FMEP was reduced by 0.1 bar over its entire operating range. Valve timing was optimized for a fixed overlap camshaft. Figure VI-33 below shows the IAV engine 5b BSFC map used for this final rule analysis.

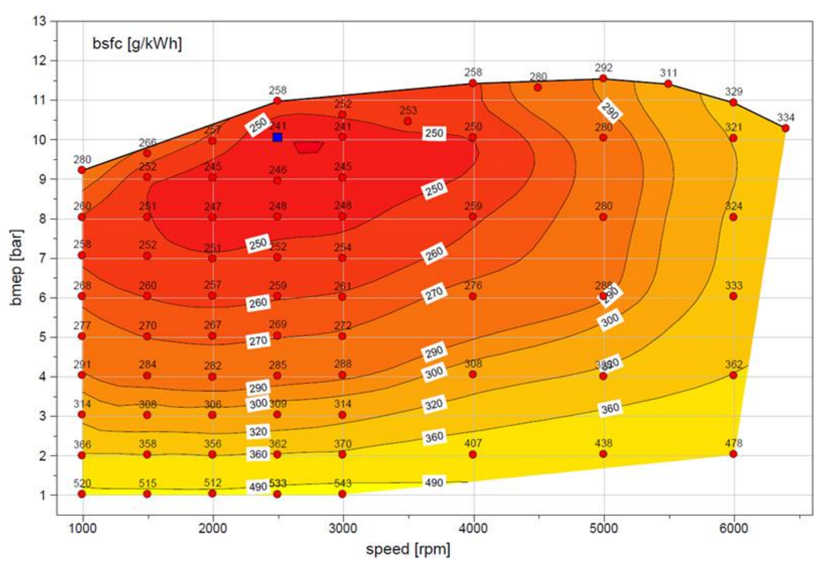

Figure VI-33 – Engine efficiency map for eng5b

Figure VI-34 shows the incremental difference BSFC and thermal efficiency between IAV engine 4 versus engine 5b.

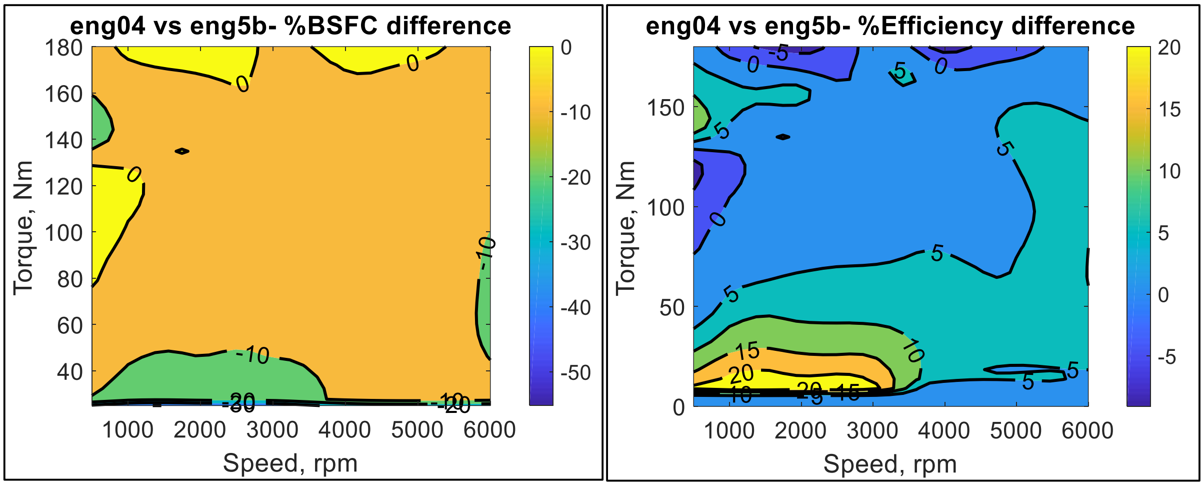

Figure VI-34 – incremental BSFC and thermal efficiency difference between eng04 versus eng05b

(6) Engine 6a – SOHC, VVT, VVL and PFI

Engine 6a reduces the friction of Engine 2. FMEP was reduced by 0.1 bar over its entire operating range. The engine also incorporated VVL technology. Reduced friction will improve efficiency at all load points as well as increase the full load torque. Figure VI-35 below shows the IAV engine 4 BSFC map used for this final rule analysis.

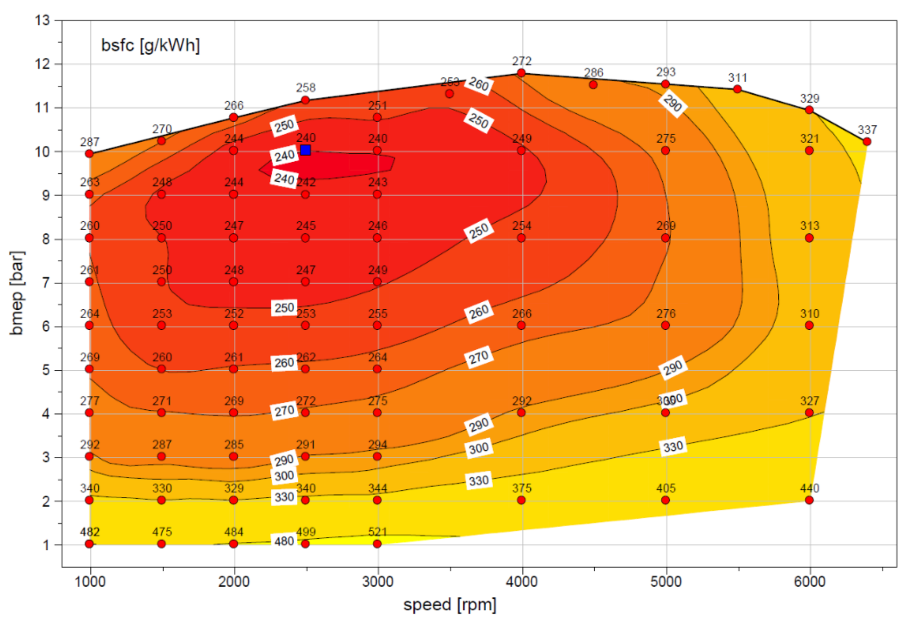

Figure VI-35 – Engine Efficiency Map for eng6a

Figure VI-36 shows the incremental difference BSFC and thermal efficiency between IAV engine 5b versus engine 6a.

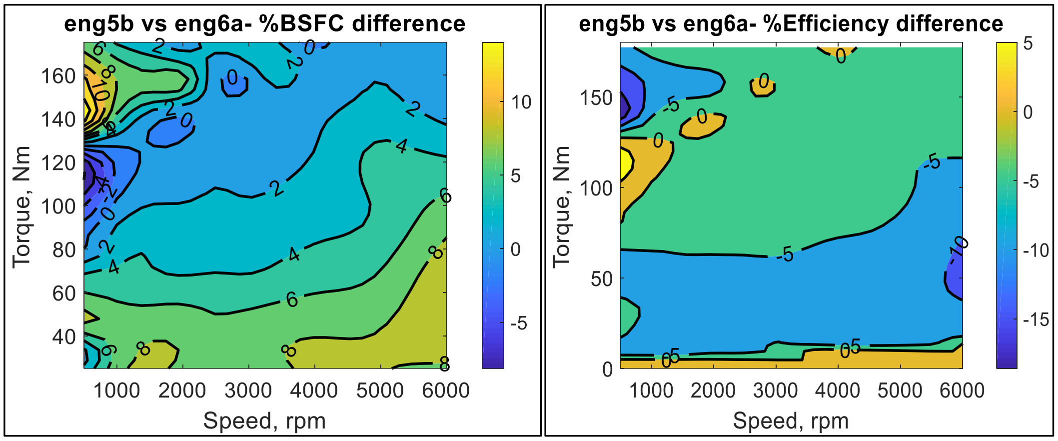

Figure VI-36 – incremental BSFC and thermal efficiency difference between eng05b versus eng6a

(7) Engine 7a – SOHC, VVT, VVL, and GDI

Engine 7a was developed to assess the friction reduction impact on Engine 3. FMEP was reduced by 0.1 bar over its entire operating range. Reduced friction will improve efficiency at all load points as well as increase the full load torque. Figure VI-37 below shows the IAV engine 7a BSFC map used for this final rule analysis.

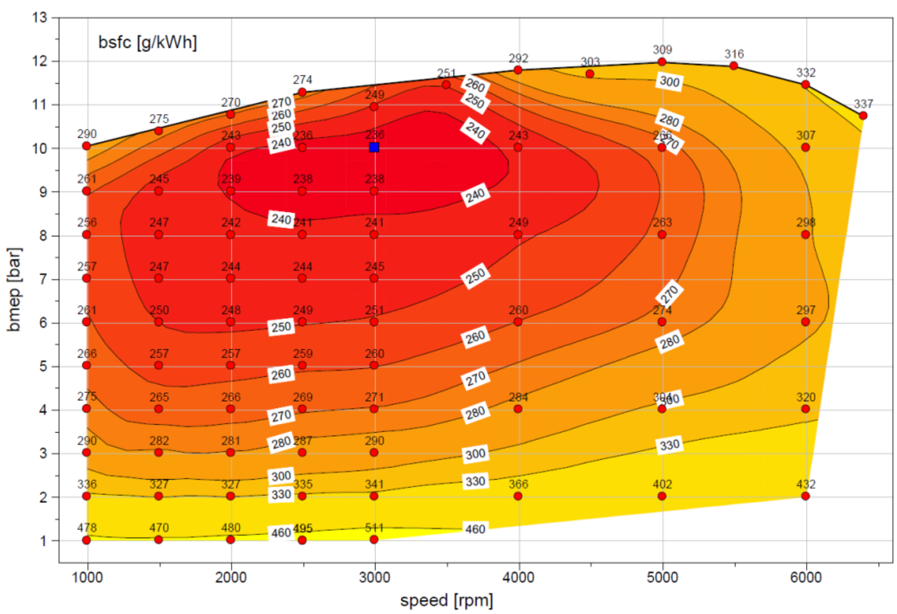

Figure VI-37 – Engine efficiency map for eng7a

Figure VI-38 shows the incremental difference BSFC and thermal efficiency between IAV engine 6a versus engine 7a.

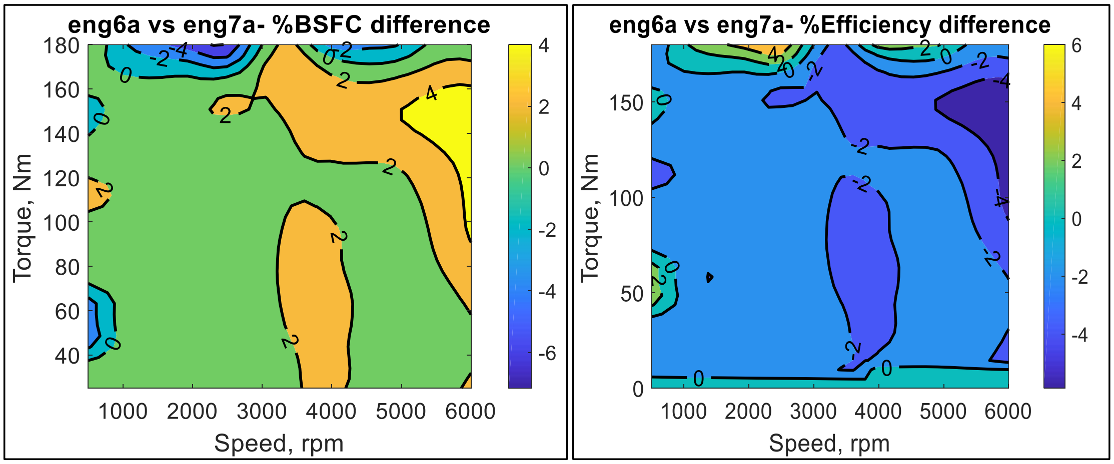

Figure VI-38 – Incremental BSFC and thermal efficiency difference between eng6a versus eng7a

(8) Engine 12 - Turbocharged, DOHC, VVT, VVL, and DI

IAV Engine 12 is the base engine for all the simulated turbocharged engines (Engines 13-14). The map was validated using engine dynamometer test data. Turbocharging and downsizing increases the available airflow and specific power, allowing a reduced engine size while maintaining performance. This also reduces pumping losses at lighter loads in comparison to a larger engine. Engine 12 is a 1.6L, 4 cylinder turbocharged, direct injection DOHC engine with dual cam VVT and intake VVL. The compression ratio is 10.5:1 and the engine uses side mounted direct fuel injectors and a twin scroll turbocharger. The calibrations were fully optimized for best BSFC. Figure VI-39 and Figure VI-41 below shows the IAV engine 12 BSFC map used for this final rule analysis.

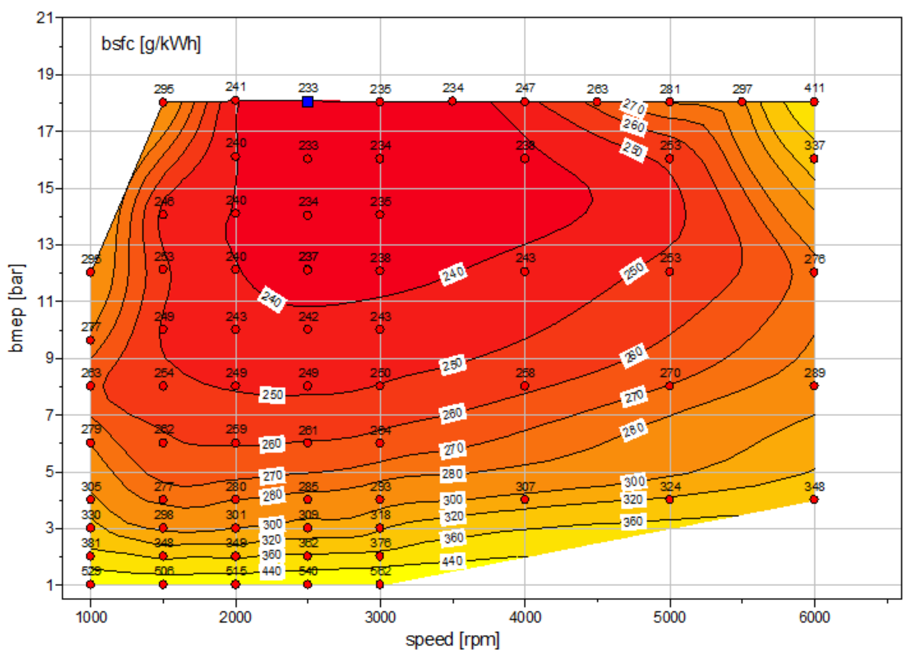

Figure VI-39 – Engine efficiency map for eng12

Figure VI-40 shows the incremental difference BSFC and thermal efficiency between IAV engine 8a versus engine 12a.

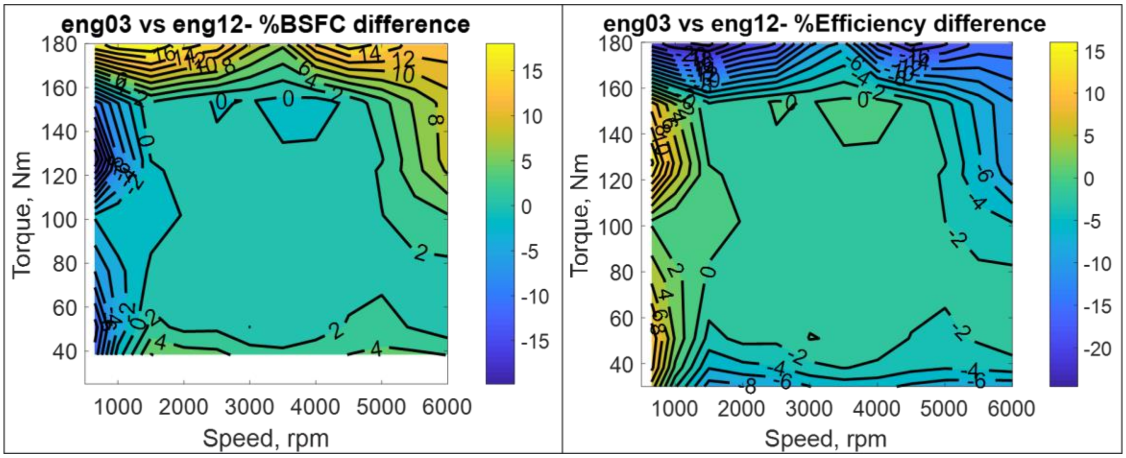

Figure VI-40 – Incremental BSFC and thermal efficiency difference between ENG3 versus ENG12

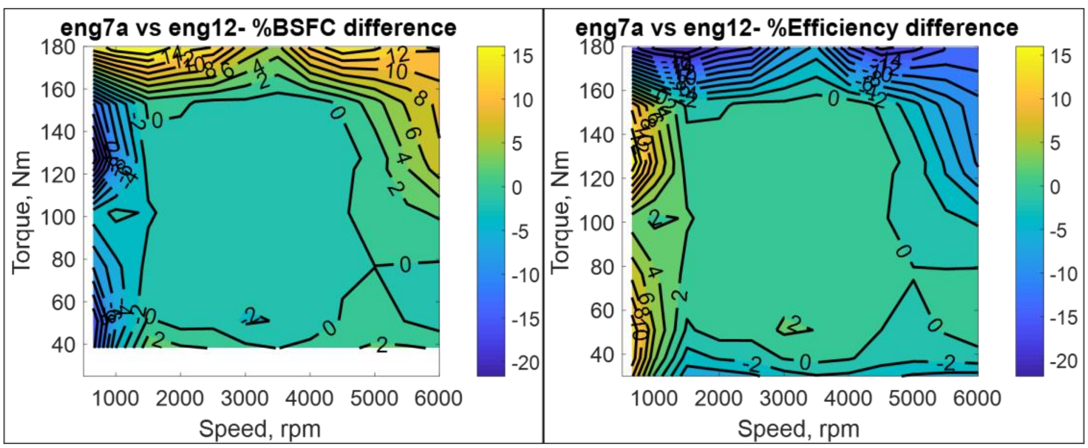

Figure VI-41 – Incremental BSFC and thermal efficiency difference between ENG7a versus ENG12

(9) Engine 13 – Turbocharged, Downsized, DOHC, VVT, VVL, and DI

Engine 12 has been further downsized to a 1.2L to create engine 13. The turbocharger maps scaled to improve torque at low engine speeds. All the turbocharged direct injection engines described below have been developed using 87 octane fuel.

Figure VI-42 below shows the IAV engine 13 BSFC map used for this final rule analysis.

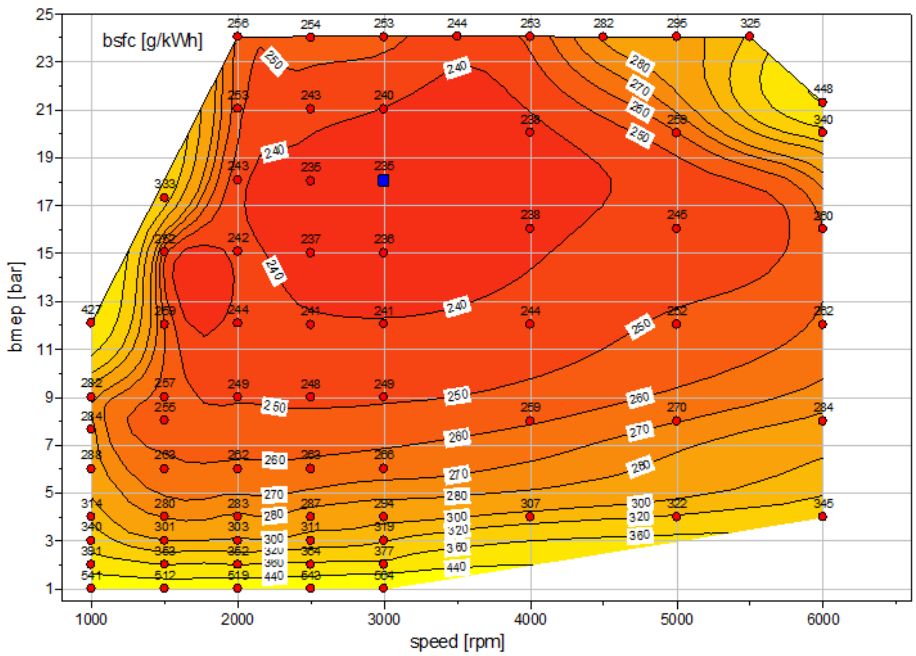

Figure VI-42 – Engine efficiency map for eng13

Figure VI-43 shows the incremental difference BSFC and thermal efficiency between IAV engine 12 versus engine 13.

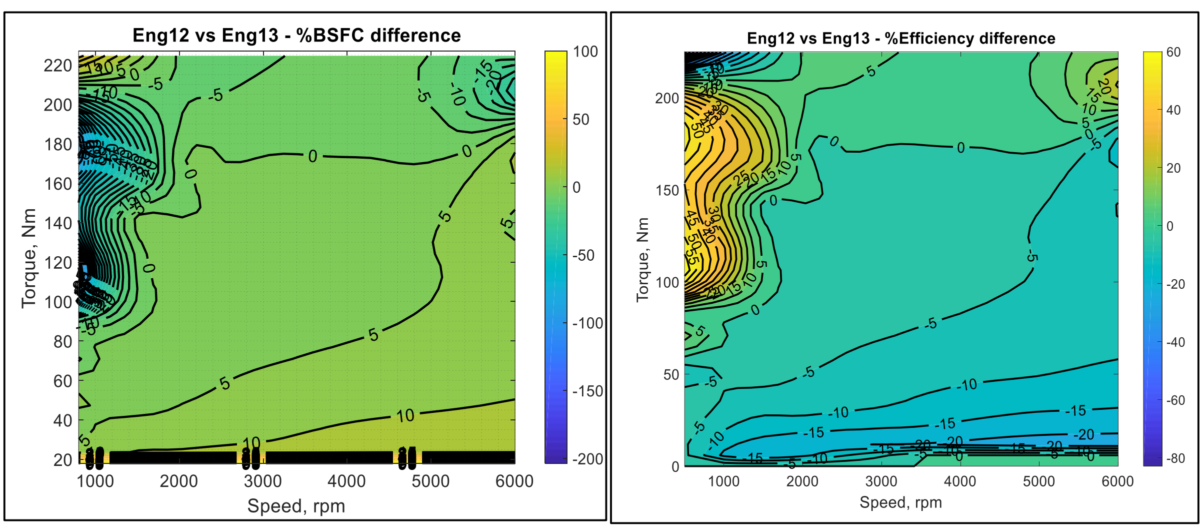

Figure VI-43 – Incremental BSFC and Thermal Efficiency between ENG12 and ENG13

(10) Engine 14 – Turbocharged, Downsized, DOHC, VVT, VVL, DI, and cEGR

High pressure cooled EGR was added to engine 13 to develop engine 14. Exhaust gas recirculation boost increases the exhaust-gas recirculation used in the combustion process to increase thermal efficiency and reduce pumping losses. Levels of exhaust gas recirculation approach 25 percent by volume in these highly boosted engines (this, in turn raises the boost requirement by approximately 25 percent). Cooled EGR target set points were optimized for best BSFC and torque. Figure VI-44 below shows the IAV engine 13 BSFC map used for this final rule analysis.

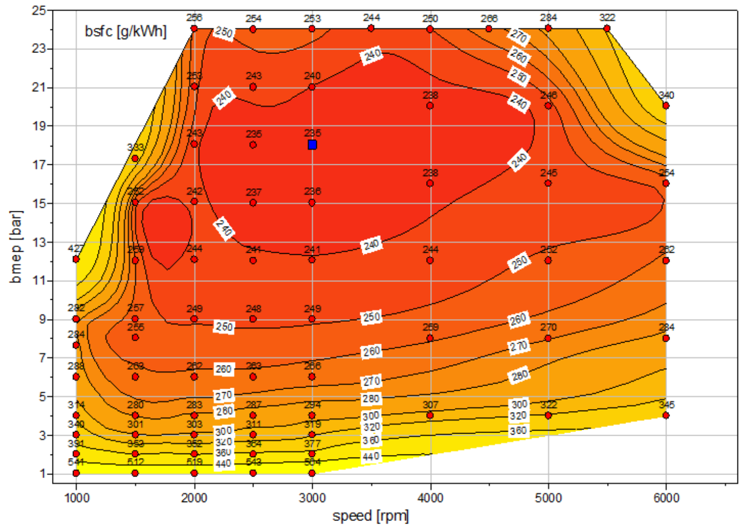

Figure VI-44 – Engine Efficiency Map for Eng14.

Figure VI-45 shows the incremental difference BSFC and thermal efficiency between IAV engine 13 versus engine 14.

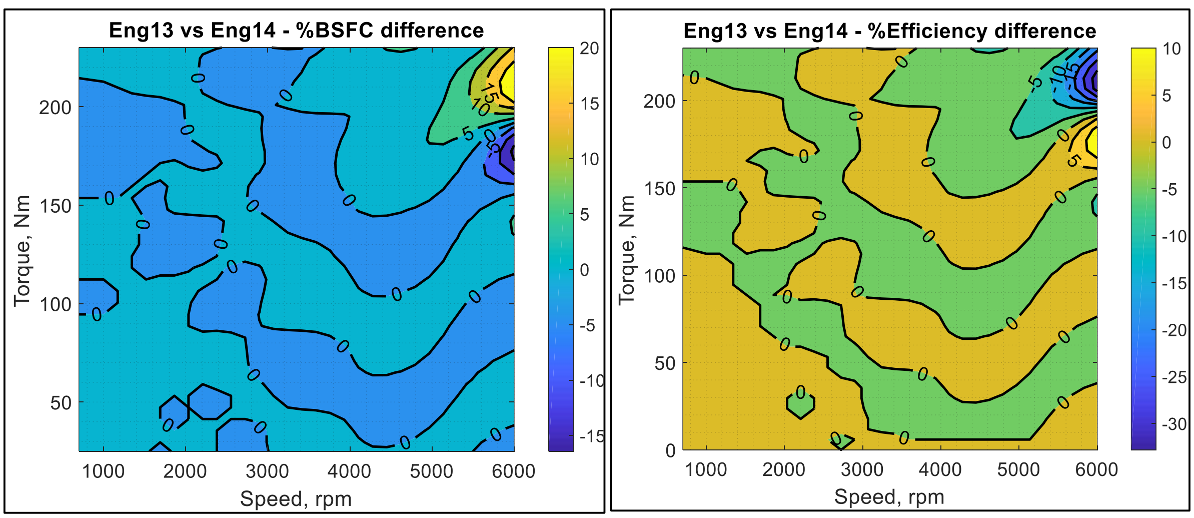

Figure VI-45 – shows Incremental BSFC and Thermal Efficiency Difference Between ENG13 Versus ENG14

(11) Engine 17 – Diesel 2.2L

Diesel engines have several characteristics that give superior fuel efficiency, including reduced pumping losses due to lack of (or greatly reduced) throttling, and a combustion cycle that operates at a higher compression ratio, with a very lean air/fuel mixture, than an equivalent-performance gasoline engine. This technology requires emission controls, such as a NO_x trap catalyst after-treatment system or a selective catalytic reduction NO_x after-treatment system. Diesel engine maps were created from measured data, including engine speed, BMEP, brake torque, brake power, and BSFC.

Figure VI-46 below shows engine 17 BSFC map used for this final rule analysis.

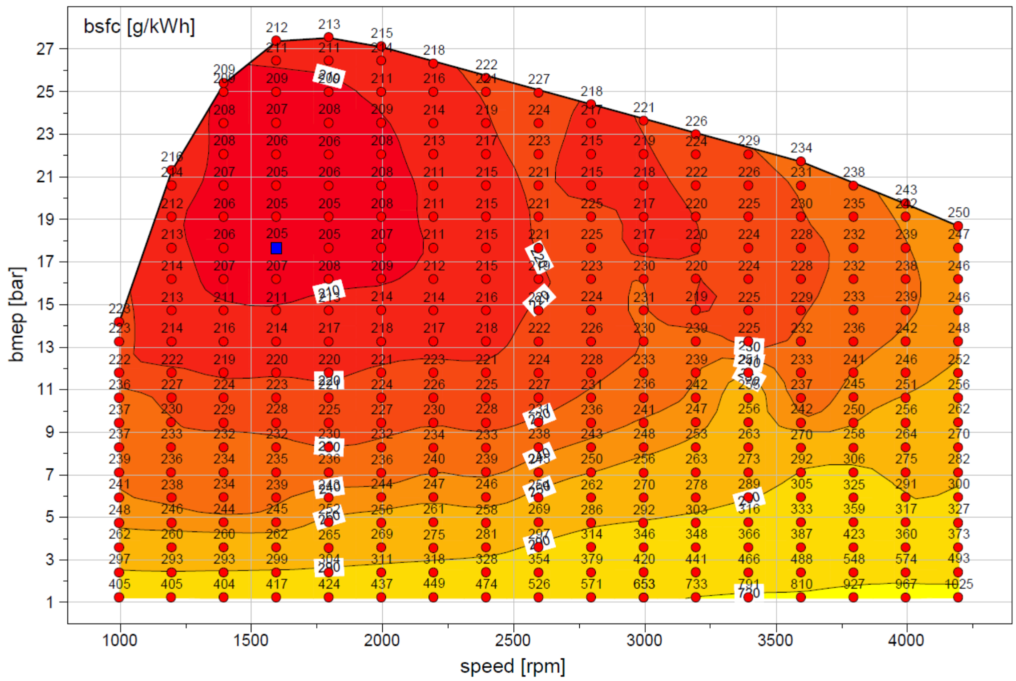

Figure VI-46 – Engine Efficiency Map for Eng17

Figure VI-47 shows the incremental difference BSFC and thermal efficiency between IAV engine 14 versus engine 17.

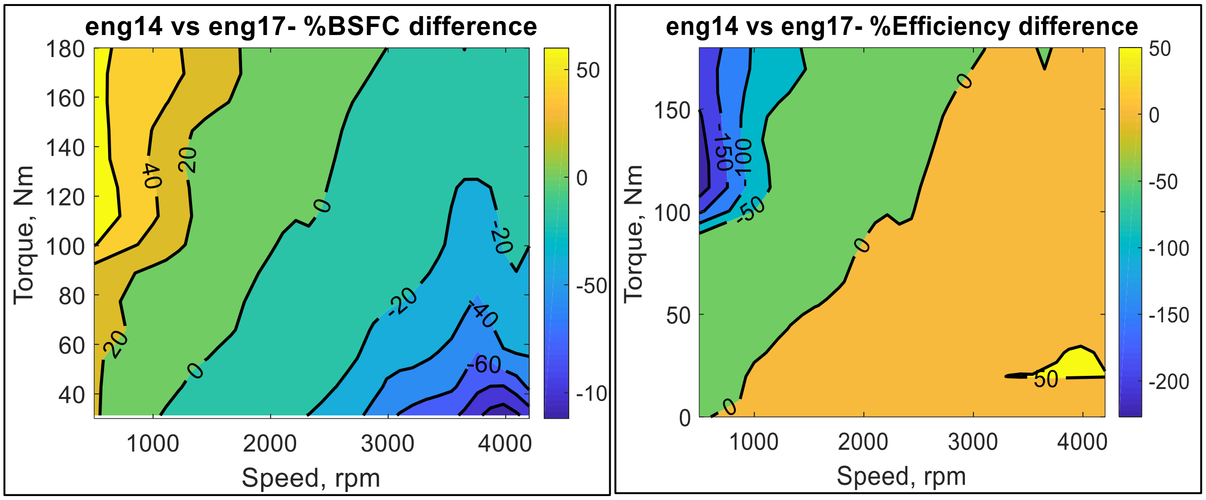

Figure VI-47 – Incremental BSFC and Thermal Efficiency Difference Between Eng14 Versus Eng17

(12) Engine 18 – DOHC, VVT, DI

Eng18 adds SGDI to Eng1, and assumes open valve injection and homogeneous operation. SGDI improves knock tolerance and volumetric efficiency due to in cylinder vaporization of the fuel. The engine map is unchanged from the Draft TAR. Figure VI-48 below shows the IAV engine 18 BSFC map used for this final rule analysis.

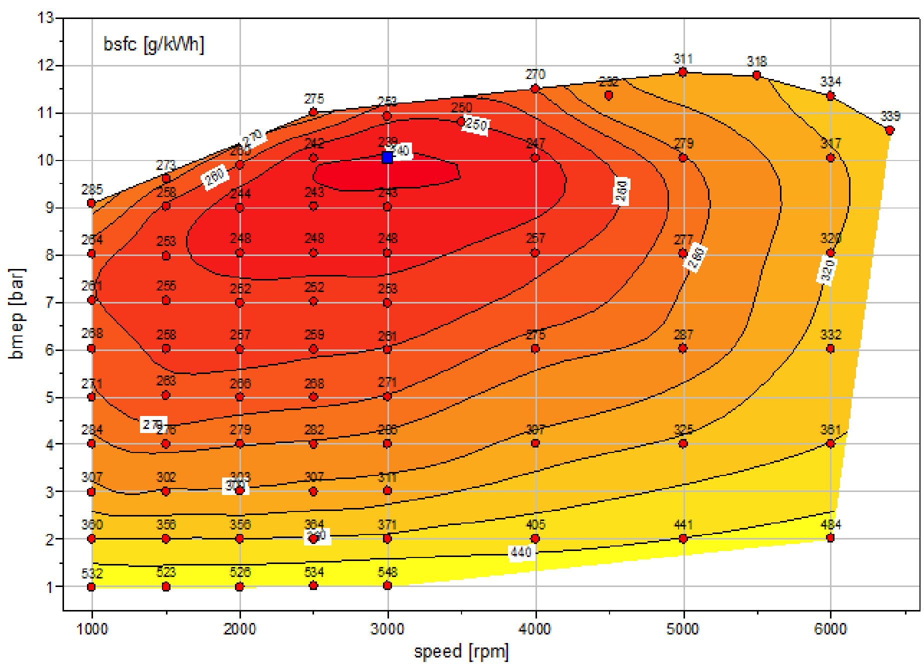

Figure VI-48 – Engine Efficiency Map for Eng18

Figure VI-49 shows the incremental difference BSFC and thermal efficiency between IAV engine 18 versus engine 1.

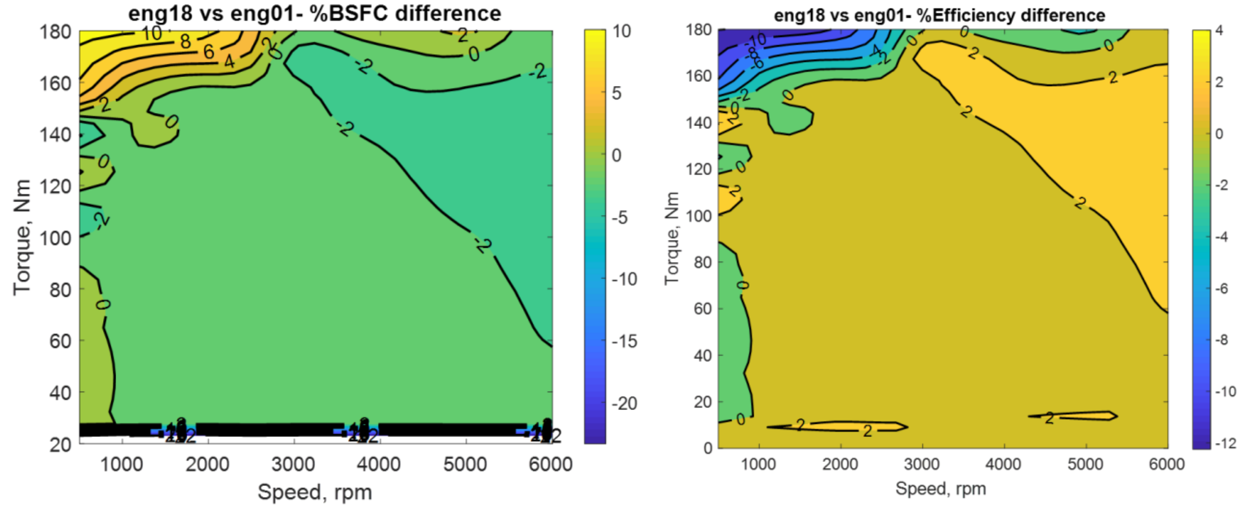

Figure VI-49 – Incremental BSFC and Thermal Efficiency Between IAV Eng18 Versus Eng01

(13) Engine 19 – DOHC, VVT, and DEAC

Eng19 was developed from Eng01 with the addition of cylinder deactivation. The VVT timing and IMEP of active cylinders are from Eng01, which does not have cylinder deactivation. The change in the manifold pressure dynamics is not large enough to warrant re-optimizing valve timing in the cylinder deactivation zone. Figure VI-50 below shows the IAV engine 19 BSFC map used for this final rule analysis.

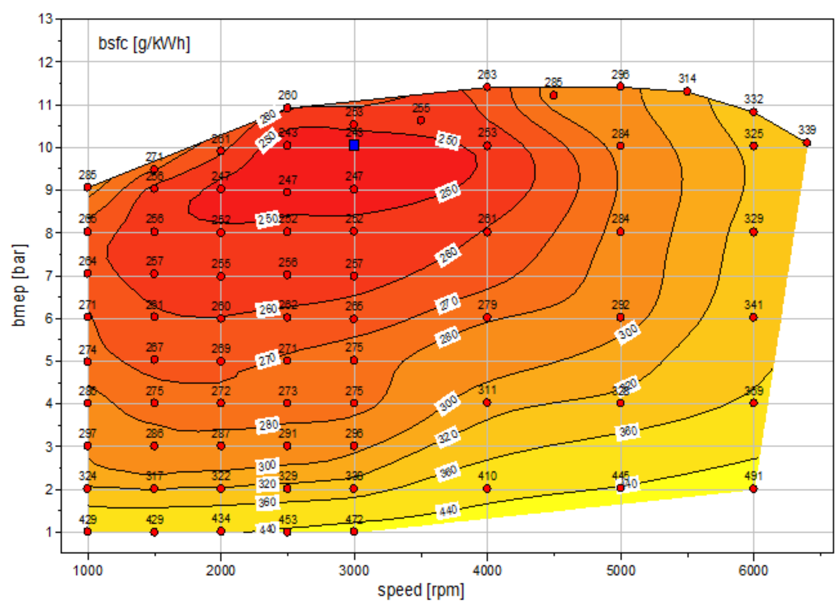

Figure VI-50 – Engine Efficiency Map for Eng19

Figure VI-51 shows the incremental difference BSFC and thermal efficiency between IAV engine 19 versus engine 1.

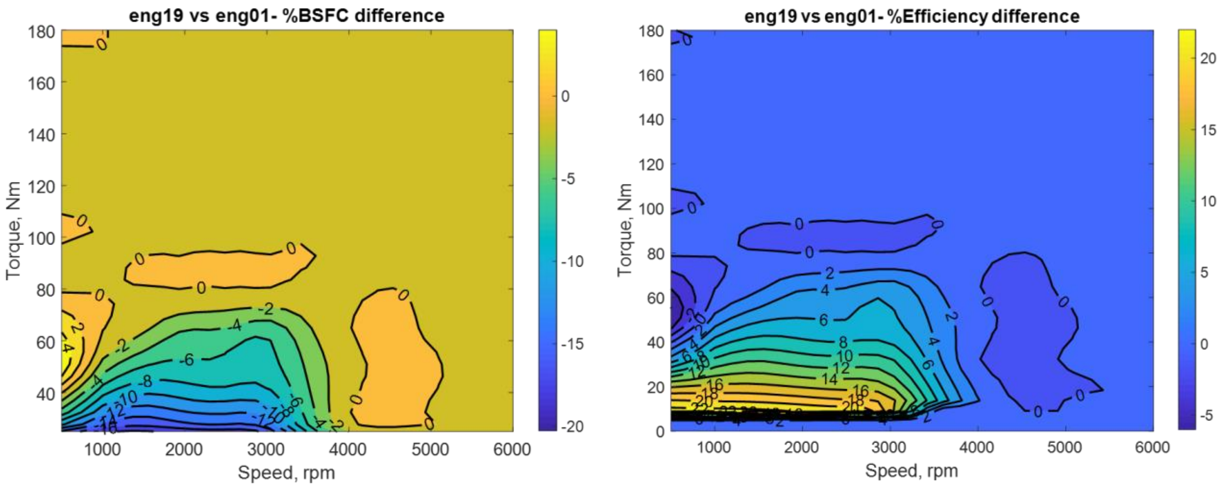

Figure VI-51 – Engine BSFC and Efficiency Difference Between Engine 19 and Engine 1

(14) Engine 20 – DOHC, VVT, VVL and DEAC

Eng20 was developed from Eng02 with the addition of cylinder deactivation. The VVT timing and lift, and IMEP of active cylinders are from Eng02 which does not have cylinder deactivation. The change in the manifold pressure dynamics is not large enough to warrant re-optimizing valve timing in the cylinder deactivation zone. Figure VI-52 below shows the IAV engine 20 BSFC map used for this final rule analysis.

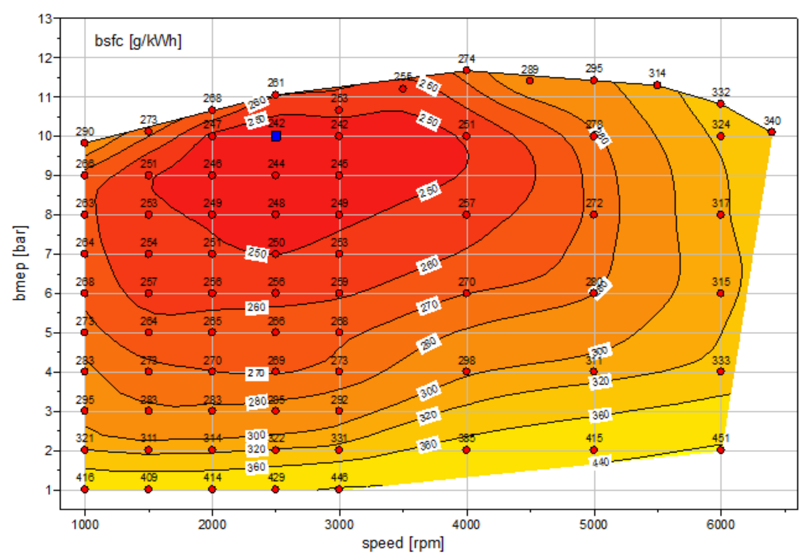

Figure VI-52 – Engine Efficiency Map for Eng20

Figure VI-53 shows the incremental difference BSFC and thermal efficiency between IAV engine 20 versus engine 2.

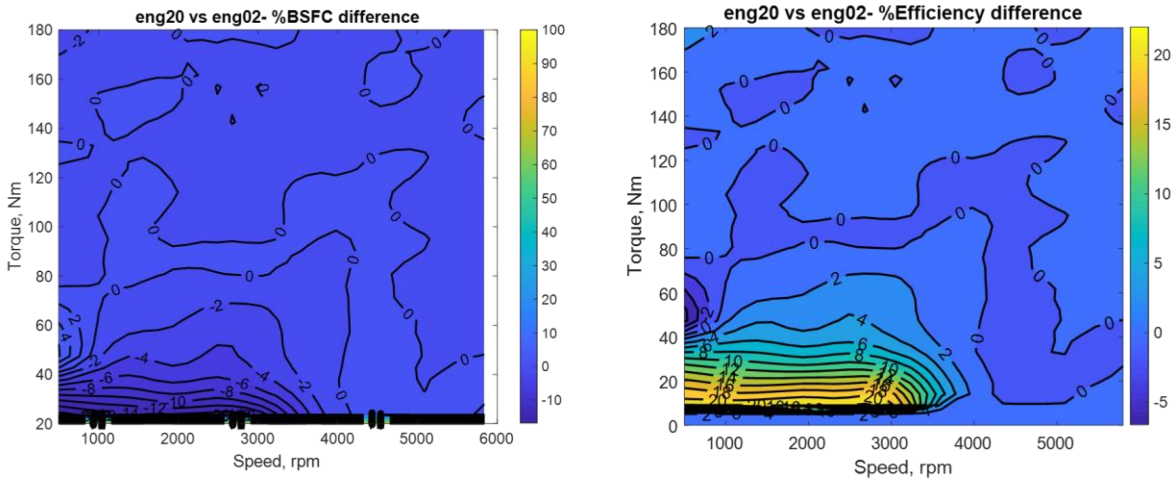

Figure VI-53 – Engine BSFC and Efficiency Difference Between Engine 20 and Engine 2

(15) Engine 21 – DOHC, VVT, DI, and DEAC

Eng21 was developed from Eng18 with the addition of cylinder deactivation. The VVT timing and lift, and IMEP of active cylinders are from Eng18 which does not have cylinder deactivation. The change in the manifold pressure dynamics is not large enough to warrant re-optimizing valve timing in the cylinder deactivation zone.

Figure VI-54 below shows the IAV engine 21 BSFC map used for this final rule analysis.

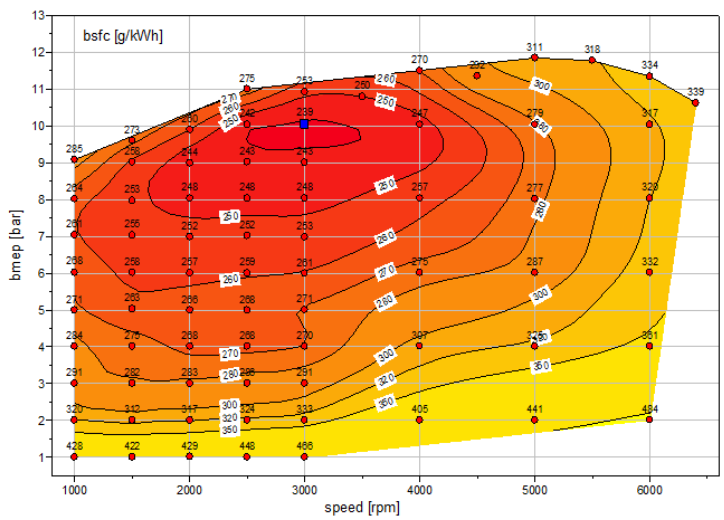

Figure VI-54 – Engine Efficiency for Eng21

Figure VI-55 shows the incremental difference BSFC and thermal efficiency between IAV engine 21 versus engine 18.

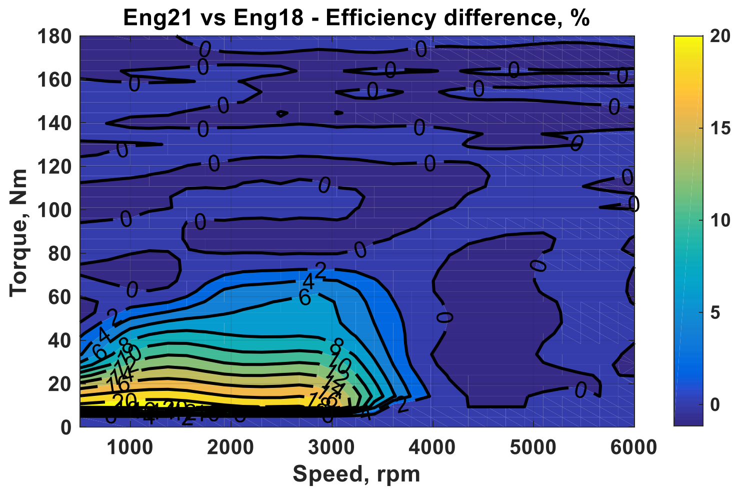

Figure VI-55 – Engine Efficiency Difference Between Engine 21 and Engine 18

(16) Engine 22b – HCR0

Engine 22b represents the a generation of non-HEV Atkinson cycle engine a typical otto-cycle engine could adopt.

Figure VI-56 below shows the engine 22b BSFC map used for this final rule analysis.

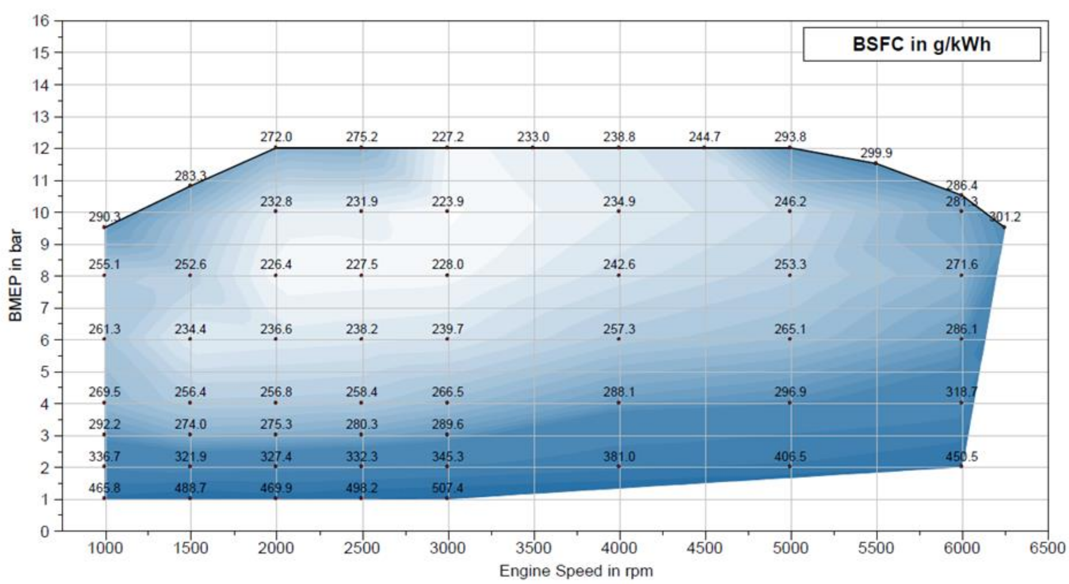

Figure VI-56 – Engine Efficiency Map for Eng22b

Figure VI-57 shows the incremental difference BSFC and thermal efficiency between IAV engine 01 versus engine 22b.

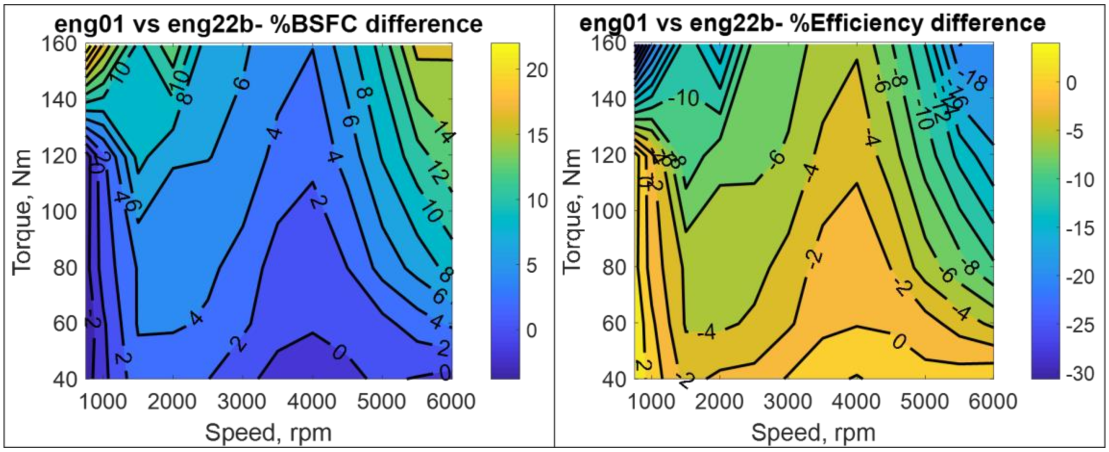

Figure VI-57 – shows Incremental BSFC and Thermal Efficiency Difference Between ENG01 versus ENG22b

(17) Engine 24 – HCR1

Engine 24 represents the current generation of non-HEV Atkinson cycle engine. The engine map for Eng24 was developed by EPA from testing of the 2.0L variate of the 2014 Mazda SkyActiv-G engine. This engine's compression ratio is 13:1 with VVT and SGDI.

Figure VI-56 below shows the engine 24 BSFC map used for this final rule analysis.

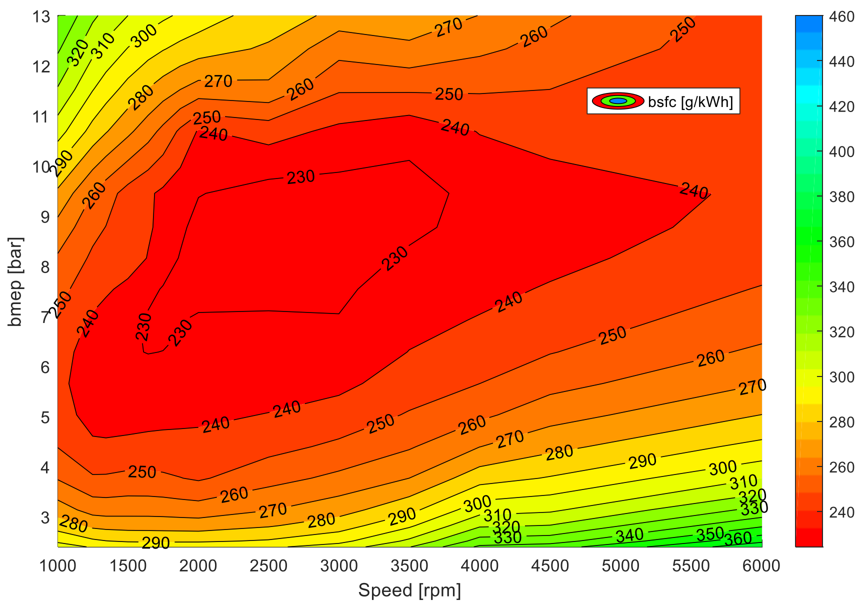

Figure VI-58 – Engine Efficiency Map for Eng24

Figure VI-57 shows the incremental difference BSFC and thermal efficiency between IAV engine 22b versus engine 24.

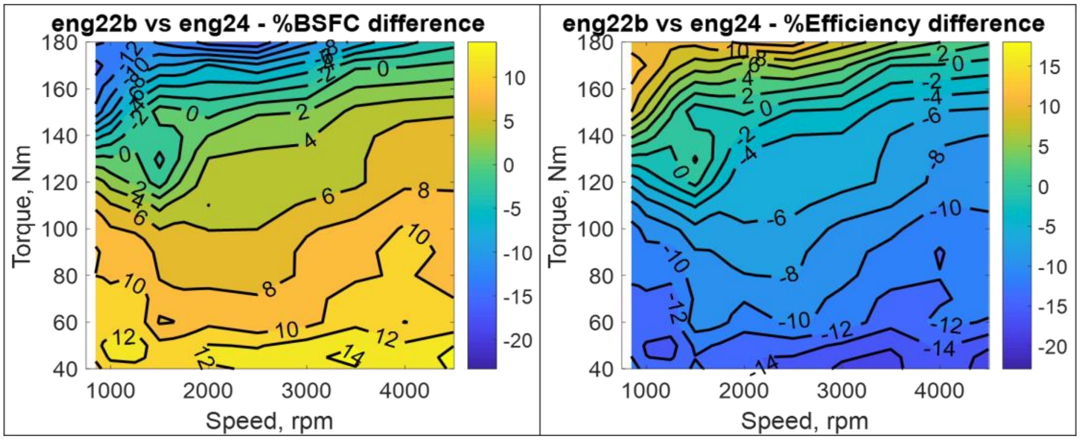

Figure VI-59 – shows Incremental BSFC and Thermal Efficiency Difference Between ENG22b Versus ENG24

(18) Engine 23b - High Compression Miller Cycle Engine with Variable Turbocharger Geometry

New for the final rule is Eng23b that represents miller cycle engines for the final rule anlaysis. Figure VI-60 below shows the bsfc map used for the final rule analysis.

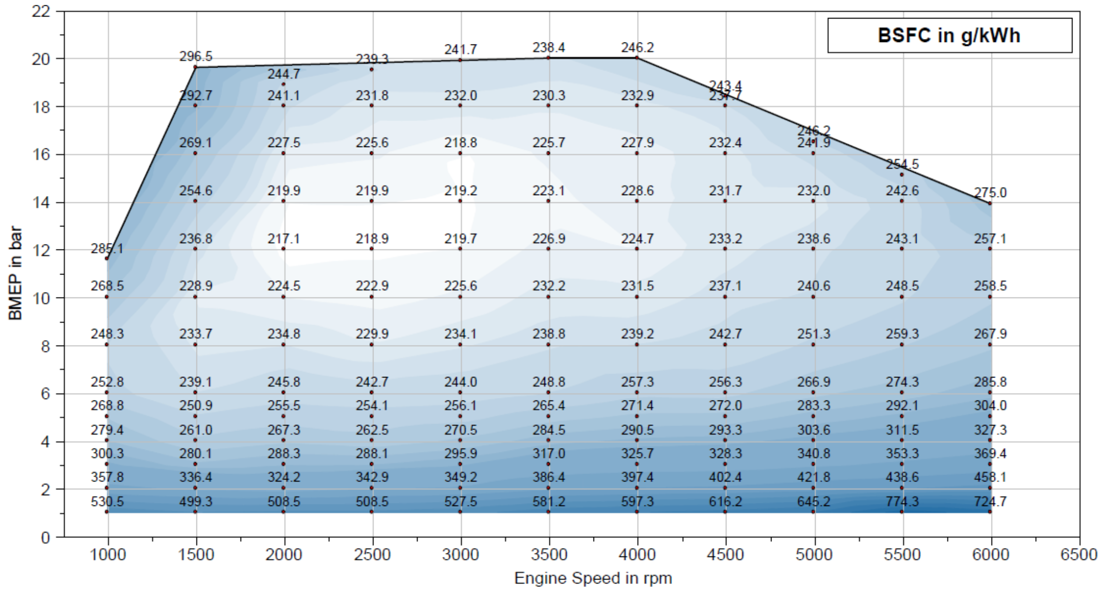

Figure VI-60 – IAV ENGINE 23b's BSFC MAP

Figure VI-61 and Figure VI-62 below shows the difference in thermal efficiencies and BSFC of eng23b versus eng24 and eng14.

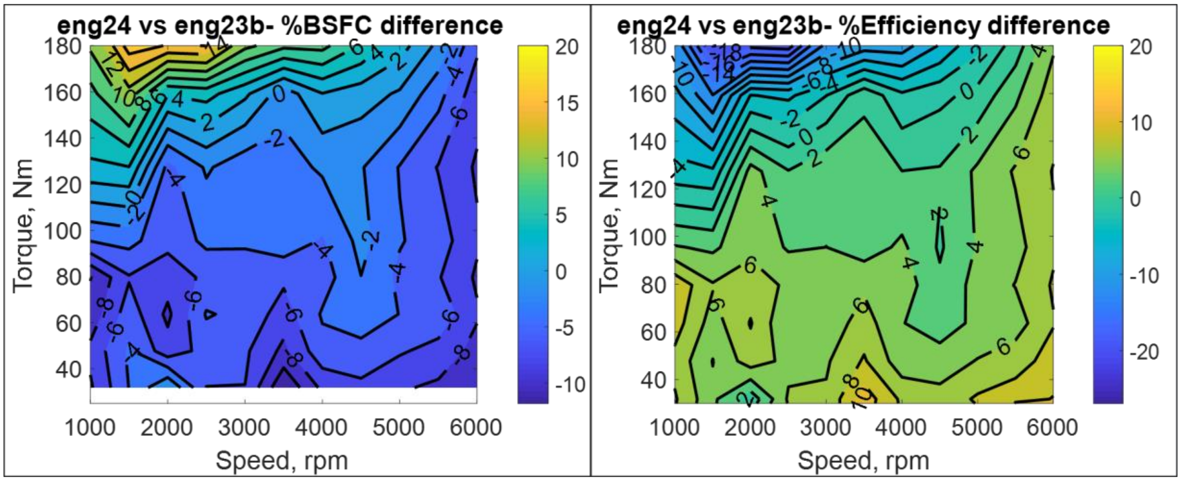

Figure VI-61 – shows incremental BSFC and Thermal Efficiency Difference Between Eng24 and Eng23b

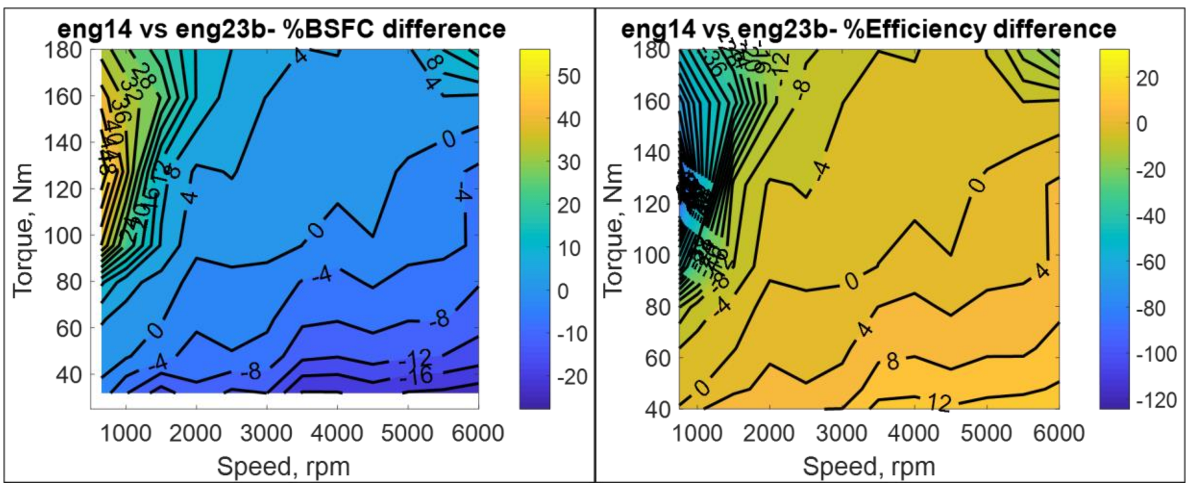

Figure VI-62 – shows Incremental BSFC and Thermal Efficiency Difference Between Eng14 and Eng23b

(19) Engine 23c - High Compression Miller Cycle Engine with Electric Supercharger

New for the final rule is Eng23c that represents miller cycle engines for the final rule anlaysis. Figure VI-63 below shows the bsfc map used for the final rule analysis.

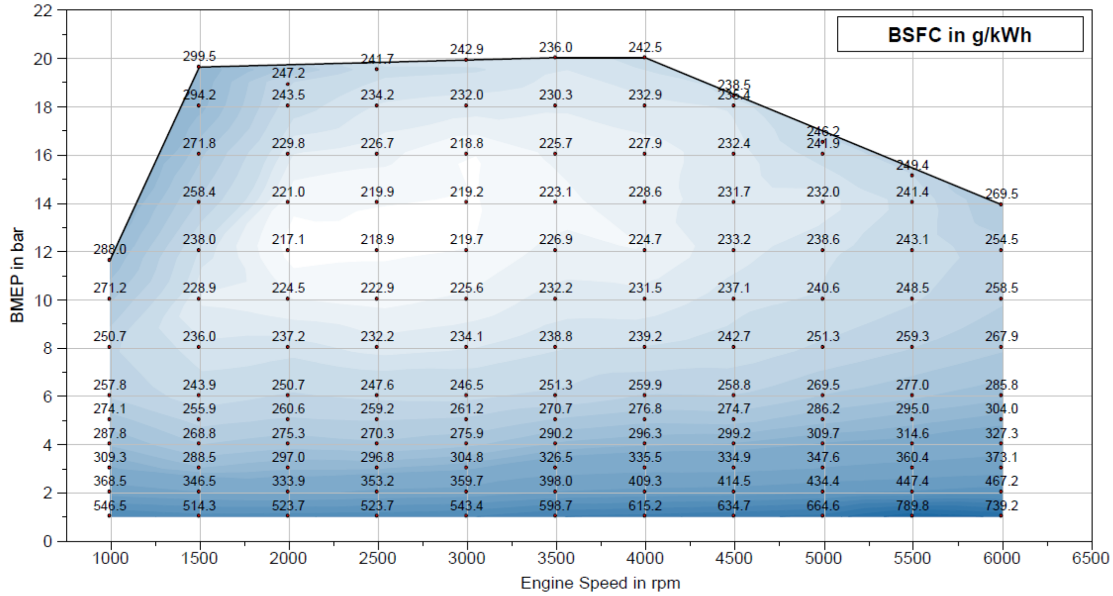

Figure VI-64 – IAV's High Compression Miller Cycle ENGINE with E-boost 23c's BSFC MAP

Figure VI-65 below shows the difference in thermal efficiencies and BSFC of eng23b versus eng23c.

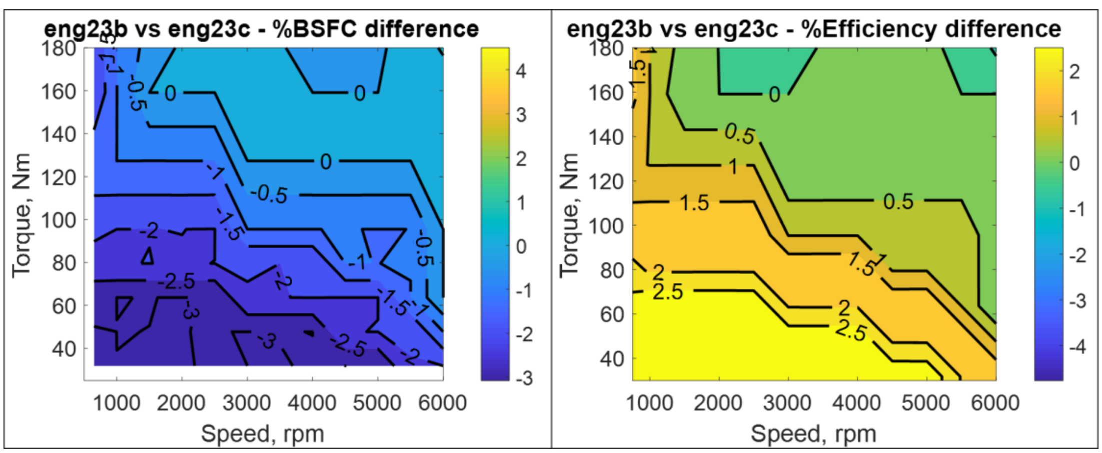

Figure VI-66 – shows Incremental BSFC and Thermal Efficiency Difference Between Eng23b and Eng23c.

(20) Engine Effectiveness Modeling and Effectiveness Values

Figure VI-67 below shows the effectivness estimates from all the vehicle types for the NPRM analysis using Autonomie full vehicle modeling and simulation.

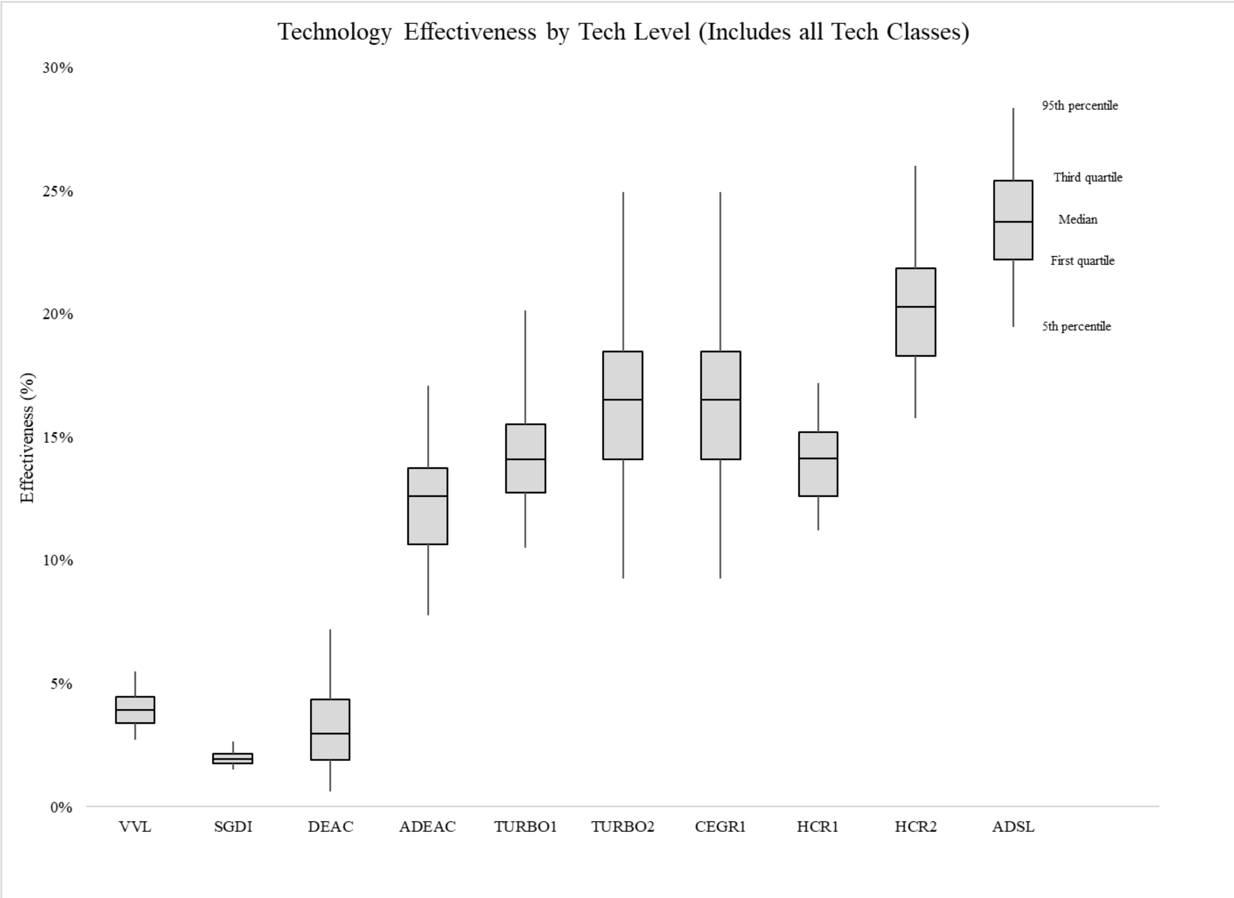

Figure VI-67 – NPRM Technology Effectiveness by Engine Technologies Relative Base

Roush commented that they had observed wide variations in estimated incremental effectiveness associated with individual technology packages between the 2016 Draft TAR and NPRM analysis.[992]

The agencies agree that to predict potential incremental improvements in fuel efficiency accurately, it is extremely important to understand the nature of the improvements being sought by each increment (improved thermodynamics, reduced friction, reduced vehicle weight, etc.). The technology modeling and large scale simulation used for the proposal and updated for the final rule does exactly that. In fact, the NPRM and final rule use these methods more expansively than any previous CAFE and CO_2 rulemaking, including the 2016 Draft TAR and 2016 EPA Proposed Determination.

One commenter stated the effectiveness for ADEAC was overestimated for the NPRM, and that data from compliance shows much lower effectiveness. The agencies disagree with this comment, as it is invalid to compare effectiveness of full vehicle compliance data directly to the

[992] NHTSA-2018-0067-11984. Roush at p. 16.

incremental effectiveness modeled for ADEAC. For reasons discussed in Section VI.B.3 data from full vehicle benchmarking cannot be used as a comparison for specific technology effectiveness. The effectiveness estimated for this technology is in line with test data, CBI, and engineering analysis.[993]

Engine effectiveness estimates remained the same for most technologies from the NPRM analysis, with the exception of some technologies that had characteristics updated, and the new added engine technologies. For the final rule analysis, the agencies used the same effectiveness values for ADEAC applied to naturally aspirated engines as in the NPRM, and incorporated estimated effectiveness values for TURBOAD to represent ADEAC on downsized turbocharged engines.

Other technology-specific comments and the agencies' responses are provided within the discussion of each technology throughout this section, as those comments tended to be predicated on issues surrounding the engine maps used to model technologies or technology-specific adoption features. For the final rule analysis, the technical merits of the substantive comments and any accompanying publications and information were carefully considered and discussed in the subsections where appropriate.

Figure VI-68 below shows the effectivness estimates from compact car and midsize car vehicle types for the final rule analysis using Autonomie full vehicle modeling and simulation.

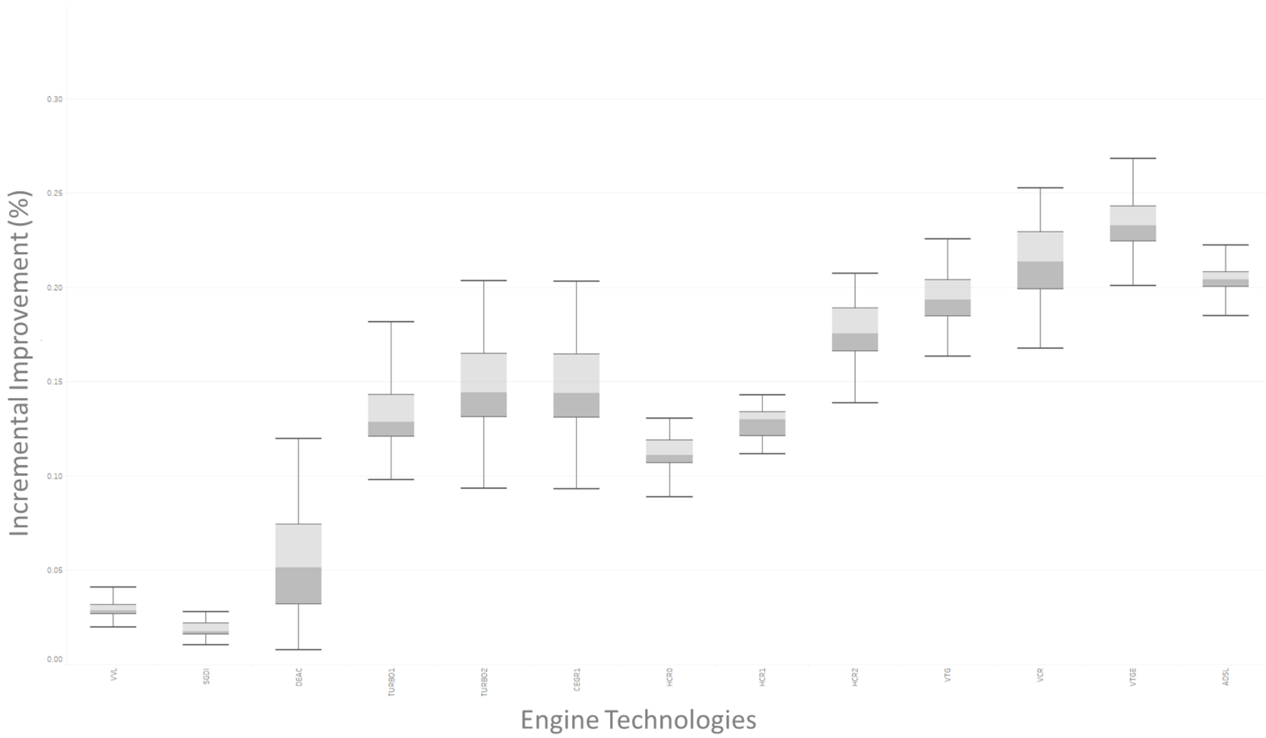

Figure VI-68 – FRM Technology Effectiveness Estimates by Engine Technologies Relative to Base for compact and midsize vehicle class

g) Engine Costs

Discussed in the PRIA, the agencies spent millions of dollars sponsoring research to determine direct manufacturing costs (DMCs) for fuel saving technologies since the 2012 rule.[994] Because a major objective of the studies was to consider costs in the rulemaking timeframe, the agencies believed that these costs were appropriate to use for the NPRM and final rule analysis. Table VI-48 below shows the DMC used for IC engine technologies for the NPRM analysis.

[994] FEV prepared several cost analysis studies for EPA on subjects ranging from advanced 8-speed transmissions to belt alternator starter, or Start/Stop systems. NHTSA also contracted with Electricore, EDAG, and Southwest Research on teardown studies evaluating mass reduction and transmissions. The 2015 NAS report on fuel economy technologies for light-duty vehicles also evaluated the agencies' technology costs developed based on these teardown studies, and the technology costs used in this proposal were updated accordingly. These studies are discussed in detail in Chapter 6 of the RIA accompanying the NPRM proposal.

Table VI-48 – Engine Technology DMC used for the NPRM analysis in 2018$

Engine Technologies – Direct Manufacturer Costs (2018$) for NPRM								Incremental To
Tech	**Basis**	**Unit DMC**	**DMC for 4-Cylinder 1-Bank Engine**	**DMC for 4-Cylinder 2-Bank Engine**	**DMC for 6-Cylinder 1-Bank Engine**	**DMC for 6-Cylinder 2-Bank Engine**	**DMC for 8-Cylinder 2-Bank Engine**

CARB commented that costs associated with IC engines were not excluded from the final costs of BEV vehicles.[995] CARB continued, stating that "the final costs of BEV vehicles are higher due to the inclusion of the base absolute costs, to which the assigned BEV incremental cost would be added."

The agencies agree with CARB that inclusion of IC engine costs in the BEV cost was an error in the analysis. In response to this comment, the agencies have developed absolute costs for baseline engines for the CAFE model in order to account for appropriate cost of removing engines from BEVs. In the final rule analysis, once a vehicle adopts BEV technology, the costs associated with powertrain systems are removed. Due to the extensive variations in engine technologies in real world production, the agencies relied on discrete publication costs and historical studies to assign costs for base engines.[996,997] For this final rule analysis, the agencies have included these costs for base engines shown in Table VI-49.

Table VI-49 – Examples of Absolute Costs for Engines in 2018 Dollars

	I4	**V6**	**V8**
SOHC	5,013.49	5,675.87	6,306.65
DOHC	5,090.94	5,830.76	6,461.54

Commenters compared engine cost data from the NPRM to other sources, in many cases to support their comments that the technology costs used in the NPRM were too high. ICCT commented that the agencies did not consider the latest reports on technology cost data, and specifically referenced an ICCT-sponsored FEV cost study for the European EU6b regulations in MY 2025,[998] as well as prior EPA cost estimates for several engine technologies including SGDI, cEGR, HCR, and others, to point out differences in cost.[999] ICCT also commented on the difficulty they had in locating the cost data used in the NPRM, stating that "because the agencies present cost data in so many different ways in dozens of different places in the NPRM, impact assessment, and supporting data files, the precise agencies' costs are obscured and not transparent." ICCT stated that "[w]ithout a clear explanation of the methodology, it is unclear precisely how price increases are determined, as well as the relationship between technology costs, fines, and price increases." Despite this claim, ICCT was able to provide several pages comparing engine technology costs.

In the NPRM PRIA Chapter 6.3.2.2.20.22, the agencies provided DMCs for all engine technologies in 2016 dollars without inclusion of RPE and learning for review. In the same chapter, the agencies also provided absolute costs that incorporated costs in 2016 dollars, RPE and learning data as used by the CAFE model to assess cost effectiveness for future MY vehicles. Where appropriate, the agencies discussed in the individual technology sections where

[999] NHTSA-2018-0067-11741 at p. I-68.

costs were updated for this final rule analysis with the latest data. This also includes cost data for new technologies available in the CAFE model for the final rule analysis.

Some engine costs were carried over from prior rulemakings, but may have looked different because they were updated to current dollars (2016 for the NPRM and 2018 for the final rule), and for engine architecture and cylinder count. In addition, costs were updated based on appropriate vehicle class. This was important to consider to maintain performance neutrality, as technology effectiveness associated with one engine technology type for a vehicle class cannot be used for the same engine technology for higher performance vehicle class. This affected total costs. For further discussion on the cost-effectiveness metric used in the CAFE model, see discussions in the Section VI.A Overview of the CAFE model and VI.B.3 Technology Effectiveness Values.

The agencies do not believe that the FEV report referenced by ICCT is applicable for this analysis for a few reasons. First, the primary focus of the FEV study "is the European Market according to the EU6b regulation as well as the consideration of emissions under both the NEDC and WLTP test procedures." This final rule analysis specifically considered the U.S. automotive market during the rulemaking timeframe based on U.S.-specific regulatory test cycles. Accordingly, the costs reflect incremental technology effectiveness for achieving improvements as measured through U.S. regulatory test methods. The agencies had discussed these test cycles and methods further in Section VI.B.3 Technology Effectiveness Values.

Second, FEV did not conduct original teardown studies for this report, as indicated by project tasks, but rather used engineering judgement and external studies in assessing incremental costs.[1000] The FEV report did not provide sources for each individual cost and it is unclear how costs in many scenarios were developed since no teardowns were used. Note that for this final rule analysis, the agencies have used previously conducted FEV cost teardown studies and the referenced 2015 NAS costs that referenced FEV teardowns. The agencies are not concluding that FEV is an unreliable source. The agencies preferred to specifically identify incremental costs of adding technology to account appropriately for the costs of those technologies in the analysis.

Finally, the cost for different vehicle classes identified by the FEV study does not line up with the vehicle classes discussed in the NPRM and this final rule analysis. FEV stated specifically, "the configuration of the vehicles has not been optimized for the US market and may not be representative of this market."[1001] The agencies have discussed the importance of aligning the CAFE vehicle models with the U.S. market earlier in Section VI.B.3 Technology Values and Section VI.C.1.d) Baseline Fleet. All of these factors make it difficult to compare directly the agencies' estimates and estimates presented in the FEV report cited by ICCT in their comments.

[1000] FEV EU Costs Tasks: "Definition of reference hardware or description made by experience of development and design engineers as well as additional research as base for cost analysis (no purchase of hardware)".
[1001] *Id.* at p.141.

HDS provided a variety of costs and effectiveness comparisons between the NPRM and previous 2012 final rule and the 2016 Draft TAR.[1002] Specifically, HDS stated that the data presented in the 2016 TAR indicated a $60 per CO_2/mile reduction for most conventional engine technologies.

Although the comparison was technically sound, there are significant differences between the Draft TAR and NPRM analyses that clearly account for the differences in engine cost. First, the NPRM analysis used the MY 2016 fleet as a starting point to model manufacturers' potential responses to CAFE and CO_2 standards, whereas the 2012 final rule and Draft TAR used older baseline fleets. Vehicles in the MY 2016 fleet already included more advanced technologies than their predecessors in prior MY fleets, which would make it more expensive for vehicles that have already adopted advanced technologies to adopt more advanced technology. Second, the agencies refined the engine modeling from previous analysis to the NPRM to account for engine configurations and cylinder count more precisely. For the final rule analysis, the same approach was taken to account appropriately for costs for different type engine designs and configurations.

Aside from these updates, engine costs were carried over from the NPRM analysis, except for newly added technologies, where costs were obtained from various sources such as NAS studies, technical publications, and CBI data. Finally, the cost estimates have been updated to account for dollar year (updated from 2016 dollars to 2018 dollars), and learning rate.

(1) Basic Engines

DMCs used for the final rule analysis for basic engine technologies were the same as NPRM costs. Table VI-50 below shows the basic engine DMC used for this final rule analysis.

[1002] Duleep, K.G., "Review of the Technology Costs and Effectiveness Utilizing in the Proposed SAFE Rule," Final Report, H-D Systems, October 2018, at p. 18-19.

Table VI-50 – Examples of Basic Engine Technology DMC used for the FRM analysis in 2018$,

Engine Technologies – Direct Manufacturer Costs (2018$) for FRM								**Incremental To**
Tech	**Basis**	**Unit DMC**	**DMC for**	**DMC for**	**DMC for**	**DMC for**	**DMC for**

(2) Turbocharged Downsized Engines

DMCs used for the final rule analysis for the turbocharged engine technologies were the same as NPRM costs. When these technologies are applied to V6 and V8 non-turbocharged engines, the incremental I4 and V6 turbocharged costs are applied, respectively. Table VI-53 below shows the DMC used for turbochared technologies for FRM analysis in 2018 dollars.

Table VI-53 – Examples of Turbocharged Downsized Engine DMC used for the FRM in 2018 Dollars

(3) Non-HEV Atkinson and Atkinson Engines

DMCs used for the final rule analysis for HCR0 and HCR1 were based on HCR1 and HCR2 from NPRM, respectively. Discussed in Section VI.C.1.c).(3), the agencies aligned the cost of HCR technologies to align with 2015 NAS effectiveness and costs.

Stakeholders commented on the costs of HCR technology compared to previous analysis. ICCT compared the NPRM costs to EPA's Proposed Determination costs, stating that "[t]his is a clear case where the agencies appear to have not used the best available data from EPA which has extensively analyzed this technology and its associated cost, nor have the agencies justified how they have increased the associated costs, apparently by a factor of three." Similarly, Roush Industries commenting on behalf of CARB stated that the costs for implementing HCR technology were 5-6 times the 2016 Draft TAR estimated costs, which are "extremely high" and "will significantly overstate the incremental cost and bias technology pathways."[1003] HDS also commented that the costs for HCR technology were higher than the costs from the 2016 Draft TAR, and speculated that was due to "the bulky exhaust system used in the Mazda ATK1 engine, which apart from being expensive also requires the vehicle to be modified to accommodate the exhaust system."[1004] HDS cited the 2018 Camry as an example of a vehicle that does not use the same exhaust system, but stated the sources of the new cost data were not documented in the PRIA. ICCT stated that "[t]he agencies should reinstate the better justified and more deeply analyzed original Proposed Determination HCR cost numbers from EPA for this rulemaking."

The NPRM analysis and the final rule analysis used the same DMCs established by the 2015 NAS report for the Atkinson cycle technologies. However, because there are many various engine configurations in the market, the agencies do not use the same fixed costs that were set for each type of vehicle described in the 2015 NAS report, such as pickup and sedan. The agencies have expanded costs by taking into account the type of technology in the baseline, like SGDI, and the configuration of the engine, such as SOHC versus DOHC. In addition, the cost used in the NPRM also included updated dollar year, learning rate, and RPE. Although EPA also used costs from the 2015 NAS report for the Proposed Determination analysis, they used a different approach to account for components.[1005] For the final rule analysis the agencies continued to use the same DMC for HCR technologies. Table VI-56 below shows HCR DMCs used for the final rule analysis in 2018 dollars.

[1003] NHTSA-2018-0067-11984.

[1004] NHTSA-2018-0067-11985.

[1005] EPA PD TSD at 2-307 to 2-308 "Note that the NAS costs include the costs of gasoline direct injection (shown as "DI" in the NAS report row header). EPA has removed those costs (using the NAS reported values) since EPA accounts for those costs separately rather than including them in the Atkinson-2 costs. Note also that EPA always includes costs for direct injection, along with variable valve timing and other costs, when building an Atkinson-2 package."

(4) Advanced Cylinder Deactivation Technologies

DMCs used for the final rule analysis for the advanced cylinder deactivation technologies were the same as NPRM costs.

Roush commented that in the NPRM analysis, the agencies did not properly consider the "very cost-effective benefits of skip-fire technology," referred to in the analysis as ADEAC. Roush stated that "due to extremely high estimated cost ($1,250.00 in MY2016), the benefits of this technology will likely not be chosen in any reasonable technology pathway. If included, the predicted cost for that pathway will be overestimated by $750 - $1,000."[1006] Similarly, Meszler

[1006] Roush at p.13.

commented on the cost for the ADEAC system stating “advanced cylinder deactivation paths are assumed (by NHTSA) to be expensive, and are selected only in rare instances.”[1007] ICCT also stated “The agencies estimated a greatly exaggerated cost of advanced cylinder deactivation for that level of the technology.”[1008]

The agencies do not agree with the commenter’s statement that the analysis did not consider ADEAC as a cost effective technology or that the agencies overestimated costs for the technology. The agencies considered the most up to date information and data for the NPRM and final rule analysis.[1009] The agencies rely on the CAFE model to determine technology cost effectiveness, and if the technology was cost effective for a manufacturer to adopt, then the model would apply it to a manufacturer’s vehicle. The adoption of ADEAC was applied to vehicles with corresponding technology combinations to reflect appropriate cost and effectiveness, as discussed in the paragraph above. The purpose of ADEAC is to reduce pumping losses, but if the engine has been downsized, or has already incorporated technologies that also reduce pumping loss, then it is likely the ADEAC has reached a point of diminishing return. As far as the agencies are aware, Roush did not provide alternative DMCs for ADEAC technology. Table VI-59 below shows the examples of advanced cylinder deactivation DMC used for both naturally aspirated and turbocharged engines for the final rule analysis in 2018 dollars.

(5) Miller Cycle Engines

The agencies estimated costs for Miller cycle engines with VTG from 2016 ICCT-sponsored FEV technology cost assessment report. The agencies considered costs from 2015 NAS study that referenced a NESCCAF 2004 report,[1010,1011] but believed that the reference material from the ICCT report had more updated cost estimates for this technology that represented what was discussed in the NPRM and modeled in the final rule analysis.

NAS estimated the incremental cost for VTG as $525 in 2010$, but this cost assumes many of the traditional turbocharged components and adds VVT, VVL and SGDI. In addition, VTG (Eng23b) and VTGe (Eng23c) engines both have similar modeled BMEP levels and a cooled EGR system to CEGR1 (Eng14), implying that the components such as cooling systems and piping will have similar costs.

The NAS template to calculating the final DMCs for the Miller cycle engines for the different engine configuration is the $525 (2010$) plus cost of cEGR1 minus cost of VVT, VVL, and SGDI. The agencies estimated the cost for electrically-assisted variable supercharger VTGe (Eng23c) engines based on the 2015 NAS study that uses a cost of $1050 (2010$) plus the cost of the mild hybrid battery. For the final rule analysis, the total costs for these technologies are shown below.

[1010] "Reducing Greenhouse Gas Emissions from Light-Duty Motor Vehicles." NESCCAF. September 23, 2004 Report. Available at https://www.nesccaf.org/documents/rpt040923ghglightduty.pdf/. Last accessed Dec. 22, 2019.
[1011] "VGT gasoline turbo, charge air cooler, piston upgrade, piston cooling, steel crankshaft, cooling system upsize, plumbing, rings, pressure sensor & bearing upgrade. Excludes any needed increase in transmission torque capacity or modifications to aftertreatment system." NESCCAF Report comment (2004).

(6) Variable Compression Ratio Engines

DMCs used for the final rule analysis for the VCR engines were based on the 2015 NAS report.[1012] The 2015 NAS reported cost for VCR in MY2025 used a naturally aspirated engine; however, for this final rule analysis the agencies have added cEGR and other engine technologies to the engine. Total costs were updated to reflect 2018 dollars and MY2017 learning rate which is based on the NPRM ADEAC learning rate. Table VI-68 below shows examples of VCR DMCs used for this this final rule analysis in 2018 dollars.

[1012] 2015 NAS at p. 93.

Table VI-68 – Examples of VCR DMCs used for the final rule analysis in 2018$.

Engine Technologies - Direct Manufacturer Costs (2018$) for FRM								Incremental To
Tech	Basis	Unit DMC	DMC for	DMC for	DMC for	DMC for	DMC for

CNG	12,748.76	12,606.09	12,462.91	12,389.57

(9) Engine Lubrication and Friction Reduction Technologies

EFR costs used for the final rule analysis are based on the 2015 NAS assessment for low friction lubrication and engine friction reduction level 2 (LUB2_EFR2). The 2015 NAS report provided estimates of $51 (I4 DOHC), and $72 (V6 SOHC and DOHC) for midsize cars, in 2015 dollars, relative to level 1 engine friction reduction (EFR1), which costs about $12 per cylinder. For this analysis, EFR technologies DMCs are estimated to be $14.05 per cylinder in 2016 dollars. Total costs were updated to reflect 2018 dollars and MY 2017 learning rate. Table VI-75 shows the EFR DMC used for the final rule analysis in 2018 dollars.

Table VI-75 – Example of EFR DMC Used for this Final Rule Analysis in 2018 Dollars.

Engine Technologies - Direct Manufacturer Costs (2018$) for FRM								Incremental To
Tech	**Basis**	**Unit DMC**	**DMC for**	**DMC for**	**DMC for**	**DMC for**	**DMC for**

EFR	99.92	99.92	95.96	88.51

2. Transmission Paths

Transmissions transmit torque from the engine to the wheels. Transmissions primarily use two mechanisms to improve fuel efficiency: (1) a higher gear count, as more gears allow the engine to operate longer at higher efficiency speed-load points; and (2) improvements in friction or shifting efficiency (e.g., improved gears, bearings, seals, and other components), which reduce parasitic losses.

a) Transmission Technologies

There are two major categories of transmission types modeled in the analysis: automatic and manual. Automatic transmissions automatically select and shift between transmission gears for the driver during vehicle operation. The automatic transmission category is further subdivided into four subcategories: traditional automatic transmissions, dual clutch transmissions, continuously variable transmissions, and direct drive transmissions. Manual transmissions require direct control by the driver to select and shift between gears during vehicle operation.

Conventional planetary gear automatic transmissions (AT) are the most popular transmission.[1013] ATs typically contain three or four planetary gear sets that provide the various gear ratios. Gear ratios are selected by activating solenoids which engage or release multiple clutches and brakes as needed. ATs with gear counts ranging from five speeds to ten speeds were considered in the NPRM and final rule analysis.[1014]

ATs are packaged with torque converters, which provide a fluid coupling between the engine and the driveline, and provide a significant increase in launch torque. When transmitting torque through this fluid coupling, energy is lost due to the churning fluid. These losses can be eliminated by engaging the torque convertor clutch to directly connect the engine and transmission ("lockup").

Conventional continuously variable transmissions (CVT) consist of two cone-shaped pulleys, connected with a belt or chain. Moving the pulley halves allows the belt to ride inward or outward radially on each pulley, effectively changing the speed ratio between the pulleys. This ratio change is smooth and continuous, unlike the step changes of other transmission varieties. CVTs were not initially chosen in the fleet modeling for the 2012 rulemaking analysis for MYs 2017 and later because of the predicted low effectiveness associated with CVTs (due to the high internal losses and narrow ratio spans of CVTs in the fleet at that time).[1015] However, improvements in CVTs in the current fleet have increased their effectiveness, leading to increased adoption rates in the fleet. In its 2015 report, the NAS recommended CVTs be added

---

[1013] "The 2018 EPA Automotive Trends Report," https://www.epa.gov/fuel-economy-trends/download-report-co2-and-fuel-economy-trends, Accessed Aug 23, 2019.
[1014] Specifically, the agencies considered five-speed automatic transmissions (AT5), six-speed automatic transmissions (AT6), seven-speed automatic transmission (AT7), eight-speed automatic transmissions (AT8), nine-speed automatic transmissions (AT9), and ten-speed automatic transmissions (AT10).
[1015] Morihiro, S.., "*Fuel Economy Improvement by Transmission*," presented at the CTI Symposium 8th International 2014 Automotive Transmissions, HEV and EV Drives.

to the list of considered technologies. The agencies included CVT technology for the NPRM and this final rule analyses.

Dual clutch transmissions (DCT), like automatic transmissions, automate shift and launch functions. DCTs use separate clutches for even-numbered and odd-numbered gears, allowing the next gear needed to be pre-selected, resulting in faster shifting. The use of multiple clutches in place of a torque converter result in lower parasitic losses than ATs. However, DCTs are seeing limited penetration in the fleet, and because of the low penetration rate, only two DCTs were considered in the analysis.

Direct drive (DD) transmissions are a direct connection between the wheels and a drive motor. In a DD transmission, the ratio between wheel speed and motor speed remains constant. A DD transmission is only used in battery electric vehicles, and in the NPRM the agencies provided the specification for comments.[1016]

Manual transmissions (MT) are transmissions that require direct control by the driver to operate the clutch and shift between gears. Manual transmissions have seen a significant reduction in application by automakers over recent years. As a result of the reduced market presence, only three variants are used in the analysis.

(1) Automatic Transmissions

Conventional planetary automatic transmissions remain the most numerous type of transmission in the light duty fleet. These transmissions will typically contain at least three or four planetary gear sets, which are connected to provide the various gear ratios. Gear ratios are selected by activating solenoids which engage or release multiple clutches and brakes.

Automatic transmissions are packaged with torque converters, which provide a fluid coupling between the engine and the driveline, and provide a significant increase in launch torque. When transmitting torque through this fluid coupling, energy is lost due to the churning fluid. These losses can be eliminated by engaging ("locking up") the torque convertor clutch to directly connect the engine and transmission. A discussion of torque converter lockup is continued in the next section below.

In general, ATs with a greater number of forward gears (and the complementary larger ratio spread) offer more potential for fuel consumption reduction, but at the expense of higher control complexity. Transmissions with a higher number of gears offer a wider speed ratio and more opportunity to operate the engine near its most efficient point.

Aug 21, 2018.

In the 2012 final rule for MYs 2017 and beyond, the agencies limited their consideration of the effect of additional gears to eight-speed transmissions. However, some ATs with more than eight gears are already in production, and more examples are in development. At this time, nine-speed transmissions are being manufactured by ZF [1017] (which produces a FWD nine-speed incorporated into Fiat/Chrysler, Honda, and Jaguar/Land Rover vehicles[1018]) and Mercedes[1019] (which produces a RWD nine-speed). In addition, Ford and General Motors have announced a jointly design and build nine-speed FWD transmissions and ten-speed RWD transmissions (2017 F150 and 2017 Camaro ZL1), and Honda developed a ten-speed FWD transmission.[1020]

Manufacturers have claimed substantial fuel consumption benefits associated with newer transmissions. ZF claims its first generation 8HP can reduce fuel consumption by 6 percent on the NEDC compared to a circa 2005 ZF 6HP, using the same engine, along with improving vehicle acceleration performance.[1021] ZF also outlined a series of potential improvements to the first generation 8HP that could provide an additional 5 to 6 percent fuel consumption reduction on the U.S. combined cycle.[1022] The second generation ZF eight-speed[1023] is expected to achieve up to 3 percent efficiency gain on the NEDC due to the improvements noted above; ZF also outlined additional potential savings associated with a third generation eight-speed transmission.[1024] Likewise, Mercedes clamed a 6.5 percent fuel consumption improvement on the NEDC with its nine-speed transmission compared to the previous seven-speed.[1025] For the references in regards to fuel consumption improvement shown in NEDC, the values will be much higher than U.S, combined cycles due to a gap between NEDC and real-world.[1026]

[1026] ICCT Report. "Real-world vehicle fuel consumption gap in Europe at all-time high." http://www.theicct.org/publications/laboratory-road-2017-update.

In FWD vehicles, ZF claims its nine-speed FWD transmission reduces fuel consumption by 10% – 16% compared to an early- 2000s six-speed transmission.[1027] Aisin claims its new FWD eight-speed transmission decreases fuel consumption 16.5 percent compared to an early generation six-speed, and nearly 10 percent compared to the previous generation six-speed.[1028] In addition, the new eight-speed improves acceleration performance. BMW, using the Aisin FWD transmission, reports a 14 percent fuel consumption reduction on the NEDC over the previous six-speed transmission.[1029] Mercedes claims a total of 6.5 percent fuel economy improvement on the NEDC by using its nine-speed 9G-TRONIC in place of the earlier generation seven-speed.[1030]

These purported efficiency improvements are due to a range of design changes in the transmissions, in addition to improved interactions with complementary equipment. In addition to improving the engine operation efficiency through changing the number of gears, overall ratio, and shift points, these transmissions also reduce parasitic losses, change torque converter behavior, and/or shift to neutral during idle. Due to the complexity of interactions between the transmission and other vehicle technologies, this analysis relies on full vehicle simulations to estimate the effectiveness of additional transmission technology on a vehicle.

With the positive consumer acceptance, higher effectiveness, and increasing production of transmissions with up to ten forward gears, it may be possible that transmissions with even more gears will be designed and built before 2025. Researchers from General Motors have authored a study showing that there is some benefit to be gained from transmissions containing up to 10 speeds.[1031] However, this appears to be near the limit for improved fuel consumption, and studies have shown that there is no added potential for reduction in fuel consumption beyond nine or ten gears.[1032, 1033] In fact, ZF CEO Stefan Sommer has stated that ZF would not design transmissions with more than nine gears - "We came to a limit where we couldn't gain any higher ratios. So, the increase in fuel efficiency is very limited and almost eaten up by adding some weight and friction and even size of the transmission."[1034] Although manufacturers may continue to add gears in response to consumer preference for other performance attributes, this

analysis assumes that it is unlikely that further increases will provide fuel consumption benefits beyond that of optimized eight, nine or ten-speeds.

Development and publications by Aisin AW CO., Honda, Ford, and GM have identified release of new advanced transmissions into the mass market. Aisin AW Co. has introduced a new FWD 8-speed and RWD 10-speed transmission that have shown significant improvements in clutches and brakes, off-axis oil pump, reduction in mass, and increased area of torque converter lock-up area.[1035, 1036] Honda has introduced the first FWD 10-speed automatic transmission. Compared to the previous 6-speed automatic, the 10AT is 22 lbs. lighter and has a 68 percent wider overall ratio range with a 43 percent lower first gear and a 17% percent taller top gear.[1037] Ford and GM has released a jointly developed RWD that has indicated fuel economy improvements over the existing 6-speed transmission.[1038] As discussed in these recent publications, these new transmissions are either replacing first level of 8-speed transmissions or 6-speed transmission in order to improvement fuel economy and performance.

(2) Continuously Variable Transmissions

Conventional continuously variable transmissions consist of two cone-shaped pulleys, connected with a belt or chain. Moving the pulley halves allows the belt to ride inward or outward radially on each pulley, effectively changing the speed ratio between the pulleys. This ratio change is smooth and continuous, unlike the step changes of other transmission varieties. CVTs were not chosen in the fleet modeling for the MY 2017-2025 analysis because of the predicted low effectiveness associated with CVTs (due to the high internal losses and narrow ratio spans of CVTs in the fleet at that time). However, improvements in CVTs in the current fleet have increased their effectiveness, leading to increased adoption rates in the fleet. In their 2015 report, the NAS recommended CVTs be added to the list of considered technologies, and the agencies are accordingly re-evaluating the cost and effectiveness numbers for this analysis.

One advantage of CVTs is that they continue to transmit torque during ratio changes. In ATs and some DCTs, energy from the engine is wasted during a ratio change or shift. ATs and some DCTs have a hesitation during shifts caused by the torque disruption during gear changes. As mentioned above, ATs' efficiency peaks with 9 to 10 gears, while going to a CVT (with an effectively "infinite" number of gear steps) adds a new level of efficiency to the overall system. This is in part due to the fact that CVTs do not need to stop transmitting torque to change ratios.

[1038] http://media.gm.com/media/us/en/gm/home.detail.html/content/Pages/news/us/en/2016/may/0511-10speed-gm.html

Another advantage of a CVT is that, within its ratio range, it can maintain engine operation closer to the maximum efficiency for the required power. CVTs were not considered in the final rule for MYs 2017 and beyond because, at the time, CVTs had a ratio range of near 4.0, limiting the range where the engine operation could be optimized. In addition, the CVTs were less than 80 percent efficient,[1039] and thus required more total output energy from the engine.

However, CVTs have demonstrated some limitations. The launch, acceleration and ratio variation characteristics of powertrains with CVTs may be significantly different than ATs leading to consumer complaints. Several manufacturers have told the agencies that they employ strategies that mimic AT shifting under some conditions for to address these issues. Also, some manufacturers have encountered significant engineering challenges in employing CVTs for use in high torque or high load applications.

Nonetheless, in the recent past, manufacturers and suppliers have intensified development of CVTs, reducing the parasitic losses and increasing the ratio spread. The current generation of CVT is now nearly 85 percent efficient, with ongoing work by suppliers to push that number to 90 percent.[1040] Ratio spreads for CVTs from Honda, Toyota, and JATCO now range between 6.0 and 7.0.[1041, 1042, 1043] JATCO has introduced a very small CVT that has a two speed output with take a CVT with a small ratio spread and doubles it for an overall ratio spread of 7.3[1044] in the base version and 8.7 in the "wide range" version.[1045] As in ATs and DCTs, it is expected that additional increase in ratio range above the current ranges will not significantly decrease fuel consumption and resulting CO_2 emissions.[1046]

Reducing losses in CVTs has been a particular focus of manufacturers. The JATCO CVT8 featured a 40 percent reduction in mechanical losses compared to their earlier generation CVT.[1047] The losses were reduced by decreasing the size of the oil pump, implementing a new, higher efficiency belt, and reducing the fluid churning losses. Honda's new compact car CVT

[1047] Shimokawa, Y. "*Technology Development to Improve JATCO CVT8 Efficiency*," SAE Technical Paper 2013-01-0364, 2013, doi - 10.4271/2013-01-0364.

increased efficiency 1% to 1.5% at higher vehicle speeds compared to their previous generation CVT.[1048] The increased efficiency was primarily due to a reduction in oil pump losses and bearing friction. Honda's new midsize CVT increased efficiency by up to 5 percent compared to the earlier generation CVT, primarily by reducing the required hydraulic pressure (by up to 38%).[1049] Toyota's new K114 CVT reduced torque losses by 22 percent, compared to the earlier generation of CVTs, primarily by reducing the losses associated with the oil pump, and reducing the size of the bearings.[1050]

The JATCO CVT8 demonstrated a 10 percent improvement in fuel economy for both the highway and city cycles compared to earlier generation CVTs.[1051] Honda's new compact car CVT increased fuel economy approximately 7 percent compared to the earlier generation CVT over both the U.S. test cycle and the Japanese JC08 test cycle.[1052] Honda's new midsize CVT increased fuel economy 10 percent over the earlier generation 5AT on the U.S. cycle, and 5 percent compared to the earlier generation CVT on the Japanese JC08 test cycle.[1053] Toyota's new K114 CVT increased fuel economy by 17 percent on the Japanese JC08 test cycle compared to the earlier generation CVT.[1054] Similar to other automatic transmissions, this analysis rely on full-vehicle simulations to consider complex interactions between CVT's and complementary engine and vehicle technologies to assess effectiveness values.

Initial introductions of CVTs suffered from consumer acceptance issues, where customers complained of the "rubber band" feel of the transmission, due to the indirect connection between the driver's throttle input and the vehicle's acceleration response. To combat this perception, vehicle manufacturers have added a shift feel calibration to the CVT control strategy, which mimics the feel of a conventional AT.[1055] This calibration, although having a slight effect on fuel economy, has improved consumer acceptance.[1056]

Nissan continued improving their third generation of The Xtronic CVT with D-Step Logic Control in both performance and fuel economy.[1057] As discussed by Nissan, "In the 2016 Versa and 2016 Sentra models equipped with third-generation XTRONIC transmission, the gear ratio range from low to high is expanded. In fact, the transmission ratio is 7.3:1, which is a broader ratio than you'll find in an average automatic, and far superior to the 6.0:1 you'd find in a similar model vehicle. The CVT is more streamlined, too, as it is 13 percent lighter and 10 percent smaller. The goal is to ensure the fuel efficiency improves at least 10 percent." Nissan's Xtronic CVT has been equipped in all of the passenger and crossover vehicles offered in MY 2016, MY 2017 and MY 2018.

In this document, only conventional belt or chain CVTs are considered. At least two other technologies – toroidal CVTs and Dana's VariGlide® technology[1058] – are under development and may be available in the 2020-2025 timeframe. The Dana VariGlide is considered a CVP (Continuously Variable Planetary), with the major design difference being that it uses balls to transmit torque and vary the ratio.

(3) Dual Clutch Transmissions

Dual clutch transmissions are similar in their basic construction to manual transmissions, but use two coaxial input shafts with two clutches to shift between the two shafts. By simultaneously opening one clutch and closing the other, the DCT "hands off" power from one shaft to the other, and thus to sequential gears. Unlike the MT, the DCT selects the appropriate gear automatically (as in an AT). DCTs offer an efficiency advantage over a typical automatic because their parasitic losses are significantly lower. In addition, DCTs in general do not require a torque converter, as gradually engaging the clutch (much like with a manual transmission) provides the application of launch torque.

Multiple DCTs have been introduced into the marketplace, primarily in six- and seven-speed versions. Volkswagen has used multiple generations of DCTs in their products. Ford has used six-speed DCTs jointly developed with Getrag. Fiat has another version of a six-speed DCT, while both Honda and Hyundai have developed seven-speed versions. Honda introduced an eight-speed DCT with a torque converter on the 2015 Acura TLX.[1059]

However, DCTs have encountered issues with customer acceptance-some so extreme as to prompt vehicle buyback campaigns, and, as the NAS stated in its 2015 report, "are not likely to reach the high penetration rates predicted by EPA/NHTSA ... primarily due to customer acceptance issues."[1060] As noted by the NAS in their 2015 report, "This difference in drivability

---

[1060] NAS (2015), Prepublication Copy, p. 5-7.

and consumer acceptance [between wet and dry clutch DCTs] can be seen in the comparison of two of Volkswagen's MY 2015 vehicles, the VW Golf and the VW Polo. The Golf, with a wet-clutch DCT, has received many positive reviews and awards, while the Polo, with a dry-clutch DCT, has received poor reviews for transmission-related drivability."[1061] The ICCT also commented that DCTs are more difficult to package in a vehicle and the dry clutch is limited by (high) temperature constraints.

Getrag announced the 7DCT300, which has a wet clutch with lubrication on demand, equaling the efficiency of a dry DCT. The wet clutch is also smaller and has a higher tolerance for engine irregularities.[1062] Wet clutch DCTs tend to have better consumer acceptance than dry clutch DCTs. The 7DCT300 is available in Europe on the 2015 Renault Espace.

As in ATs, it is expected that additional gears above the current maximum will not significantly decrease fuel consumption and resulting GHG emissions. A 2012 study by DCT manufacturer Getrag indicated that additional gears above seven and additional ratio spread above 8.5 provided minimal additional fuel economy benefits.[1063]

Generally, DCTs are very cost effective technologies in simulation, but consumer acceptance issues currently limit their appeal in the American market. For these reasons, the agencies limit the application of additional DCT technology to vehicles that already use DCT technology.

(4) Manual Transmissions

In a manual transmission, gear pairs along an output shaft and parallel layshaft are always engaged. Gears are selected via a shift lever, operated by the driver. The lever operates synchronizers, which speed match the output shaft and the selected gear before engaging the gear with the shaft. During shifting operations (and during idle), a clutch between the engine and transmission is disengaged to decouple engine output from the transmission.

As with ATs, the average number of gears in MTs has increased in the MY 2016 analysis fleet, albeit at a reduced rate compared to ATs. As in ATs, the higher number of gears and associated increase in ratio spread increases potential fuel savings.

However, manual transmissions have only a small market share, estimated at only 2.2 percent in MY 2016.[1064] Automatic transmissions (ATs, CVTs, and DCTs) are more popular at least in part because customers prefer not to manually shift gears.

b) Transmission Modeling in the CAFE Model

The NPRM analysis modeled pathways for applying improved technology for each of the transmission categories and subcategories, except for the direct drive, which was only available in the battery electric vehicles. The MT and DCT pathways only included increasing gear counts (e.g. 5-speed manual transmission, 6-speed manual transmission, and 7-speed manual transmission) as improved technologies.

The traditional ATs and CVTs included both increased gear counts and high efficiency gearbox (HEG) technology improvements as options. HEG improvements for transmissions represent incremental advancement in technology that improves efficiency, such as: reduced friction seals, bearings and clutches, super finishing of gearbox parts, and improved lubrication. All these advancements are aimed at reducing frictional and other parasitic loads in transmissions to improve efficiency. Three levels of HEG improvements are considered in this analysis, based on 2015 NAS recommendations and based on CBI data.[1065] HEG efficiency improvements were applied to ATs and CVTs, as those transmissions inherently have higher friction and parasitic loads related to hydraulic control systems and greater component complexity, compared to MTs and DCTs.

In total, 18 unique transmission technology combinations were simulated, using explicit input values for gear ratios, gear efficiencies, gear spans, shift logic, and transmission architecture.[1066,1067] Table VI-78 shows a list of the multi-gear transmissions used for the NPRM.[1068]

[1065] 2015 NAS Report, at 191.

The technologies that made up the four transmission/level paths defined by the modeling system for the NPRM analysis are shown in Figure VI-69. Each vehicle model in the analysis fleet is assigned an initial transmission type and level that most closely matches its configuration and characteristics. The baseline-level technologies (AT5, MT5 and CVT) appear in gray boxes and are only used to represent the initial configuration of a vehicle's transmission in the analysis fleet. Because there are only a few manual transmissions with less than five forward gears in the analysis fleet, for simplicity, all manual transmissions with five forward gears or fewer were designated MT5 for the analysis. Similarly, all automatic transmissions with five forward gears or fewer have been assigned the AT5 technology. For the NPRM analysis, the agencies included a 7-speed automatic and a 9-speed automatic to account for effectiveness of those transmissions in the analysis fleet. These two transmissions were not available for adoption but were available as initial configurations, and appear in gray boxes in Figure VI-69.

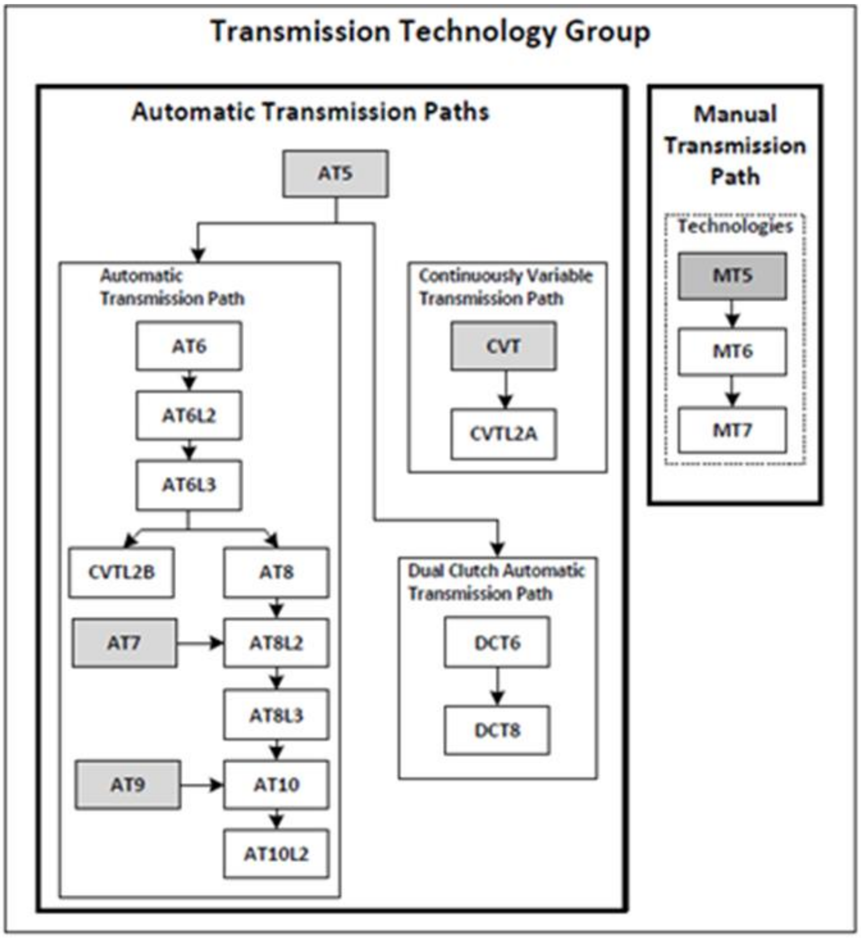

Figure VI-69 – NPRM Transmission Paths

The model generally may apply any of the more efficient transmission technologies that are contained within the pathway of the baseline vehicle initial transmission configuration. The model prohibits manual transmissions from becoming automatic transmissions. Automatic transmissions may become CVT level 2 after progressing though the 6-speed automatic, as shown in Figure VI-69. While the structure of the model could allow automatic transmissions to consider applying a DCT, the market data file was used to preclude the application of DCTs to automatic transmission vehicles, as discussed further in Section VI.C.2.d) Transmission Adoption Features, below.

The model does not attempt to simulate "reversion" to less advanced transmission technologies, such as replacing a 6-speed AT with a DCT and then replacing that DCT with a 10-speed AT. The agencies invited comment on whether the model should be modified to simulate "reversion" and, if so, how this possible behavior might be practicably simulated. Richard Rykowski, supporting comments from the Environmental Defense Fund (EDF), broadly discussed the concept of reversion in the CAFE model, and included an example relating to the transmission technology paths.[1069] Mr. Rykowski stated that it is "possible that the model could add a 10-speed transmission to a vehicle with a very basic engine" and then as the simulation progressed and "the manufacturer required greater fuel or CO_2 emission control, the Volpe Model might move to a TURBO1 or HCR engine" and the vehicle would no longer need the 10-speed transmission to meet standards, and a 6-speed or 8-speed transmission might be more cost effective.

The scenario discussed by Mr. Rykowski is very unlikely. The CAFE model cost optimization algorithm considers both current and future standard requirements when selecting current MY technologies. The algorithm will look multiple years into the future and compare multiple potential technology paths going forward for the most cost-effective path. For a more detailed discussion on the cost optimization algorithm see Section VI.A.4, Compliance Simulation.

Regarding the types of transmission technologies modeled, Meszler Engineering Services provided a comment criticizing the limited number of manual transmission model options and the limited technology paths available to vehicles with manual transmissions.[1070] The agencies do not agree with Meszler Engineering Service's assessment. The manual transmission path includes three model options and allows for the vehicles to receive electrification in the form of SS12V and BISG technologies. The agencies believe the technology paths dedicated to manual transmission was appropriate for vehicles that typically represent manufacturers' specialty performance cars, such as the Subaru STI or BMW M-series, that comprise an overall fleet share of less than 2 percent.

Commenters also discussed potential missing transmission technologies in the NPRM analysis. ICCT stated that the agencies failed to consider transmission warm-up technologies, which are available in 3.7 million new vehicles in the MY 2016 fleet, that are being deployed due to regulatory test-cycle benefits and off-cycle credits.[1071] In addition, the Fiat Chrysler Automobiles (FCA) also expressed concern over the lack of inclusion of thermal bypass devices in the modeling of transmission technologies.[1072]

The agencies agree with parts of ICCT's and the FCAs comments and disagree with other parts. The agencies do agree with ICCT and the Auto Alliance that the analysis should consider the off-cycle benefits of transmission warm-up technology. For the final rule analysis, the agencies applied off-cycle technologies in the CAFE model. For the final rule analysis, the agencies applied off-cycle technologies at the maximum menu regulatory value of 10 g/mile for all manufacturers by MY 2023. The modeled adoption included benefits of transmission warm-

[1071] Comments from ICCT, NPRM Docket No. NHTSA-2018-0067-11741 full comments, at I-28.
[1072] Comments from Fiat Chrysler Automobiles, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11943, at 97.

up as a menu item. The modeling of off-cycle technologies is further discussed in Section VI.C.8. The agencies disagree with ICCT and the Auto Alliance comments that transmission warm-up technologies were not included in the NPRM on-cycle analysis. For the NPRM, and for the final rule, the HEG level 2 technology package includes rapid transmission oil warm-up technology.[1073] The inclusion of the HEG2 technology package in AT and CVT models accounts for impacts of this technology to performance on the standard test-cycle.

For the final rule analysis the transmission model paths are shown in Figure VI-70. For the final rule analysis, the baseline-only technologies (MT5, AT5, AT7L2, AT9L2, and CVT) are grayed and are only used to signify initial vehicle transmission configurations. For simplicity, all manual transmissions with five forward gears or fewer are assigned the MT5 technology in the analysis fleet. Similarly, all automatic transmissions with five forward gears or fewer are assigned the AT5 technology.

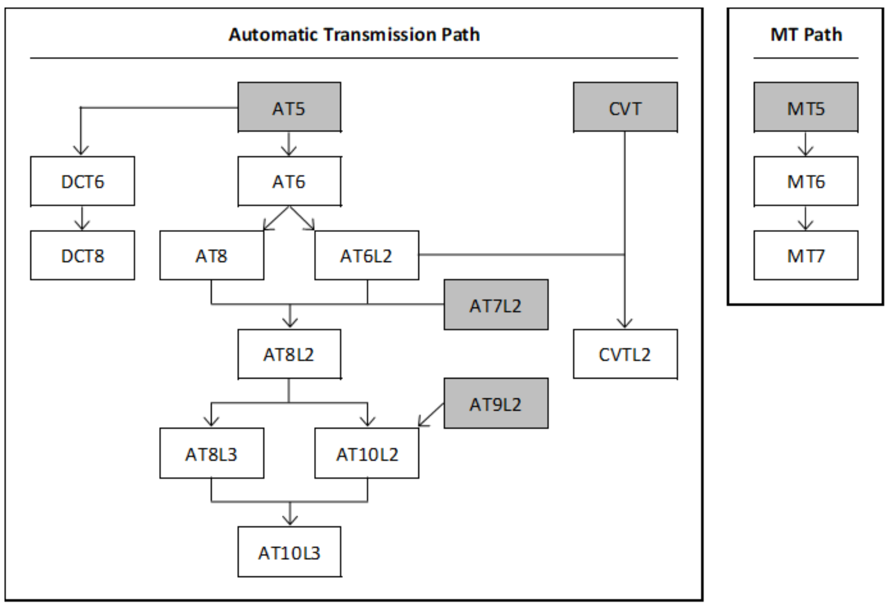

Figure VI-70 – The Transmission CAFE Model Pathways for Transmission Technologies

Since the Manual Transmission path terminates with MT7, the system assumes that all manual transmissions with seven or more gears are mapped to the MT7 technology. Moreover, all dual-clutch (DCT) or auto-manual (AMT) transmissions with five or six forward gears are mapped to the DCT6 technology, and all DCTs or AMTs with seven or more forward gears are mapped to DCT8.

For the final rule analysis, the naming convention for the transmission technology models was updated to identify better the technologies represented in each transmission. Although the technologies in each transmission configuration were described in the NPRM, there appears to

[1073] 2015 NAS Report, at 191.

have been confusion among some commenters about the technology content of some transmission configurations. Some commenters compared the NPRM AT10 to the NPRM AT8, and commented on unexpected differences in effectiveness relative to the differences in transmission gear count.[1074] For the given example, the NPRM AT8 represented a baseline 8-speed automatic transmission, with level 1 HEG technology applied, and the NPRM AT10 represented a 10-speed automatic transmission with level 2 HEG technology applied. A direct comparison of gear count would occur by comparing the NPRM AT8L2 to the NPRM AT10. The updated naming convention identifies the transmission technology type, gear count and HEG technology level. Table VI-79 shows the final rule names for transmission models compared to the names used for the NPRM analysis.

Table VI-79 – NPRM transmission model names versus final rule transmission model names

Transmission	NPRM Name	Final rule Name
5-speed automatic	AT5 / 5AU	AT5
6-speed automatic baseline	AT6 / 6AU	AT6
6-speed automatic level 2 HEG	AT6L2 / 6AUp	AT6L2
7-speed automatic level 2 HEG	AT7 / 7AU	AT7L2
8-speed automatic baseline	AT8 / 8AU	AT8
8-speed automatic level 2 HEG	AT8L2 / 8AUp	AT8L2
8-speed automatic level 3 HEG	AT8L3 / 8AUpp	AT8L3
9-speed automatic level 2 HEG	AT9 / 9AU	AT9L2
10-speed automatic level 2 HEG	AT10 / 10AUp	AT10L2
10-speed automatic level 3 HEG	AT10L2 / 10Upp	AT10L3

8-speed dual-clutch	8DCT	8DCT
Continuous variable transmission	CVT	CVT
Continuous variable transmission level 2HEG	CVTL2A/2B	CVTL2
5-speeed manual transmission	MT5	MT5
6-speed manual transmission	MT6	MT6
7-speed manual transmission	MT7	MT7

c) Transmission Analysis Fleet Assignments

The agencies discussed in the NPRM the process for developing the 2016 analysis fleet, including how the agencies weighed using confidential business information versus publicly-releasable sources, the use of compliance data, and decision to use a 2016 analysis fleet over other alternatives.[1075] As discussed above, this final rule analysis used the 2017 vehicle fleet as the analysis fleet input, and the agencies followed largely the same process for assigning initial transmission assignments as in the NPRM.

[1074] Comments from CARB, Attachment 2018-10-26 FINAL CARB Detailed Comments on SAFE, NPRM Docket No. NHTSA-2018-0067 at 110-13.
[1075] 83 FR 43003.

For the 2017 analysis fleet, transmission data was gathered from the manufacturer final model year CAFE compliance submissions to the agencies as well as manufacturer press releases. The data for each manufacturer was used to determine which platforms shared transmissions and to establish the leader-follower relationships between vehicles. Within each manufacturer fleet, transmissions were assigned unique identification designations based on technology type, drive type, gear count, and technology version. The data were also used to identify the most similar transmission among the Autonomie transmission models, as discussed further below.

The transmission characteristics of vehicles in the analysis fleet show manufacturers use transmissions that are the same or similar on multiple vehicle models. Manufacturers have told the agencies they do this to control component complexity and associated costs for development, manufacturing, assembly, and service. Both the NPRM and final rule analyses account for this sharing. To identify common transmissions, the agencies considered the transmission type (manual, automatic, dual-clutch, continuously variable), number of gears, and vehicle architecture (front-wheel-drive, rear-wheel-drive, all-wheel-drive based on a front-wheel-drive platform, or all-wheel-drive based on a rear-wheel-drive platform). If multiple vehicle models shared these attributes, the transmissions were treated as single group for the analysis. Vehicles in the analysis fleet with the same transmission configuration adopted transmission technology together.

For ATs and CVTs, the identification of the most similar Autonomie transmission model required additional steps beyond just assigning gear count for ATs, or just assigning the CVT model. A review of the age of the transmission design, relative performance versus previous designs, and technologies incorporated was conducted, and the information obtained was used to assign a HEG level. Engineering judgment was used to compare the technologies and performance improvements reported versus descriptions of HEG technology discussed in the NAS report.[1076]

In addition, no automatic transmissions in the 2017 analysis fleet were determined to be initially at a HEG Level 3. However, all 7-speed automatic transmissions, all 9-speed automatic transmissions, all 10-speed automatic transmissions and some 8-speed automatic transmissions were found to be advanced transmissions operating at a Level 2 HEG equivalence. All other transmissions were assigned at the minimum level.

d) Transmission Adoption Features

The agencies included several transmission adoption features in the NPRM that have been carried over for the final rule analysis. For a detailed discussion of path logic applied in the final rule analysis, including technology supersession logic and technology mutual exclusivity logic, please see FRM CAFE Model Documentation Section S4.5, Technology Constraints (Supersession and Mutual Exclusivity).[1077]

[1076] 2015 NAS Report, at 191.
[1077] Available at https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system.

(1) Automatic Transmissions

Automatic transmission technology adoption is defined by path logic and technology availability. The transmission path precludes adoption of other transmission types once a platform progresses past an AT6. This restriction is used to avoid the significant level of stranded capital that could result from adopting a completely different transmission type shortly after adopting an advanced transmission, which would occur if a different transmission type was adopted after AT6 in the rulemaking timeframe. Stranded capital is discussed in more detail in Section VI.B.4.c), Stranded Capital Costs. In addition, any automatic transmissions that use HEG3 technology cannot be phased in until the 2020 model year. The technology phase-in year is based on the estimated availability of HEG3 technology from the NAS (2015) report and confidential data obtained from OEM's and suppliers. Finally, all P2HEVs are paired with an AT8 transmission, which is also discussed further in Section VI.C.3.c).

One commenter expressed concern that all P2HEVs were paired with an AT8 transmission, and argued that the full slate of transmission technology should be available for adoption with that powertrain technology.[1078] The commenter correctly observed a limit of transmission technologies for use only with the P2HEV technology option; all other HEV based technology options did not have this limitation.

The agencies disagree that a greater variety of transmission technologies are necessary to model the P2HEV technology reasonably. The P2HEV demonstrated limited response to transmission technologies beyond the AT8L2, and access to those technologies were limited to reflect the diminishing returns anticipated for higher gear counts used in conjunction with the P2 system, and trends in industry.[1079] Adopting P2HEV to a conventional vehicle provides a significant fuel consumption improvement, agnostic of transmission type, based on the agencies' full vehicle simulation results.

(2) Continuously Variable Transmissions

Application of CVTs in the NPRM and final rule analysis was not allowed for high torque vehicle applications. The launch, acceleration, and ratio variation characteristics of powertrains with CVTs may be significantly different than ATs leading to potential consumer acceptance issues and/or complaints. Several manufacturers have told the agencies that they employ strategies that mimic AT shifting under some conditions to address these issues. Some manufacturers have also encountered significant engineering challenges in employing CVTs for use in high torque or high load applications.

In addition, the CVT adoption was limited by technology path logic. CVTs cannot be adopted by vehicles that do not start with a CVT or by vehicles beyond the AT6 in the baseline fleet which have a greater number of gear ratios and therefore increased ability to operate the

[1079] Greimel, H. "ZF CEO - We're not chasing 10-speeds," Automotive News, November 23, 2014, http://www.autonews.com/article/20141123/OEM10/311249990/zf-ceo:-were-not-chasing-10-speeds.

engine at a highly efficient speed and load. Once on the CVT path the platform is only allowed to apply improved CVT technologies. This restriction is used to avoid the significant level of stranded capital that could result from adopting a completely different transmission type shortly after adopting an advanced transmission, which would occur if a different transmission type was adopted in the rulemaking timeframe. Stranded capital is discussed in more detail in Section VI.B.4.c), Stranded Capital Costs.

The Alliance commented that the analysis "appropriately restricts the application of CVT technology on larger vehicles."[1080] The agencies concurred with the Alliance's observations and thus the limitations on CVT application were continued in the final rule analysis.

(3) Dual Clutch Transmission

For DCTs, while the structure of the model could allow automatic transmissions to consider applying a DCT, the market data file was used to preclude the application of DCTs to vehicles that had already adopted an automatic transmission with six or more gears (e.g., AT6 through AT10). The model allows baseline vehicles that have DCTs to apply an improved DCT (if opportunities to do so exist), and allows vehicles with an AT5 to consider DCTs. This was done to ensure vehicle functionality is maintained as technologies are applied, and accounts for consumer acceptance issues related to the drivability and launch performance tradeoffs. These issues with DCTs resulted in a low relative adoption rate over the last decade.[1081] It also is broadly consistent with manufacturers' technology choices.

(4) Manual Transmissions

Manual transmission technology adoption in the CAFE model remained unchanged from the NPRM and is only limited by the technology path limits discussed above. Manual transmissions cannot be adopted by vehicles that do not start with a manual transmission in the analysis fleet. Vehicles with manual transmissions cannot receive an alternate transmission technology, and may only progress to more advanced manual transmissions. These restrictions are in recognition of the low customer demand for manual transmissions.[1082]

e) Transmission Effectiveness Modeling and Resulting Effectiveness Values

For the NPRM and final rule analysis, full vehicle simulation was used to understand how transmissions work within the full vehicle system to improve fuel economy, and how changes to the transmission subsystem influence the performance of the full vehicle system.

[1080] Comments from Auto Alliance, Attachment 1, NHTSA-2018-0067-12073, at 142.

[1081] "The 2018 EPA Automotive Trends Report," Page 60, figure 4.18, https://www.epa.gov/fuel-economy-trends/download-report-co2-and-fuel-economy-trends, Accessed Aug 23, 2019.

[1082] "The 2018 EPA Automotive Trends Report," https://www.epa.gov/fuel-economy-trends/download-report-co2-and-fuel-economy-trends, Accessed Aug 23, 2019.

The Autonomie tool models transmissions as a sequence of mechanical torque gains. The torque and speed are multiplied and divided, respectively, by the current ratio for the selected operating condition. Furthermore, torque losses corresponding to the torque/speed operating point are subtracted from the torque input. Torque losses are defined based on a three-dimensional efficiency lookup table that has as inputs: input shaft rotational speed, input shaft torque, and operating condition.[1083]

The general transmission models are populated with characteristics data to model specific transmissions. Characteristics data are typically provided in the form of tabulated data for transmission gear ratios, maps for transmission efficiency, and maps for torque converter performance, as applicable. The quantity of data needed depends on the transmission technology being modeled. The characteristics data for these models was collected from peer-reviewed sources, transmission and vehicle testing programs, results from simulating current and future transmission configurations, and confidential data obtained from OEMs and suppliers.[1084]

The level of HEG improvement applied to a given transmission was modeled by improvements made to the efficiency map of the transmission. As an example, the 8-speed automatic transmission models show how a model can be incrementally improved with the addition of the HEG enhancement. The AT8 is the model of a baseline transmission developed from a transmission characterization report.[1085] The AT8L2 has the same gear ratios as the AT8, however the gear efficiency map has been improved to represent application of the HEG level 2 technologies. The AT8L3 models the application of HEG level 3 technologies using the same principle, further improving the gear efficiency map over the AT8L2 improvements.

The NPRM and final rule analysis, using the Autonomie tool, comprehensively simulated each of the 18 transmission technologies. Each transmission was modeled with explicit gear ratios, gear efficiencies, gear spans, adaptive shift logic, and transmission architecture individually for each of the ten vehicle types. The NPRM and final rule analysis clearly showed the specific contributions to effectiveness provided by each transmission technology combination and the associated cost. This provided greater transparency for public review and comment.

The implementation of the full vehicle simulation approach used in the NPRM analysis, and carried forward to the final rule analysis, clearly defines the contribution of individual transmission technologies and separates those contributions from other technologies. This modeling approach comports with the National Academy of Science 2015 recommendation to use full vehicle modeling supported by application of collected improvements at the sub-model

Kim, N., Lohse-Bush, H., Rousseau, A.., "Development of a model of the dual clutch transmission in Autonomie and validation with dynamometer test data," International Journal of Automotive Technologies, March 2014, Volume 15, Issue 2, pp 263-271.

[1085] *See* PRIA Section 6.3.3.2

level.[1086] The approach allows the isolation of technology effects in the analysis which contributes to an accurate cost assessment.

This approach was supported by the Auto Alliance, who commented in support of the agencies' explicit and transparent modeling of the cost and effectiveness for each of the transmission technologies. The Alliance contrasted the NPRM approach with the transmission modeling methodology used in the Proposed Determination—which they strongly objected to—which had lumped together fundamentally different transmission technologies into bundles with identical cost and efficiencies, "making it impossible to fully comprehend the rationale" for the Proposed Determination's high effectiveness estimates.[1087]

However, other stakeholders were not supportive of the modeling approach used in the NPRM. The Union of Concerned Scientists (UCS) thought a level of abstraction was necessary to account for unpredictability in the market, such as the failure of the dual-clutch transmission to reach widespread use as anticipated in the agencies 2012 analysis for MYs 2017 and later. UCS thought that keeping the transmission technology generalized would avoid the pitfalls of potentially picking the wrong technology leader, but would still predict the general trend of behavior, stating that "[i]ncidentally, this is an example of why we supported EPA's move to a more generic representation of transmissions in its OMEGA modeling."[1088]

The agencies disagree with UCS's suggestion to generalize the transmission technology groupings for the analysis. By grouping the technologies into overly broad, generic categories, the analysis loses accuracy on the costs and the effectiveness for specific systems. The OMEGA model used general transmission categories, asked for by UCS's comments, as part of the CO_2 analysis in the Draft TAR and in the Proposed Determination, and the assumptions and limitations were acknowledged at the time.[1089,1090] One assumption used by the OMEGA model approach was "[t]he incremental effectiveness and cost for all automated transmissions are based on data from conventional automatics."[1091] In response, the Alliance observed that the transmission groups used "do not recognize unique efficiencies of different transmission technologies."[1092] At the time EPA stated "the potential effectiveness gains between TRX levels, while arising from different technology packages within each transmission type, will be very

[1091] "Proposed Determination on the Appropriateness of the Model Year 2022-2025 Light-Duty Vehicle Greenhouse Gas Emissions Standards under the Midterm Evaluation, Technical Support Document," Pages 2-327, EPA-420-R-16-021, November 2016.
[1092] "Proposed Determination on the Appropriateness of the Model Year 2022-2025 Light-Duty Vehicle Greenhouse Gas Emissions Standards under the Midterm Evaluation, Technical Support Document," Pages 2-329, EPA-420-R-16-021, November 2016.

similar among the transmission types."[1093] However, as shown in Table VI-98 and Table VI-99, there are nontrivial differences in the costs of different transmission technologies.

The approach used in the NPRM analysis and this final rule analysis is an evolution of the approach used for the Proposed Determination model, and avoids the issue described above. The NPRM and final rule analyses reduce the span of transmission technology groupings, with the intent to provide an increase in fidelity and precision for cost and performance, as was requested by stakeholders such as the Auto Alliance, while including tools to mitigate market effects, which addresses other concerns such as those expressed by UCS. In the analysis for the final rule the transmissions are grouped by technology type (AT, DCT, CVT, etc.) and gear count (5,6,7, etc.). The level of HEG technology applied as a separate factor further subdivided the transmission groups. Defining technology adoption features addresses the potential for market forces, such as those that affected the sales of DCTs, and supports the narrower technology groupings. Technology adoption features are defined through market research, historic and current fleet composition analysis, and dialogue with manufacturers.

Commenters also provided general comments regarding the values of effectiveness for advanced transmissions used for the NPRM analysis versus values used for the Draft TAR. For example, CARB noted a "2 percent-3 percent lower efficiency assumed for advanced 8- and 9-speed transmissions relative to the data EPA itself previously developed with back to back testing on FCA vehicles,"[1094] with similar concerns expressed by other commenters.[1095] Meszler Engineering Services wondered "why the AT10 technology was being so widely adopted when its associated benefits appeared negligible for a particular vehicle" and noted "[t]he wide ranging effectiveness estimates were unexpected."[1096] Senator Tom Carper also noted "the most advanced eight speed transmission technology are assigned unrealistically low fuel efficiency effectiveness values for some vehicle types."[1097]

The Auto Alliance also provided comments with regards to the larger variation of effectiveness values that were of concern to commenters such as Meszler Engineering Services and Senator Tom Carper. The Auto Alliance acknowledged that the use of full vehicle simulation, with more details, results in greater diversity of results. The comment stated, "Over an entire fleet, a more reasonable expectation is that there will be some vehicles with higher fuel economy than expected for a given technology set and some vehicles with a lower fuel economy than expected for a given technology set. As discussed above, these differences arise for a

[1097] Comments from Senator Tom Carper, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11910, at 4.

variety of reasons, and cannot simply be attributed to "less than optimal technology integration."[1098]

The Auto Alliance also specifically commented on the FCA vehicle study used to support CARB's comment and used to generate the TAR analysis values. The Auto Alliance pointed out that the vehicles used in the study had other technology differences, however the study still "proceeds to compare the fuel economy of these variants to assert support for its own estimate of transmission effectiveness. This comparison neglects that the 2.4L engines in these variants are not the same and that the variant with the nine-speed transmission was a redesigned vehicle." The Alliance concluded, therefore, that "the Chrysler 200 comparison provided by H-D Systems does not compare a transmission change in isolation from other changes that impact fuel economy and likely overestimates the benefits associated with the transmission change." The Auto Alliance summarized the analysis of the study by noting that "[s]uch differences also impact fuel economy, confounding an analysis which purports to compare the fuel economy benefits associated directly with the transmission."[1099]

The agencies agree with the Auto Alliance assessment of the 8- and 9-speed FCA vehicles, and have based analysis inputs on alternate information sources.[1100] However, the observations by commenters of a wider range of values for the NPRM effectiveness when compared to the Draft TAR compliance analyses are a direct result of the improvements in modeling approach. As discussed above the NPRM compliance analysis increased the number of transmission technology paths considered by further subdividing the technology groupings. The change resulted in a wider range of effectiveness, as the specific transmission technologies are paired across all the configurations of vehicle technologies. In addition to this greater range, there were also specific effectiveness issues identified for some of the transmission technologies, which are addressed in the sections below.

Commenters may also be observing, with comments like "advanced transmissions have low effectiveness with some vehicles types," an expected effect when an advanced transmission is coupled to an advanced engine. The National Academy of Science, in their 2015 report, noted that "as engines incorporate new technologies to improve fuel consumption, including variable valve timing and lift, direct injection, and turbocharging and downsizing, the benefits of increasing transmission ratios or switching to a CVT diminish."[1101] This is not to say that transmissions are not an important technology going forward, but rather a recognition that advanced engines have larger "islands" of low fuel consumption that rely less on the

[1101] 2015 NAS Report, at 175.

transmission to improve the overall efficiency of the vehicle. Thus, effectiveness percentages reported for transmissions paired with unimproved engines would be expected to be reduced when the same transmission is paired with a more advanced engine.

Commenters also expressed concern for the transmission gear set and final drive values used for the NPRM analysis, or, more specifically, that the gear ratios were held constant across applications. Roush commented that "all transmissions with a given number of ratios (8-speed, 10-speed) maintain the same individual step ratios" and that this would lead to "powertrain inefficiencies and under-predict potential fuel economy benefits."[1102] CARB, quoting a report from its contractor, noted that "the final drive ratio was kept constant as powertrains were changed and that transmission gear ratios were not optimized," and suggested that manufacturers forgoing improvements from gear ratio or final drive ratio changes is unrealistic and results in an underestimation of the benefits from advanced transmissions.[1103]

However, the Auto Alliance stated that "[m]anufacturers share major technologies such as transmissions and engines across multiple vehicle models and platforms." The Auto Alliance also supported the agencies' approach of not including final drive ratio changes, particularly when only minor system changes are incurred. The Auto Alliance continued further stating that "[i]n the case of passenger cars, the final drive ratio is frequently the same across multiple models that use the same transmission."[1104]

The agencies disagree with Roush, Duleep, and CARB's assessment. It is an observable practice in industry to use a common gear set across multiple platforms and applications. The most recent example is the GM 10L90, a 10-speed automatic transmission that used the same gear set in both pick-up truck and passenger car applications.[1105] Optimization of performance is achieved through shift control logic rather than customized hardware for each vehicle line. The use of a single gear set for each transmission technology also supports the overall analysis approach. The level of technology performance modeled must reasonably represent a typical level of performance representative of the industry range of performance. If the systems were over-optimized for the agencies' modeling, such as applying a unique gear set for each individual vehicle configuration, the analysis would likely over-predict the reasonably achievable fuel economy improvement for the technology. Over-prediction would be exaggerated when applied under real-world large-scale manufacturing constraints necessary to achieve the estimated costs for the transmission technologies. Accordingly, the agencies used the NPRM approach for the final rule analysis.

In response to comments related to the effectiveness of micro-HEV systems, which are discussed in Section VI.C.3.d)(2)(a), and comments related to the effectiveness of diesel engines, which are discussed in Section VI.C.1.c)(9), the agencies took a close look at NPRM

effectiveness results. Two issues were identified related to the interaction between Autonomie transmission models and other Autonomie powertrain technology models. First, a logic issue was found in a transmission control subroutine and, second, there was an issue with a sub-model input. While these items were caused by issues in the transmission model sub-systems, the effects manifested in the effectiveness of the micro-HEV systems and the diesel engine systems. Autonomie uses a gearbox transient sub-model to control the simulated state of powertrain components during a transmission event, such as shifting or vehicle starting and stopping. The simulated powertrain component states include conditions such as clutch engagement, or engine operation mode. A detailed discussion of the Autonomie control model can be found FRM Argonne Model Documentation file at Section 4.4. Different versions of the sub-model are used for micro-HEV technologies (12VSS and ISG) than for conventional drivetrains, mild-HEV or Strong-HEV systems.

An issue was found in the control logic used in the micro-HEV version related to the sequence of powertrain component modes during shifting events for automatic transmissions, regenerative braking events for automatic transmissions, and stop start events for manual transmissions. While these issues reduced the effectiveness of the micro-HEV technology in the Argonne modeling results, they had very minimal effect on the overall NPRM Analysis. The control logic issue was resolved for the final rule analysis. There also was an issue with the gearbox transient sub-model used for micro HEVs that impacted calculation of the CVT best efficiency operating ratio targets under low torque conditions. This resulted in some negative effectiveness values for certain CVT technology combinations, but had very minimal effect on the overall NPRM results. This software item was also resolved for the final rule analysis.

As discussed in the Autonomie model documentation, FRM Argonne Model Documentation file at Section 4, the full vehicle model is created from a network of subsystem models. The subsystems all interact through data connections transferring outputs from one subsystem model to the inputs of another. An issue was identified with the definition of the connection between the gearbox transient sub-model for DCT's with diesel engines, which impacted the values provided to the diesel control model. This caused reduced effectiveness values for the diesel engines with DCTs in the Argonne modeling results, however it had very minimal effect on the overall NPRM analysis. The data connection issue was resolved for the final rule analysis.

Lastly, the agencies received several comments on transmission shifting logic, which are addressed in the following section.

(1)　Shift Logic

Transmission shifting logic has a significant impact on vehicle energy consumption and was modeled in Autonomie to maximize the powertrain efficiency while maintaining acceptable drive quality. The logic used in the Autonomie full vehicle modeling relied on two components: (1) the shifting controller, which provides the logic to select appropriate gears during simulation; and (2) the shifting initializer, an algorithm that defines shifting maps (i.e., values of the parameters of the shifting controller) specific to the selected set of modeled vehicle characteristics and modeled powertrain components.[1106]

(a) Shifting Controller

The shift controller is the logic that governs shifting behavior during simulated operation. The shift controller performance was informed by inputs from the model. The inputs included: specific engine or transmission used, and instantaneous conditions in the simulation. Instantaneous conditions included values such as vehicle speed, driver demand and a shifting map unique to the full vehicle configuration.[1107] The shift controller logic was consistently applied for all vehicles simulated.

Although no comments were received specifically on shift control logic, the agencies tracked several effectiveness concerns identified by commenters back to how the agencies modeled some transmissions paired with turbocharged engines. Meszler Engineering Services discussed an unexpected range of effectiveness observed for transmissions when coupled to different engine technologies, and concluded that "[m]oreover, the variation across technology combinations is markedly different."[1108] Senator Carper's comments mirrored Meszler's, noting that "the more expensive version of an engine technology (TURBO2), which would be expected to be more fuel-efficient, was instead assigned a negative fuel-efficiency value for some types of vehicles."[1109] The Senator also observed the same phenomenon for cooled exhaust gas recirculation (CEGR I), which "was assigned a fuel-efficiency effectiveness of at or near zero." Similarly, UCS noted that "many simulations of improved transmissions and turbocharged engines show little incremental improvement over less complex technologies."[1110]

In response to the comments, the agencies conducted an in-depth review of these technology combinations. The agencies determined the minimum lugging speed for turbocharged engines, which controls the minimum engine speed allowed before down-shifting, caused the observed behavior. The issue was isolated to some combinations of advanced transmissions and turbocharged engines. For the final rule analysis, a modification was made to the shift controller logic of transmissions coupled to turbocharged engines. Specifically, the minimum lugging speed allowed for turbocharged engines was increased in the shift controller. An increase in lugging speed increases the minimum speed at which the shift controller will allow the engine to operate before down-shifting, resulting in increased operation in better efficiency regions of the engine map.[1111] The updated lugging speeds are based on Argonne benchmarking data of the 2017 F150.[1112] The updated values are shown in Table VI-80, the

lugging speeds for naturally aspirated engines are shown as reference and remain unchanged from the NPRM.

Table VI-80 – Lugging speeds for transmissions in the final rule analysis

	5-speed	6-speed	7-speed	8-speed	9-speed	10-speed
Naturally Aspirated Lugging speed (rad/s)	140	130	120	110	110	110
Turbocharged Lugging speed (rad/s)	140	130	130	130	130	130

(b) Shift Initializer

As defined above, the shifting initializer is an algorithm that defines shifting maps (i.e., values of the parameters of the shifting controller) specific to the selected set of modeled vehicle characteristics and modeled powertrain components.

Commenters stated that the model did not customize shifting maps for each transmission application. Roush Industries commented, "[t]he 2018 PRIA analysis assumes that all transmissions with a given number of ratios maintain the same individual step ratios and shift maps."[1113] Roush also commented that the effectiveness of transmissions were understated due to inaccurate transmission maps or "the lack of vehicle system optimization and calibration."[1114] UCS stated that the "transmission shift strategy does not deploy gear-skipping or other more modern control strategies."[1115] HDS provided similar comments to Roush, observing that the Autonomie models "do not optimize engine efficiency after most changes in tractive load because the model employs fixed shift points, gear ratios, and axle ratios."[1116] Finally, CARB expressed that "[f]or the Autonomie modeling, a fixed final drive ratio was utilized and, presumably, a fixed shift logic based on the selected transmission."[1117]

The commenters seem to conflate the practice in the analysis of using the same gear sets across vehicle configuration with using the same shift maps. As commenters stated, they assumed the same maps were applied across vehicle models. However, the shift initializer routine was run for every unique Autonomie full vehicle model configuration and generated customized shifting maps. The algorithms' optimization was designed to balance minimization of energy consumption and vehicle performance.[1118] This balance was necessary to achieve the best fuel efficiency while maintaining customer acceptability by meeting performance neutrality requirements, as discussed in Performance Neutrality, Section VI.B.3.a)(6).

[1118] *See* FRM ANL Model Documentation at Paragraph 4.4.5.2.

While discussing shift logic, commenters also expressed concern about the capturing of fuel efficiency losses associated with shifting events. Roush stated, "[t]he 2018 PRIA transmission modeling does not accurately capture the losses and FE penalty associated with a shift event."[1119] The agencies disagree with this statement. While losses associated with a shifting event are not modeled as a single factor, the mechanisms that cause the loss are appropriately incorporated in the Autonomie transmission models. The automatic transmission models have an associated torque converter model.[1120] The torque converter model is designed to simulate the inertial and torque loads imposed on an engine because of shift events. Other clutch-based transmission models, MTs and DCTs, apply a general loss of efficiency across transmission efficiency maps to account for losses due to shift events.

(2) Transmission Effectiveness Values

The NPRM technology effectiveness modeling results showed that the effectiveness of a technology often varies with the type of vehicle and the other technologies that are on the vehicle. Figure VI-71 shows the range of effectiveness for each transmission technology across the range of vehicle types and technology combinations in the NPRM analysis. The data reflect the change in effectiveness for applying each transmission technology by itself while all other technologies are held unchanged. The effectiveness improvement range is over a 5-speed automatic transmission.

[1119] Comments from Roush Industries, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11984, at 14-15.
[1120] *See* FRM ANL Model Documentation at Paragraph 4.5 and Paragraph 5.4.

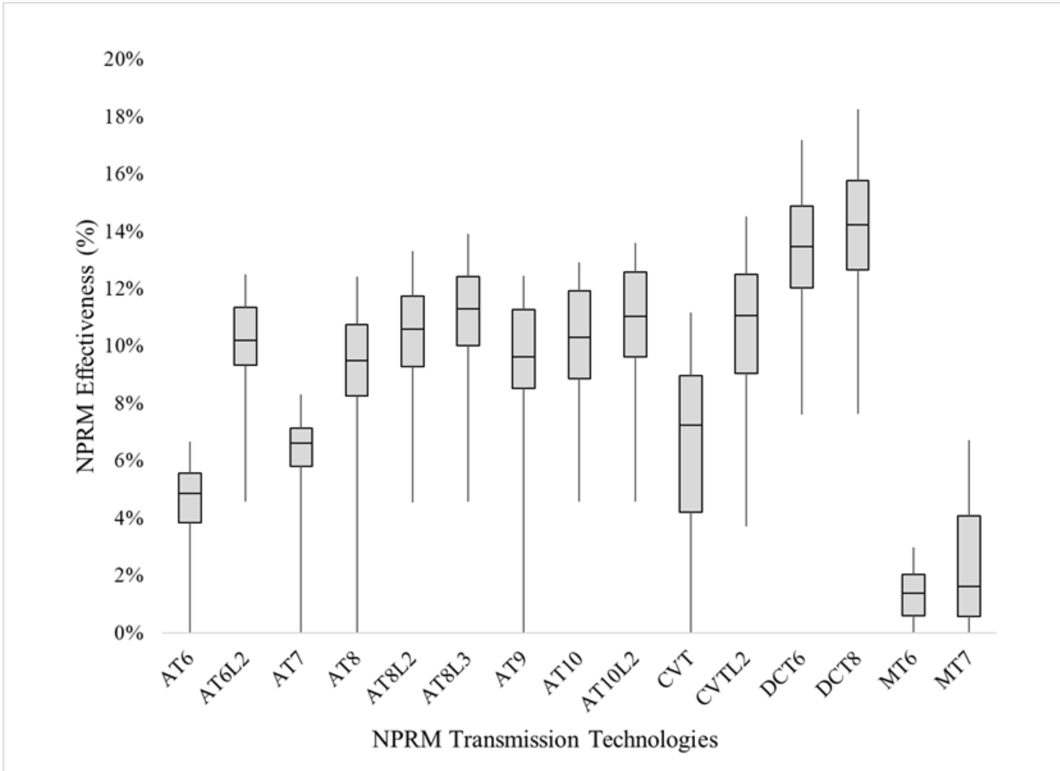

Figure VI-71 – Range of Effectiveness for Transmission Technologies in NPRM Analysis

(a) Automatic Transmissions

Regarding AT effectiveness values, commenters pointed out the unusually high level of effectiveness displayed by the AT6L2 transmission. ICCT and UCS both specifically expressed concern with the effectiveness of the AT6L2 compared to other advanced transmissions.[1121,1122] The performance of the AT6L2 was central to ICCT's analysis of the NPRM inputs, which highlighted the AT6L2 models' performance, showing the cost versus effectiveness of the AT6L2 outperformed more advanced transmission options.[1123]

Evaluation of the AT6L2 transmission model in response to these comments revealed an overestimated efficiency map was developed for the NPRM model. The high level of efficiency

[1121] Comments from International Council on Clean Transportation, Attachment 3, NPRM Docket No. NHTSA-2018-0067-11741, at I-26, I-64 (""However, the impact of adding level 2 transmission efficiency technologies varies wildly and produces absurd results. A 6-speed AT6L2 Is modeled as much more efficient (12.0% improvement) than a comparable 8-speed AT8L2 (9.1%) and even slightly more efficient than a comparable 10-speed AT10L2 (11.5%).")%).".

[1122] Comments from Union of Concerned Scientists, Attachment 1, NPRM Docket No. NHTSA-2018-0067-12039, at 32. ("[I]n the NPRM analysis, 0 percent of vehicles had an AT6L2 transmission while 52.4 percent adopted AT10L2 transmissions, even though the latter supplies virtually identical modeled efficiency.").

[1123] Comments from International Council on Clean Transportation, Attachment 3, NPRM Docket No. NHTSA-2018-0067-11741, at I-64 – I-65.

assigned to the transmission surpassed benchmarked advanced transmissions.[1124] To address the issue, the agencies replaced the effectiveness values of the AT6L2 model for the final rule analysis with AT7L2 effectiveness values.

The updated estimate of effectiveness is supported by values shown in the NAS 2015 analysis.[1125] The study estimated the difference in effectiveness between a 6-speed automatic transmission and a 7-speed automatic transmission of approximately the same technology level to be 0.8 percent. The difference is reduced further when application of high efficiency gear box technology ranges of effectiveness is applied. Because the 7-speed automatic transmission and the advanced 6-speed automatic transmission technologies are parallel on the technology tree, the agencies felt using the same effectiveness value was reasonable and appropriate.

Commenters also pointed out a lack of skip-shift logic used in the NPRM analysis, and an increase in the shift busyness observed for the high gear count transmissions. Roush commented on the NPRM analysis "not incorporating the concept of 'Skip shifting' which is important for reducing shift busyness and increasing FE especially in vehicles equipped with transmission with a large number of ratios (8-10)."[1126] Both CARB and UCS repeated similar concerns.[1127]

After consideration of the comments and re-evaluation of the NPRM results, the agencies concurred with the commenters. The lack of skip-shift logic and increased shift busyness can result in lower overall efficiency and decreased consumer acceptance. For the final rule analysis, a skip-shift logic was applied to the 10 speed automatic transmissions. The logic was based on the baseline 2017 Ford F150 10-speed transmission benchmarking performed by Argonne.[1128] The introduction of the skip-shift logic impacted effectiveness and reduced the number of shifts by 23 percent for the 10-speed automatic transmission over the UDDS cycle.[1129]

In the NPRM analysis, transmission gear spans increased as the number of gears increased.[1130] However, to address further the comments related to optimization, the gear span of the AT10L3 was increased over the AT10L2, based on gear span data for the Honda 2018 10-speed transmission.[1131] The AT10L3 span was increased to 10.10 in the final rule analysis from

7.34 in the NPRM analysis. However, the efficiency map for the AT10L3 remained the same for the final rule analysis.[1132]

Finally, in the agencies' review of NPRM model inputs, a weight discrepancy for the AT10 transmissions was identified. The weight assigned to the AT10 transmission in the NPRM analysis was too high. The weights were corrected for the final rule analysis. The AT10 transmission weights were reduced by 20-45 kg, depending upon vehicle type.[1133]

The AT effectiveness values used for the final rule analysis can be seen in Figure VI-72. For automatic transmission technologies, the effectiveness improvement range is relative to a 5-speed automatic transmission. The new effectiveness values are a result of the aforementioned changes implemented to address comments. To summarize, the changes included an adjustment to the modeled effectiveness of the AT6L2, the use of skip-shift logic on the 10-speed transmissions, and the increase of the AT10L2 gear span.

[1133] *See* FRIA VI.C.2.d.2.

Figure VI-72 shows the automatic transmission's effectiveness increases progressively in a logical order and behaves in an expected manner. Gains in effectiveness can be observed increasing as gear count increases, and as HEG levels increase. The effects of diminishing returns can be observed as gear count reaches higher levels, and effectiveness effects for increased gear count are reduced. This agrees with observed data reported by the NAS and industry stakeholders.[1134,1135]

(i) Gear Ratios and Spans

The gear ratios and gear spans used by the automatic transmission models are shown in Table VI-81. The gear ratios are assigned based on transmission gear count. Development of the gear spans, gear ratio, and final drive ratios are discussed in FRM ANL Model Documentation file at Paragraph 5.3.

Table VI-81 – Gear Ratios and Spans for Automatic Transmission Models

Model Name	**Gear**										**Gear Span**	**Final Drive**
	1	2	3	4	5	6	7	8	9	10		
AT5	3.85	2.3262	1.5039	1.0403	0.77						5	3.31

(iii) Efficiency

A study by ZF suggests that the largest sources of losses over the combined city/highway cycle in conventional automatic transmissions are the oil supply and the drag torque.[1136] This is followed by the creep torque (on the city cycle), with the electrical requirements and gearing efficiency being relatively minor.

For conventional ATs, power required to supply oil to the transmission is one of the largest sources of parasitic loss. An oil pump is required for lubrication and for hydraulic pressure for clamping the clutches. A baseline transmission would typically use a gerotor-type pump driven off the torque converter. Replacing or resizing the oil pump can result in a substantial decrease in torque losses. For example, Aisin claims a 33% reduction in torque loss in its new generation transmission from optimizing the oil pump,[1137] and Mercedes claims a 2.7%

[1136] Dick, A., Greiner, J., Locher, A., & Jauch, F. "Optimization Potential for a State of the Art 8-Speed AT," *SAE Int. J. Passeng. Cars - Mech. Syst.* 6(2):899-907, 2013, doi - 10.4271/2013-01-1272.
[1137] Aoki, T., Kato, H., Kato, N., & Masaru, M. "*The World's First Transverse 8-Speed Automatic Transmission*," SAE Technical Paper 2013-01-1274, 2013, doi - 10.4271/2013-01-1274.

increase in fuel economy on the NEDC by changing the pumping system.[1138] Pump-related losses can be reduced by substituting a more efficient vane pump for the gerotor. Losses can be further reduced with a variable-displacement vane pump, and by reducing the pressure of the system. Losses can be further decreased by using an on-demand electric pump - Mercedes claims an additional 0.8% increase in fuel economy on the NEDC by implementing a lubrication on demand system.[1139] Another way to reduce losses from the pump is by reducing leakage in the system. Reducing leakage reduces parasitic losses by reducing the amount of fluid that needs to be pumped through the system to maintain the needed pressure.

A second large source of parasitic loss in ATs is the drag torque in the transmission from the clutches, brakes, bearings, and seals. These components have the potential to be redesigned for lower frictional losses. New clutch designs offer potential reductions in clutch drag, promising up to a 90% reduction in drag.[1140] Replacing bearings can reduce the associated friction by 50 to 75%. New low-friction seals for can reduce friction by 50% to provide an overall reduction in bearing friction loss of approximately 10%.[1141] Optimizing shift elements improved fuel economy on the Mercedes 9G-TRONIC by 1% over the NEDC.[1142]

Drag torque can be further reduced by decreasing the viscosity of the automatic transmission fluid used to lubricate the transmission. A study of transmission losses indicates that an approximate 2% fuel consumption reduction was obtained on the FTP 75 cycle by switching to the lowest viscosity oil.[1143] However, reduction of transmission fluid viscosity may have an adverse effect on long-term reliability.

Torque converters are typically associated with conventional ATs and CVTs, although they have appeared on Honda's newest eight-speed DCT. Torque converters provide increased torque to the wheels at launch, and serve as a torsional vibration damper at low engine speeds. However, this comes at the cost of energy loss in the torque converter fluid, and modern torque converters typically have a lockup clutch that mechanically locks the impeller and turbine together, bypassing the fluid coupling.

Although in the past torque converters remained unlocked up to high vehicle speeds, recent trends are to lock at much lower speeds. Improvements in torsional vibration dampers, and

"Development of Transmission Fluids Delivering Improved Fuel Efficiency by Mapping Transmission Response to Viscosity and Additive Changes," Presentation at the SAE Transmission & Driveline Symposium, Troy, Michigan, October 16-17. [as cited in NAS (2015), Prepublication Copy, p. 5-25.].

the ability to utilize micro-slip across the lockup clutch has enabled lower lockup speeds. Mazda, for example, claims torque converter lockup as low as 5 mph for its SKYACTIV-Drive AT.[1144] Although not as aggressive, BMW claims a 1% reduction in CO_2 from an early torque converter lockup.[1145]

Based on these considerations efficiency for the automatic transmission was modeled in the following manner.

In the equations below, τ is the normalized torque (Torque/Max rated input torque). In the specific data set that was used to generate these equations, the maximum torque was taken to be 450 Nm.

The maximum efficiency is given by

$$\eta = 100 - 1.385 \times \tau^{-1.0127} \quad (1)$$

The temperature dependence is considered as a function of torque for temperatures ranging from $T = 38\,°C\ to\ T = 93\,°C$:

$$\Delta\eta = 0.3612 \times \tau^{-0.9238} \quad (2)$$

The speed dependence is a function of input torque, for speeds ranging from 500 rpm to 5000 rpm:

$$\Delta\eta = 0.6394 \times \tau^{-1.3068} \quad (3)$$

The efficiency data is generated using the following steps:

- Start with the "maximum efficiency curve," which essentially represents the efficiency for direct drive (1:1 ratio) at 93°C.
- The temperature offset is applied when calculating efficiency at 38°C.
- The speed offset is applied.
- The gear ratio other than the direct drive is scaled.

Figure VI-73 shows the plot of the efficiency for direct drive, for the range of temperatures and speeds considered. For other gears, the results are scaled down by a factor ranging between 0.97 and 1.0.

Table VI-84 summarizes the automatic transmission models selected and efficnecy data source. The efficiency maps used for the automatic transmission models are shown in Figure VI-74 and Figure VI-75. The efficiency model maps are based on transmission test data. [1146]

[1146] EPA contracted with FEV Engine Technologies to test specific transmissions in a transmission component test stand. The testing program was primarily designed to determine transmission efficiency and torque loss over a range of input speeds, input loads, and temperatures. In addition, other driveline parameters, such as transmission rotational inertia and torque converter K-factor were characterized. Two automatic transmissions have been characterized in this test program, the 6T40 GM six-speed automatic transmission and the 845RE FCA eight-speed automatic transmission.

Table VI-84 – Simulation Automatic Transmission Selections[1147]

Simulation Name	Transmission Type	Description/ Source
AT5	5-speed automatic (premium class)	1:1 ratio efficiency from 6AU (premium) and use rule to generate the efficiency for other ratios
AT6	6-speed automatic (base class)	Transmission used for low-torque engines. Source - U.S. EPA test data – GM 6T40
AT6	6-speed automatic (premium class)	Transmission used for high-torque engines Source - NHTSA test data - GM 6L80E
AT6L2	6-speed automatic+	1:1 ratio efficiency from 8AU+ and use rule to generate the efficiency for other ratios
AT7L2	7-speed automatic+	1:1 ratio efficiency from 8AU+ and use rule to generate the efficiency for other ratios
AT8	8-speed automatic	Source - U.S. EPA test data – Ram 845RE
AT8L2	8-speed automatic+	845RE (8AU) with improved efficiency (NHTSA data)
AT8L3	8-speed automatic++	845RE (8AU) with improved efficiency (NHTSA data)
AT9L2	9-speed automatic+	1:1 ratio efficiency from 8AU+ and use rule to generate the efficiency for other ratios
AT10L2	10-speed automatic+	1:1 ratio efficiency from 8AU+ and use rule to generate the efficiency for other ratios
AT10L3	10-speed automatic++	1:1 ratio efficiency from 8AU++ and use rule to generate the efficiency for other ratios

(b) Continuously Variable Transmissions

For CVTs, the agencies also identified a discrepancy with the NPRM CVT weights. The weight assigned to the CVT class during the NPRM analysis was incorrect. Corrected values were assigned for the final rule analysis. The CVT weights were reduced by 9-10 kg based on vehicle type.[1148]

The CVT effectiveness values used for the final rule analysis can be seen in Figure VI-76, shown as an effectiveness improvement over a 5-speed automatic transmission. The effectiveness values were not changed significantly from the values used in the NPRM analysis.

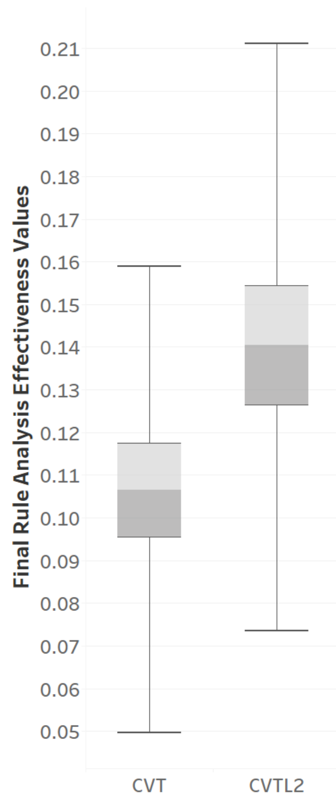

Figure VI-76 – Effectiveness of Continuously Variable Transmissions for Final Rule Analysis

(i) Gear Spans

The gear spans used by the continuously variable transmission models are shown in Table VI-85. Development of the gear spans, and final drive ratios are discussed in FRM ANL Model Documentation file at Paragraph 5.3.

Table VI-85 - Gear Spans for Continuously Variable Transmission Models

Model Name	Gear	Gear Span	Final Drive
CVT	Ratios from 0.529 to 3.172		4.44

[1148] *See* FRIA VI.C.2.d.2.

Model Name	Gear	Gear Span	Final Drive
CVTL2	Ratios from 0.45 to 3.6		4.44

(ii) Gear Box and Final Drive Weight

The weights assigned for the continuously variable transmission models are shown in Table VI-86 and Table VI-87. The weights are developed from a review of the A2Mac1 database (A2Mac1, 2018). The distribution analysis and weight selection are discussed in the ANL Model Documentation file Paragraph 5.3.3.

(iii) Efficiency

CVTs tend to have higher losses than either ATs or DCTs, in large part due to the high oil pressures required to keep the belt and pulleys securely clamped. These losses increase significantly at high input torques, as even higher pressures are required to maintain the clamping force.[1149]

A study by JATCO suggests that losses in the CVT are dominated by oil pump torque and losses in the belt-pulley system, with fluid churning losses as the next largest player.[1150] By

[1149] NAS (2015), Prepublication Copy, p. 5-27.
[1150] Shimokawa, Y. "*Technology Development to Improve JATCO CVT8 Efficiency*," SAE Technical Paper 2013-01-0364, 2013, doi - 10.4271/2013-01-0364.

reducing leakage in the oil system and reducing line pressure when possible, JATCO's CVT8 was able to run with a reduced size oil pump and considerable reduction in oil pump torque loss. JATCO also redesigned the belt for lower loss, and reduced the oil level and viscosity to reduce churning losses. The overall result was a 40 percent reduction in mechanical losses compared to the earlier generation CVT.

Honda developed a new CVT using a comparable strategy.[1151] They decreased the required pulley thrust by refining the control strategy and by using a fluid with increased coefficient of friction, which combined for a transmission efficiency increase of 2.8 percent. They also altered the belt trajectory around the pulley for an added 0.4 percent efficiency increase.

Table VI-88 summarizes the continuously variable transmission models selected, and source of efficiency data. Figure VI-77shows the component efficiency maps used for the baseline CVT. Figure VI-78 shows the component efficiency maps used for the advanced CVT.

(iii) Efficiency

Advanced DCTs typically have lower losses than ATs, largely due to having an on-demand pump, splash lubrication, and fewer open clutches. The primary losses in DCTs are load-independent drag and splash losses. Unlike ATs, DCTs typically depend on splash lubrication for their internal components rather than forced lubrication. This eliminates the losses associated with oil supply pumps, but adds churning losses due to rotating components moving through the oil. Churning losses can be minimized by keeping oil levels low and warming up the lubrication oil.

A primary consideration in DCT losses is the use of wet or dry clutches.[1153] Dry clutches do not require oil cooling flow, and therefore do not contribute to oil churning losses that are incurred with wet clutch systems; this has traditionally meant that dry clutch reduced fuel consumption by an additional 0.5 to 1% over wet clutch DCTs. However, dry clutches have a limited maximum torque capacity, and have suffered from customer acceptance issues.

Based on these considerations efficiency for the dual clutch transmissions were modeled in the following manner.

[1153] NAS (2015), Prepublication Copy, p. 5-28.

The efficiency of the DCT is broken down into a speed-dependent term (spin loss) and a load dependent term (gear train mechanical efficiency).

For the speed-dependent part, the turning torque (Nm) is given by the following equations through curve fit as a function of the overall gear ratio R:

- @ 93°C, 500 rpm
  - $T = 4.89 \times \left(\frac{1}{R}\right)^2 + 0.135 \times \left(\frac{1}{R}\right) + 0.21 \qquad (1)$
- @ 93°C, 5000 rpm
  - $T = 23.5 \times \left(\frac{1}{R}\right)^2 + 1.4 \times \left(\frac{1}{R}\right) + 1.7 \qquad (2)$

The turning torque is approximately linear between 500 rpm and 5000 rpm.

The gear mechanical efficiency is very high, and can be assumed to be in the range of 99% to 99.5% per gear mesh. The mesh efficiency is higher when the meshing gears are of similar size.

The efficiency data set is based on a DCT with a rated input torque of up to 250 Nm s and generated by the following steps:

- The torque loss is subtracted from the input torque.
- The additional torque loss due to constant mechanical efficiency is calculated by multiplying the difference between the input torque and the torque loss by (1 - efficiency).
- The efficiency is calculated by taking the sum of the (spin) torque loss and the loss due to mechanical efficiency and dividing it by the input torque.

Table VI-92 summarizes the dual clutch models selected, and source of efficiency data. The efficiency maps used for the dual clutch transmission models are shown in Figure VI-80.

Table VI-92 – NPRM DCT selection

Midsize SUV	35	35	35
Pickup	60	65	65

(iii) Efficiency

Manual transmissions are in general lighter, cheaper to manufacture, and have lower parasitic losses than automatic transmissions. The 2015 NAS report found the overall energy loss in a manual transmission to be approximately 4%, as compared to a 13% loss in automatic transmissions.[1155]

Table VI-96 summarizes the manual transmission models selected, and source of efficiency data. The manual transmission models used the same efficiency calculation rules as the dual clutch transmissions.The efficiency maps used for the manual transmission models are shown in Figure VI-82.

Table VI-96 – NPRM Manual Transmission Selection

Simulation Name	Transmission Type	Description/ Source
5DM	5-speed manual	1:1 ratio efficiency from 6DCT and use rule to generate the efficiency for other ratios
6DM	6-speed manual	1:1 ratio efficiency from 6DCT and use rule to generate the efficiency for other ratios
7DM	7-speed manual (premium class)	1:1 ratio efficiency from 6DCT and use rule to generate the efficiency for other ratios

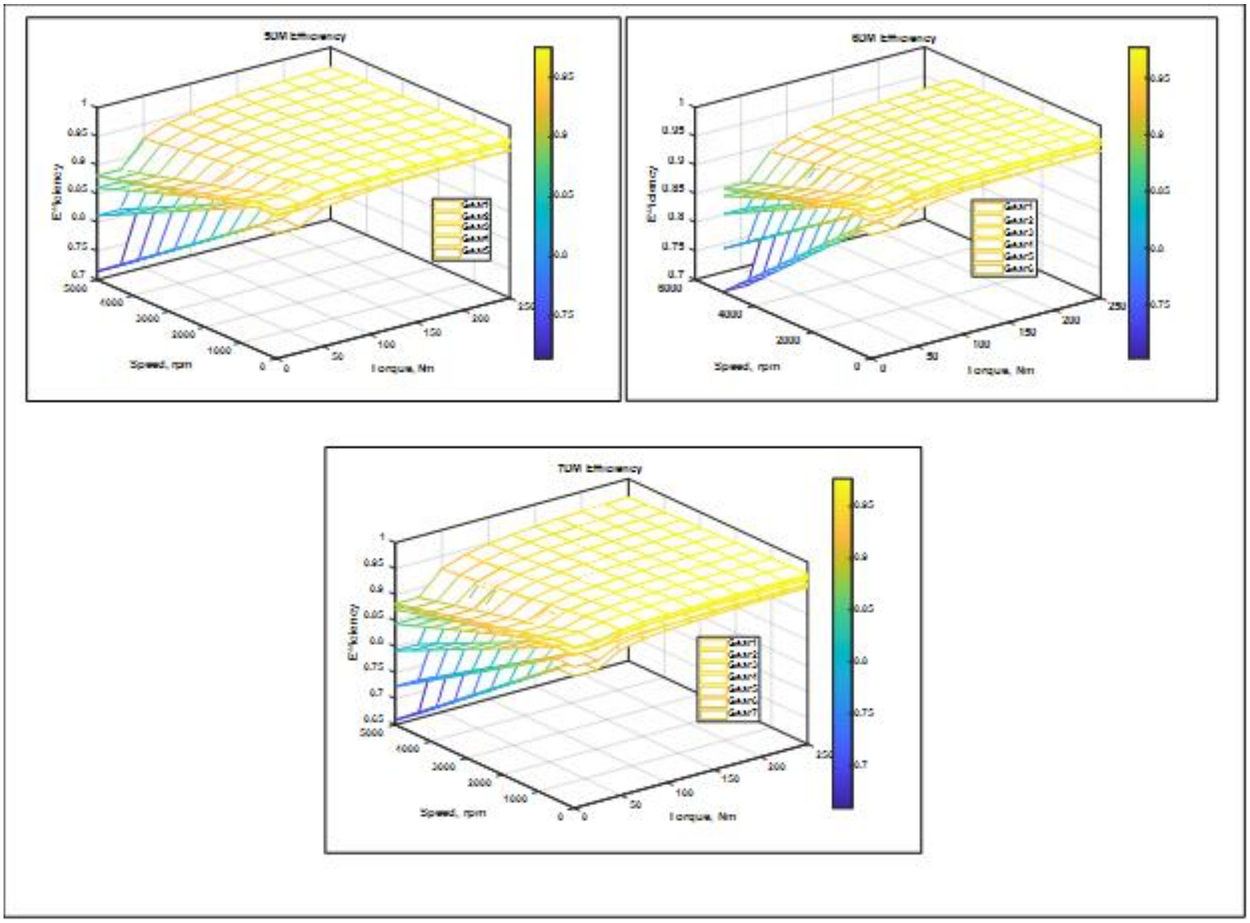

Figure VI-82 – Manual Transmission Model Efficiency Maps for 5 speed, 6 speed and 7 speed Transmissions

f) Transmission Costs

For the NPRM, the transmission technology costs used as inputs for the CAFE model were retail price equivalent costs with learning curves applied. For a complete discussion on how the retail price equivalent and learning effects were applied to direct manufacturing costs see Section VI.B.4.b), Indirect Costs, and Section VI.B.4.d), Cost Learning. The direct manufacturing costs for the transmission technologies used in the NPRM were derived from technical sources and manufacturer's CBI.[1156]

Table VI-97 below shows the relative costs of the transmissions used in the NPRM analysis including learning and retail price equivalent.

[1156] *See* PRIA Section 6.3.7.3.

Table VI-97 – Summary of Relative Transmission Technology Cost vs. Basic Transmission, including Learning Effects and Retail Price Equivalent used in NPRM

Name	Technology Pathway	C-2017	C-2021	C-2025	C-2029
MT5	Manual Transmission	$ -	$ -	$ -	$ -
MT6	Manual Transmission	$ 359.92	$ 346.99	$ 338.66	$ 333.62
MT7	Manual Transmission	$ 760.72	$ 596.88	$ 514.71	$ 460.49
AT5	Automatic Transmission	$ -	$ -	$ -	$ -

DCT8	Sequential Transmission	$ 693.34	$ 692.36	$ 691.62	$ 691.47
CVT	CVT	$ 246.08	$ 235.16	$ 227.62	$ 221.79
CVTL2A	CVT	$ 430.97	$ 411.83	$ 398.64	$ 388.43

(1) Automatic Transmissions

Several comments were received on technology costs, or cost effectiveness. Meszler Engineering Services noted that "AT10L2 (level 2 ten-speed automatic) transmission technology is another example of an end-of-path technology with very poor cost effectiveness relative to other transmission options."[1157] A cost analysis by ICCT also showed relative costs of transmission technologies may not be in line with the modeled effectiveness.[1158]

The agencies conducted a review of transmission costs in response to the comments. For the final rule analysis, adjustments were made to costs of the AT6L2, AT7L2, AT9L2, AT10L2, and the AT10L3. The costs were adjusted based on reviewing the recommended relative costs discussed in the NAS 2015 report. Table VI-98 shows the cost for the automatic transmissions in the final rule analysis.

The direct manufacturing cost (DMC) estimate for the AT6 is drawn from Table 5.7 of the NAS report. The DMC estimate for the AT6L2 is based on the cost of the AT6 with HEG

[1157] Comments from Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA-2018-0067-11723, at 33.
[1158] Comments from International Council on Clean Transportation, Attachment 3, NPRM Docket No. NHTSA-2018-0067-11741, at I-64.

level 2 technology costs applied. This cost change is applied in accordance with the effectiveness adjustment made for the AT6L2.

A DMC estimate for the AT7 was drawn from Table 5.9 of the NAS report and was based on the cost of a system already equipped with HEG technology. The DMC estimate was given in 2007 dollars and relative to an AT5/AT4. The new DMC replaces the DMC from the NPRM, which did not account for the HEG technology.

The DMC for the AT9 technology was drawn from Table 8A.2a of the NAS (2015) report and per the NPRM description of the technology made relative to the AT8L2. The AT9 is assumed to have at least the level 2 HEG technology applied. The NPRM analysis assumed the AT9 cost was only relative to the AT8 and did not account for the cost of the HEG technology.

The DMC for the AT10 technologies was drawn from Table 8A.2a of the NAS report and per the NPRM description of the technology made relative to the AT8L2. The AT10L2 is assumed to have at least the level 2 HEG technology applied. The AT10L3 has the HEG3 technology applied. The NPRM analysis assumed the AT10 costs were only relative to the AT8 and did not account for the cost of the HEG technology.

Table VI-98 – Summary of Absolute Automatic Transmission Technology Cost, including Learning Effects and Retail Price Equivalent for the Final Rule Analysis for the Final Rule Analysis

Name	Technology Pathway	C-2017	C-2021	C-2025	C-2029
AT5	Automatic Transmission	$ 2,085.30	$ 2,085.30	$ 2,085.30	$ 2,085.30
AT6	Automatic Transmission	$ 2,063.19	$ 2,063.19	$ 2,063.19	$ 2,063.19
AT6L2	Automatic Transmission	$ 2,397.50	$ 2,323.16	$ 2,303.65	$ 2,294.85

AT8L3	Automatic Transmission	$ 2,787.99	$ 2,631.74	$ 2,590.74	$ 2,572.25
AT9L2	Automatic Transmission	$ 2,659.49	$ 2,531.80	$ 2,498.29	$ 2,483.17
AT10L2	Automatic Transmission	$ 2,659.49	$ 2,531.80	$ 2,498.29	$ 2,483.17
AT10L3	Automatic Transmission	$ 2,917.97	$ 2,737.81	$ 2,684.21	$ 2,662.29

(2) Continuously Variable Transmissions

No adjustments were made to the NPRM costs of the CVT technologies for the final rule analysis. Table VI-99 shows the cost for the CVTs in the final rule analysis.

Table VI-99 – Summary of Absolute Transmission Cost, including Learning Effects and Retail Price Equivalent for the Final Rule Analysis

Name	Technology Pathway	C-2017	C-2021	C-2025	C-2029
CVT	CVT	$ 2,341.87	$ 2,330.48	$ 2,322.63	$ 2,3165.55
CVTL2	CVT	$ 2,534.64	$ 2,514.69	$ 2,500.94	$ 2,490.29

(3) Dual Clutch Transmissions

The agencies received one comment on cost learning over time for DCT technologies. Roush Industries "believes that the [actual] learning factors for such systems are significantly better than those estimated by either the 2018 PRIA or the 2016 Draft TAR." Roush stated that "eight-speed DCTs (DCT8) are currently in production (MY2018), with quantities increasing significantly,"[1159] but provided no specific supporting data.

The current learning curve for the DCT technologies was established based on recommendations from the NAS 2015 report and on CBI data collected from manufacturers and suppliers. Since Roush did not supply any data to support its comment, the agencies decided it was reasonable to make no change to the DCT learning curve for the final rule analysis. Table VI-100 shows the cost for the DCTs in the final rule analysis.

Table VI-100 – Summary of Absolute Transmission Cost, including Learning Effects and Retail Price Equivalent for the Final Rule Analysis

Name	Technology Pathway	C-2017	C-2021	C-2025	C-2029
DCT6	Sequential Transmission	$ 2,115.92	$ 2,115.88	$ 2,115.84	$ 2,115.84
DCT8	Sequential Transmission	$ 2,654.56	$ 2,653.75	$ 2,653.15	$ 2,653.02

(4) Manual Transmissions

No adjustments were made to the NPRM costs of the manual transmission technologies for the final rule analysis. Table VI-101 shows the cost for the MTs in the final rule analysis.

Table VI-101 – Summary of Absolute Transmission Cost, including Learning Effects and Retail Price Equivalent for the Final Rule Analysis

Name	Technology Pathway	C-2017	C-2021	C-2025	C-2029
MT5	Manual Transmission	$ 1,563.97	$ 1,563.97	$ 1,563.97	$ 1,563.97
MT6	Manual Transmission	$ 1,939.24	$ 1,925.76	$ 1,917.08	$ 1,911.82
MT7	Manual Transmission	$ 2,357.13	$ 2,186.30	$ 2,100.64	$ 2,044.10

[1159] Comments from Roush Industries, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11984, at 14-15.

3. Electric Paths

The electric paths include a large set of technologies that share the common element of using electrical power for certain vehicle functions that were traditionally powered mechanically by engine power. Electrification technologies thus can range from electrification of specific accessories (for example, electric power steering to reduce engine loads by eliminating parasitic loss) to electrification of the entire powertrain (as in the case of a battery electric vehicle).

Electrified vehicles are considered, for this analysis, to mean vehicles with a fully or partly electrified powertrain. These include several electrified vehicle categories, including: battery electric vehicles (BEVs), which have an all-electric powertrain and use only batteries for propulsion energy; plug-in hybrid electric vehicles (PHEVs), which have a primarily electric powertrain and use a combination of batteries and an engine for propulsion energy; and hybrid electric vehicles (HEVs), which use electrical components and a battery to manage power flows and assist the engine for improved efficiency and/or performance. HEVs are further divided into strong hybrids (including P2 and power-split hybrids) that provide strong electrical assist and in many cases, can support a limited amount of all-electric propulsion, and mild hybrids (such as belt integrated starter generator (BISG) hybrids, crankshaft integrated starter generator (CISG) hybrids, and 48V mild hybrids) that typically provide only engine on/off with minimum electrical assist.

Fuel cell electric vehicles (FCEVs) are also another form of electrified vehicle having a fully electric powertrain, and are distinguished by the use of a fuel cell system rather than grid power as the primary energy source.

The factors that influence the cost and effectiveness of electrification technologies are their components. These include: energy storage components such as battery packs; propulsion components such as electric motors; and power electronics components, such as inverters and controllers, that process and route electric power between the energy storage and propulsion components. For the purpose of this analysis, these components are divided into battery components and non-battery components.

Battery components strongly influence the cost of electrified vehicles.[1160] Because developments in battery technology may apply to more than one category of electrified vehicles, they are discussed collectively in Section VI.C.3.e). That section details battery-related topics that directly affect the specification and costing of batteries for all types of electrified vehicles considered in this analysis.

Non-battery components also have an influence on both the cost and effectiveness of electrified vehicles. The selection and configuration of non-battery technologies distinguish the different architecture among electrified vehicles. Non-battery components largely consist of propulsion components and power electronics.

[1160] Battery costs are not necessarily a strong influence on fuel Cell Electric Vehicles, where the cost of the fuel cell technology has a larger influence.

Propulsion components typically include one or more electric machines (an umbrella term that includes what are commonly known as motors, generators, and motor/generators). Depending on how they are employed in the design of a vehicle, electric machines commonly act as motors to provide propulsion, and/or act as generators to enable regenerative braking and conversion of mechanical energy to electrical energy for storage in the battery.

"Power electronics" refers to the various components that control or route power between the battery system and the propulsion components, and includes components such as: motor controllers, which issue complex commands to control torque and speed of the propulsion components precisely; inverters and rectifiers, which convert and manage DC and AC power flows between the battery and the propulsion components; onboard battery chargers, for charging the BEV or PHEV battery from AC line power; and DC-to-DC converters that are sometimes needed to allow DC components of different voltages to work together.

Onboard chargers are charging devices permanently installed in electrified vehicles to allow charging from grid electrical power. Onboard chargers travel with the vehicle and are distinct from stationary charging equipment. Level 1 charging refers to charging powered by a standard household 110-120V AC power outlet. Level 2 charging refers to charging at 220-240V AC power.

The agencies included a more extensive overview of charging technology and the state of charging infrastructure in the NPRM and PRIA, however, this was purely qualitative because charging was not accounted for in any respect in the NPRM analysis. The Alliance commented that "[w]hile the costs of installing chargers and charger convenience were not taken into account within the Volpe model…these factors will continue to have an impact on the overall penetration of electrification technologies that the market will be willing to accept."[1161] In contrast, the National Coalition for Advanced Transportation (NCAT) commented that the qualitative discussion overstated the risks and understated the benefits of electric vehicle charging.[1162] Specifically, NCAT took issue with the characterization of potential risks of charging to the electric grid, stating that "the PRIA's focus on worst case hypotheticals does not reflect the current capabilities of the grid, nor the dynamic nature of EV charging to mitigate any potential negative impacts. In both in the short-term and long-term, the impact of EVs with respect to the electric grid would have a net-positive impact to society, including the EV owners and utility customers broadly." NCAT also commented that "[w]hile substantial investments in EV infrastructure have and will be made, the costs and benefits to consumers must be put into the appropriate context." NCAT cited two studies for the proposition that the average lifetime distribution electric vehicle infrastructure impact is about $80-$90 per electric vehicle sold, with the adoption of time of use rates and assuming a diversity of charging rates. NCAT also cited the California Public Utilities Commission 2016-2017 Electric Vehicle Load Research Report in support of their statement that the additional service and distribution system upgrades due to additional plug-in electric vehicle load is minimal, as "of the approximately 275,000 [electric]

[1161] NHTSA-2018-0067-12073.
[1162] NHTSA-2018-0067-11969.

vehicles estimated to be on the road as of October 2017 in the service areas of California's three investor-owned utilities, only 460, or 0.16 percent required a service line or distribution system upgrade solely to support the plug-in electric vehicle load at their residential charging location."[1163]

The agencies agree that adding electric vehicle infrastructure will require additional costs, and information about what that cost is and how it can or should be accounted for in the analysis is helpful for commenters to submit in order to put those considerations in the appropriate context. For this final rule, the agencies did not incorporate any costs related to electric vehicle charging infrastructure in the technology compliance analysis because those costs are separate from the costs that manufacturers and consumers would directly incur from a manufacturer transitioning part of their fleet to plug-in electric vehicles and consumers paying for those vehicles, even though local electric ratepayers will in all likelihood pay higher rates to upgrade local power grids to accommodate any widespread adoption of electrified vehicles. Accordingly, this means that the actual costs associated with electrified vehicles have been underestimated for the final rule analysis. The agencies did refine the estimates for the value of refueling time for electric vehicles, and that topic is discussed in Section VI.D.1.b)(11). The agencies will continue to explore whether and how charging infrastructure should be incorporated into the analysis for future actions.

The following sections discuss vehicle electrification issues that were accounted for in the analysis, including the agencies' characterizations of electric vehicle technology, additional electric vehicle configurations added for the final rule analysis per commenters' requests, and the sources and methods used to develop battery and non-battery components, which were also refined for this final rule.

a) Electrification Modeling in the CAFE Model

A set of technologies was chosen to represent the spectrum of electrification methods observed in the baseline fleet and that the agencies believed could be applied to vehicles in the rulemaking timeframe. Each technology was placed in a specific electrification pathway, grouping and defining the progression of related technologies. In the NPRM analysis, a total of eleven electrification technologies were contained in four electrification pathways. In consideration of comments received, the electrification technologies and associated pathways were modified for the final rule analysis, resulting in a total of eighteen variants of electrification technologies. Each of these NPRM and final rule technologies, and the electrification pathways they belong to, are detailed below. Operational modes of electrified vehicles are further described in the Argonne Model Documentation for the final rule.

[1163] Citing Joint IOU Electric Vehicle Load Research Report (December 29, 2017), pp. 1-2, 12, available at http://www.cpuc.ca.gov/zev/ (2016-2017 Load Research Report).

(1) Electrification Technologies

(a) Electric Improvements

The electrification of power steering (EPS) and other accessories (IACC) have the potential of reducing fuel consumption by facilitating power-saving control strategies that avoid parasitic loss of engine power. These accessories traditionally are directly coupled to and driven by the conventional combustion engine; any time the engine is running some energy is continuously consumed by each accessory, even when it is not needed. By decoupling these accessories from the engine and instead driving them "on-demand" with electric motors, a more energy-efficient control strategy can be employed to reduce fuel consumption. EPS and IACC are discussed in detail in Section VI.C.7, Other Vehicle Technologies.

(b) Micro Hybrid

12-volt stop-start (SS12V), sometimes referred to as start-stop, idle-stop or 12-volt micro hybrid, is the most basic hybrid system that facilitates idle-stop capability. In this system, the integrated starter generator is coupled to the internal combustion (IC) engine. When the vehicle comes to an idle-stop the IC engine completely shuts off and, with the help of 12-volt battery, the engine cranks and starts again in response to throttle to move the vehicle, or release of the brake pedal. The 12-volt battery used for the start-stop system is an improved unit capable of higher power, increased life cycle, and capable of minimizing voltage drop on restart. This technology is beneficial to reduce fuel consumption and emissions when the vehicle frequently stops, such as in city driving conditions or in stop and go traffic, and can be applied to all vehicle technology classes.

(c) Mild Hybrids

The belt integrated starter generator (BISG) and crank integrated starter generator (CISG), sometimes referred to as mild hybrid systems, provide idle-stop capability and use a higher voltage battery with increased energy capacity over typical automotive batteries. The higher voltage allows the use of a smaller, more powerful and efficient electric motor/generator, which replaces the standard alternator. In BISG systems, the motor/generator is coupled to the engine via belt (similar to a standard alternator), while the CISG integrates it to the crankshaft between the engine and transmission; both of these systems allow the engine to be automatically turned off as soon as the vehicle comes to a full stop. In addition, these motor/generators can recover braking energy while the vehicle slows down (regenerative braking) and in turn can propel the vehicle at the beginning of launch, allowing the engine to be restarted later. Some limited electric assist is also provided during acceleration to improve engine efficiency. The CISG system has a higher efficiency, but also higher cost than the BISG.

The agencies received limited high-level comments on CISG systems, with CARB stating that CISG systems are generally considered more capable and more efficient relative to BISG systems because they do not have the same belt-related constraints including maximum torque limitations, load restrictions on the front crank to avoid uneven crankshaft bearing wear, and mechanical energy transfer losses.[1164] CARB also noted that the decision to implement a CISG system is typically made early in the design process because doing so often requires an engine block casting change. CARB stated that the current high costs and larger dimensions, compared to BISGs, will likely delay major market penetration of CISG systems until beyond the MY 2025 timeframe.

For the final rule analysis, the agencies did not include CISG systems. The effectiveness of CISG systems were similar to the BISG, and the high cost of the CISG caused it to be applied infrequently. Other packaging and integration issues make it difficult for most vehicles to adopt CISG technology. Typically, a manufacturer would have to modify the flywheel housing to allow the installation of an electric motor, which must also fit where the system is mounted between the transmission and the engine block. Space in that part of the vehicle also comes at a premium because other components such as exhaust systems and piping systems must also be housed in the same area. In the final rule analysis, all vehicles previously considered to possess CISG technology were instead assigned a BISG system.

(d) Strong Hybrids

A hybrid vehicle is a vehicle that combines two or more sources of propulsion energy, where one uses a consumable fuel (like gasoline), and one is rechargeable (during operation, or by another energy source). Hybrids reduce fuel consumption through three major mechanisms, including (1) potential engine downsizing, (2) optimizing the performance of the engine to operate at the most efficient operating point and under some conditions storing excess energy such as by charging the battery, and (3) capturing energy during braking and some decelerations that might otherwise be lost to the braking system and using the stored energy to provide launch assist, coasting, and propulsion during stop and go traffic conditions. The effectiveness of the hybrid systems depends on how the above factors are balanced, taking into account complementary equipment and vehicle application. For some performance vehicles, the hybrid technologies are used for performance improvement without any engine downsizing.

The NPRM analysis evaluated the following strong hybrid vehicles: hybrids with “P2” parallel drivetrain architecture (SHEVP2),[1165] and hybrids with power-split architecture (SHEVPS). The parallel hybrid drivetrain, although enhanced by the electric portion, remains fundamentally similar to a conventional powertrain. In contrast, the power-split hybrid drivetrain is novel and considerably different than a conventional powertrain. Although these hybrid architectures are quite different, both types provide start-stop or idle-stop functionality, regenerative braking capability, and vehicle launch assist. A SHEVPS has a higher potential for fuel economy improvement than a SHEVP2, although its cost is also higher.

[1164] Roush Industries on behalf of California Air Resources Board, Rogers_Final_Final_NPRM_10.26.2018, Docket No. NHTSA-2018-0067-11984, at 15.
[1165] Depending on the location of electric machine (motor with or without inverter), the parallel hybrid technologies are classified as P0–motor located at the primary side of the engine, P1–motor located at the flywheel side of the engine, P2–motor located between engine and transmission, P3–motor located at the transmission output, and P4–motor located on the axle.

Power-split hybrid (SHEVPS) is a hybrid electric drive system that replaces the traditional transmission with a single planetary gear set (the power-split device) and a motor/generator. This motor/generator uses the engine either to charge the battery or to supply additional power to the drive motor. A second, more powerful motor/generator is permanently connected to the vehicle's final drive and always turns with the wheels. The planetary gear splits engine power between the first motor/generator and the drive motor either to charge the battery or to supply power to the wheels. During vehicle launch, or when the battery state of charge (SOC) is high, the engine, which is not as efficient as the electric drive, is turned off and the electric machine propels the vehicle. During normal driving, the engine output is used both to propel the vehicle and to generate electricity. The electricity generated can be stored in the battery and/or used to drive the electric machine. During heavy acceleration, both the engine and electric machine (by consuming battery energy) work together to propel the vehicle. When braking, the electric machine acts as a generator to convert the kinetic energy of the vehicle into electricity to charge the battery.

The Autonomie simulations assumed all SHEVPS' used an Atkinson cycle engine (Eng26). Therefore, all vehicles equipped with SHEVPS technology in the CAFE model simulations were assumed to have Atkinson cycle engines. This Atkinson cycle engine with high compression ratio is optimized for efficiency, rather than performance. Accordingly, SHEVPS technology as modeled in this analysis was not suitable for large vehicles that must handle high loads.[1166] Further discussion of Atkinson engines and their capabilities is discussed in Section VI.C.1 Engine Paths.

P2 parallel hybrids (SHEVP2) are a type of hybrid vehicle that uses a transmission-integrated electric motor placed between the engine and a gearbox or CVT, with a clutch that allows decoupling of the motor/transmission from the engine. Although similar to the configuration of the CISG system discussed previously, a P2 hybrid would typically be equipped with a larger electric machine and battery in comparison to the CISG. Disengaging the clutch allows all-electric operation and more efficient brake-energy recovery. Engaging the clutch allows efficient coupling of the engine and electric motor and, when combined with a transmission, reduces gear-train losses relative to power-split or 2-mode hybrid systems. P2 hybrid systems typically rely on the internal combustion engine to deliver high, sustained power levels. Only low and medium power demands are allowed for electric-only mode.

In the NPRM CAFE modeling, the SHEVP2 system represented a hybrid system paired with an existing engine on a given vehicle, while the SHEVPS removed and replaced the previous engine with an Atkinson cycle engine. The agencies explained that while many vehicles may use HCR1 engines as part of a hybrid powertrain, HCR1 engines may not be suitable for some vehicles, such as high performance vehicles or vehicles designed to carry or tow large loads (this is further discussed in Section VI.C.1, Engine Paths). Many manufacturers may prefer turbocharged engines (with high specific power output) for P2 hybrid systems, in

---

[1166] Kapadia, J., Kok, D., Jennings, M., Kuang, M. et al., "Powersplit or Parallel - Selecting the Right Hybrid Architecture," SAE Int. J. Alt. Power. 6(1):68-76, 2017, https://doi.org/10.4271/2017-01-1154.

order to maintain performance. Accordingly, in the NPRM analysis, to satisfy power demands, many SHEVP2 systems were paired with non-HCR powertrains.

ICCT and Meszler Engineering Services commented that as a result of NPRM CAFE model constraints, low-cost, HCR engines were too infrequently paired with SHEVP2 technology. These commenters claimed that frequent pairing of SHEVP2 with downsized turbocharged engines resulted in higher cost and lower effectiveness for these strong hybrids.[1167,1168]

In consideration of these comments, the final rule analysis includes additional strong hybrids (P2HCR0, P2HCR1, and P2HCR2[1169]) that use HCR engines in a P2 parallel hybrid system. The SHEVP2 technology allows the engine type to be inherited from the outgoing engine; this is unchanged from the NPRM and provides a good solution for vehicles that need to undergo hybridization but require other engine technologies (such as turbocharging) to meet performance requirements. In addition, this final rule analysis allows any conventional engine technology to go to P2HCR strong hybrid technology within the set performance requirements. This is further discussed in the Section VI.C.3.c), Electrification Adoption Features.

(e) Plug-in Hybrids

Plug-in hybrid electric vehicles (PHEV) are hybrid electric vehicles with the means to charge their battery packs from an outside source of electricity (usually the electric grid). These vehicles have larger battery packs with more energy storage and a greater capability to be discharged than other non-plug-in hybrid electric vehicles. PHEVs also generally use a control system that allows the battery pack to be substantially depleted under electric-only or blended mechanical/electric operation and batteries that can be cycled in charge-sustaining operation at a lower state of charge than is typical of other hybrid electric vehicles. These vehicles generally have a greater all-electric range than the typical SHEVs discussed above. In the NPRM analysis, PHEVs with two all-electric ranges—a 30 mile and a 50 mile all-electric range (AER)—were included as technologies that vehicles could adopt. The PHEV30 represented a "blended-type" plug-in hybrid, which can operate in all-electric (engine off) mode only at light loads and low speeds, and must blend electric machine and engine power together to propel the vehicle at medium or high loads and speeds. The PHEV50 represented an extended range electric vehicle (EREV), which is capable of travelling in all-electric mode even at higher speeds and loads.

Unlike other alternative fuel systems that require specific infrastructure for refueling or recharging (e.g., hydrogen vehicles or rapidly charged battery electric vehicles), PHEV batteries can be charged using existing infrastructure, although widespread adoption may require upgrades to electrical power distribution systems.[1170] PHEVs are considerably more expensive than

[1168] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-25.
[1169] P2HCR2 was included in simulations used for sensitivity studies, but was excluded in the central analysis simulations for reasons surrounding the HCR2 engine, as discussed in Section VI.C.1.
[1170] See above for a discussion of electrical vehicle infrastructure.

conventional vehicles and more expensive than SHEVPS technologies because of larger battery packs and charging systems capable of connecting to the electric grid.

Commenters, such as CARB, stated that in the NPRM analysis the PHEV motors were oversized and overpowered, and that model-built PHEV30s have excessive battery pack size and electric range when compared to actual production vehicles.[1171] In response to such comments, the agencies, in collaboration with Argonne, conducted further market study to confirm CARB's observations and determined that replacing PHEV30 (with a nominal 30 mile AER) with PHEV20 (with a nominal 20 mile AER) would more closely characterize the PHEVs actually in production.[1172] The agencies therefore elected to replace PHEV30 with PHEV20 in the final rule.

The final rule also includes four additional types of plug-in hybrids; two additional plug-in hybrids were added to allow the use of turbocharged engines (PHEV20T, PHEV50T), and two additional plug-in hybrids were added to provide maximum efficiency by utilizing an Atkinson cycle engine (PHEV20H, PHEV50H).

In practice, many PHEVs recently introduced in the marketplace use turbocharged engines in the PHEV system, and this is particularly true for PHEVs produced by European manufacturers and for other PHEV performance vehicle applications. However, the NPRM Autonomie simulations (and thus all the CAFE model simulations) assumed all PHEVs used a naturally aspirated, Atkinson cycle engine. The agencies determined through continued marketplace observation that PHEV vehicles should indeed be allowed to adopt or retain turbocharged engines. Also, BorgWarner commented that modeling of PHEVs should include turbocharged engines, since these engines can be downsized to reduce vehicle mass and fit into smaller engine compartments, and offer efficiency and performance advantages especially when paired with a higher expansion ratio.[1173] Thus, in addition to the PHEV20 and PHEV30, the final rule analysis included PHEV20T and PHEV50T variations which are, respectively, 20 and 50 mile all electric range PHEVs with turbocharged engines.

This final rule also added PHEV20H and PHEV50H, although effectively these are not used by the model simulations. These plug-in types represent 20 and 50 mile all electric range plug-in hybrids that use particularly efficient high-compression, Atkinson cycle engines. These were added with the intent to provide PHEVs with a maximum level of fuel economy at a lower cost. However, they proved to be too similar to existing plug-in technology choices and were thus assigned identical characteristics as the PHEV20 and PHEV50. In this final rule analysis, PHEV20 and PHEV50 sizing were updated and so the similarities in performance between different engines converged. For further discussion on PHEV sizing, see Section VI.C.3.d),

Electrification Effectiveness Modeling and resulting Effectiveness values.[1174] The PHEV20H and PHEV50H technologies are still considered by the CAFE model but they remain as "placeholders" for potential incorporation in future analyses.

(f) Battery Electric Vehicles

Electric vehicles (EVs), or battery electric vehicles (BEVs) are equipped with all-electric drive and with systems powered by energy-optimized batteries charged primarily from grid electricity. The range of a battery electric vehicle depends on the vehicle's class and the battery pack size. The NPRM analysis included BEVs with a range of 200 miles.

Following the NPRM, the agencies conducted continued market analysis of production BEVs, and observed a growing number of vehicles with nominal ranges above 200 miles. CARB also commented that certain BEVs modeled as BEV200 in the NPRM in fact had "well over 200 miles of range."[1175] The agencies thus concluded that a 300-mile-range BEV300 should be included in the final rule to represent better these higher-range electric vehicles as well as a potential future range alternative more comparable to IC engines. The agencies still believe that, in the rulemaking timeframe, BEV300 will be the most cost effective extended range BEVs that could be available for adoption. Longer-range electric vehicles could have been modeled in the analysis, but the compliance simulation would likely not have selected the longer-range vehicle if lower-range vehicles were still available. This is because the CAFE model only applies technologies until a manufacturer meets its CAFE or CO_2 standard, and the BEV200 and BEV300 vehicles operate functionally the same in helping a manufacturer towards meeting its compliance obligations. The only difference between these vehicles is cost. As discussed further in Section VI.C.3.c), the agencies used phase-in caps to control expected BEV200 and BEV300 penetration based on the current trend and future assumption that consumers will transition towards longer-range electric vehicles.

(g) Fuel Cell Vehicles

Fuel cell electric vehicles (FCEVs or FCVs) utilize a full electric drive platform but consume hydrogen fuel to generate electricity in an onboard fuel cell. Fuel cells are electrochemical devices that directly convert reactants (hydrogen and oxygen via air) into electricity, with the potential of achieving more than twice the efficiency of conventional internal combustion engines. High pressure gaseous hydrogen storage tanks are used by most automakers for FCEVs. These high-pressure tanks are similar to those used for compressed gas

---

[1174] This final rule analysis used Atkinson Engine for PHEVPS electrified vehicles. The components such as electric motor and engine power in these hybrid systems were sized in ways to meet vehicle class performance characteristics and efficiency. And after these vehicle components were sized, the Atkinson engines in these vehicles were operating in similar efficiency as HCR engines as the full vehicle modeling and simulation. As discussed in PO 06 C.1.c.1 Non-HEV Atkinson Engine Modes, power-split hybrid-based Atkinson engines attempt to operate in the most efficient regions while using electric motors to meet deficiencies in performance. And so, PHEV20H and PHEV50H HCR engines compared to PHEV20 and PHEV50 Atkinsons engines would have be sized to operate in the most efficiency regions and the thermal efficiency between these two set of combinations would have had similar efficiency for this analysis.

[1175] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 147.

storage in more than 10 million CNG vehicles worldwide, except that they are designed to operate at a higher pressure (350 bar or 700 bar vs. 250 bar for CNG), and to contain the very small, and very flammable, gaseous hydrogen molecule. FCEVs are currently produced in limited numbers and are available in limited geographic areas.

(2) Electrification Pathways

The electrification technologies described above were applied in the CAFE model through a number of technological pathways. Three main electrification technology pathways were modeled: the Electric Improvements Path, the Electrification Path, and the Hybrid/Electric Path. These three electrification pathways are evaluated in parallel by the CAFE model; the model can consider any of the three right away, and does not need to go "through" one pathway in order to begin evaluating another. Any superseded technology is also disabled whenever a succeeding technology is applied to a vehicle, even if a specific superseded technology was not previously utilized on that vehicle. As previously explained, this requirement exists so that the modeling system does not downgrade technologies during analysis.

The Electrics Improvements Path defined in the NPRM and final rule is shown in Figure VI-83 below, which starts with EPS and progresses to IACC. While these two electrified-accessory technologies are mutually exclusive, either one can be modularly paired with any other technology, including those in the other electrification pathways.

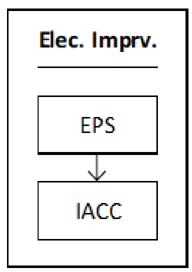

Figure VI-83 – NPRM and FRM Electrics Improvement Path

The Electrification Path shown in Figure VI-83 allows a conventional powertrain to become a micro-hybrid with SS12V, or a mild hybrid with BISG, or CISG (which is no longer available for the final rule analysis, as discussed previously) technologies. All three of the Electrification Path technologies are mutually exclusive with respect to all conventional powertrain technologies, as well as technologies contained in the Hybrid/Electric path discussed below. The model first evaluates SS12V, and then progresses to BISG or CISG (NPRM-only). The conventional engine technology CONV is grayed out to indicate that the model uses information about the previous conventional (non-electrified) powertrain to map properly to simulation results found in the vehicle simulation database. Although the adoption of these technologies will classify a vehicle as a micro/mild hybrid (MHEV) and no longer a conventional (CONV), the vehicle is allowed to retain the engine and transmission technologies possessed before entering the Electrification Path.

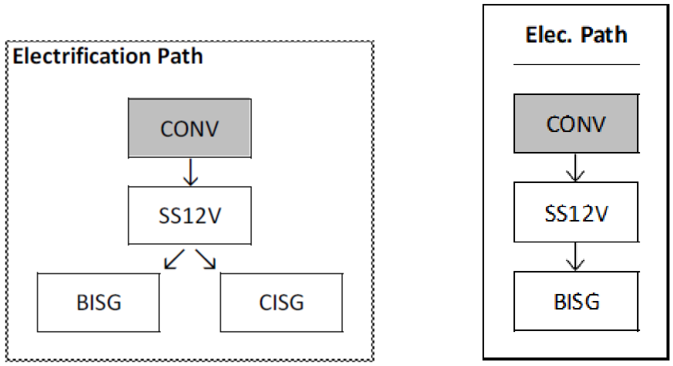

Figure VI-84 – NPRM (Left) and Final Rule (Right) Electrification Pathways

The Hybrid/Electric Pathways are shown in Figure VI-84. Both the NPRM and final rule Hybrid/Electric paths begin at the "strong hybrid" technology types, each of which is mutually exclusive of the others; once one is chosen, the other is eliminated from future selection for that vehicle. The paths then progress into plug-in hybrids and then culminate with the mutually exclusive battery electric vehicles or fuel cell vehicles. The additional final rule technologies described above can be found in the final rule Hybrid/Electric pathway on the right side of Figure VI-85, in comparison to the NPRM technologies shown on the left side of the figure.[1176] The hybrid/electric pathways contains multiple "roots," or starting points, which force a vehicle to remain within the branches of a chosen root. For example, the final rule hybrid/electric pathway has three roots: SHEVP2, SHEVPS, and P2HCR0. If a vehicle uses SHEVPS, then SHEVP2 technology and the entire P2HCR0 through PHEV50H branch will be disabled from further consideration. In other words, from one technology in the pathway, a vehicle can only move forward along any of the indicated arrows, and never in the reverse direction. Also, when using any technology in the Hybrid/Electric pathway, with the exception of SHEVP2, all engine and transmission technologies as well as the Electrification Path technologies shown in Figure VI-85 are prohibited. SHEVP2 is an exception because it allows engine technologies previously held by the vehicle to be inherited into the parallel hybrid system.

[1176] Note that the NPRM Hybrid/Electric Path (left side of **Error! Reference source not found.**) refers to a portion o f the path containing plug-in hybrids and electric vehicles as the "Advanced Hybrid/Electric Path." For this discussion, we will simply refer to the entire collection of these technologies, including the "Advanced" technologies, as the "Hybrid/Electric Path."

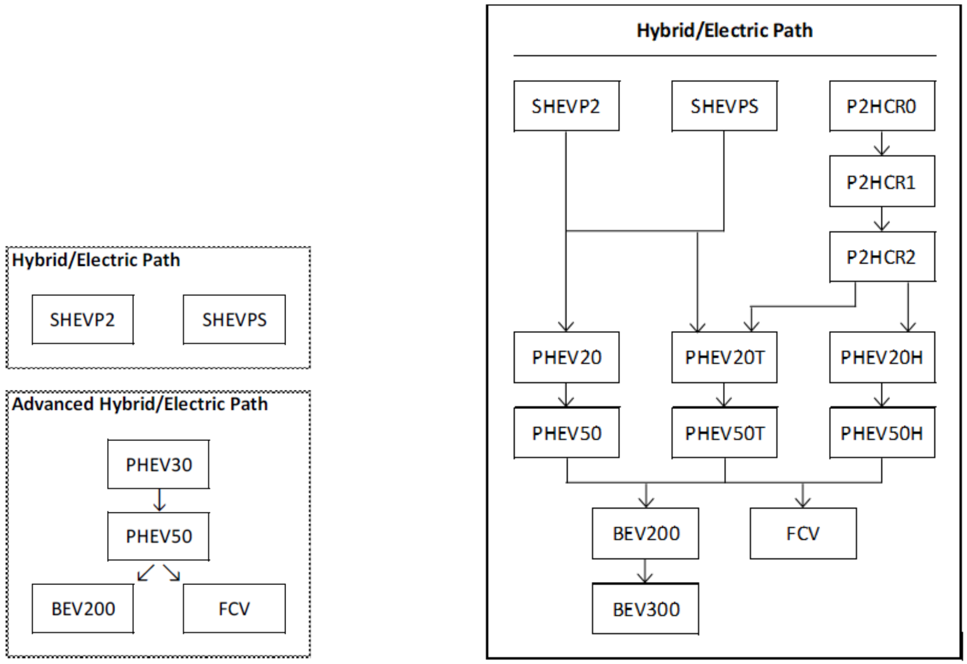

Figure VI-85 – NPRM (Left) and Final Rule (Right) Hybrid/Electric Pathways

b) Electrification Analysis Fleet Assignments

Since the 2012 rulemaking, manufacturers have implemented a number of powertrain electrification technologies, including 48V mild hybrid, strong HEV, PHEV, and BEV powertrains.[1177,1178] For the NPRM analysis, the agencies identified the specific electrification technologies in each vehicle model in the MY 2016 analysis fleet, and used those technology levels as the starting point for the regulatory analysis. The agencies assigned electrification technology levels based on manufacturer-submitted CAFE compliance information, vehicle technical specifications released publicly by manufacturers, agency-sponsored vehicle benchmarking studies, technical publications, and manufacturer CBI.[1179] For the final rule analysis, the agencies used a similar process and data sources to identify the electrification technologies in the MY 2017 analysis fleet.[1180]

The agencies received comments regarding the application of electrification technologies in the MY 2016 analysis fleet. Commenters, such as the California Air Resources Board, stated the agencies mischaracterized some hybrid technologies, such as power-split and P2 hybrid

[1180] FRM Market Data central analysis input file.

architectures.[1181] Specifically CARB was concerned about the "misclassification of the 2016 Chevrolet Malibu Hybrid as having a P2 hybrid," noting the Malibu shared many of its drivetrain components with the 2016 Chevy Volt, a vehicle classified as a power-split HEV.

BorgWarner stated that the "modeling should be inclusive of all approaches of PHEV and HEV and not be limited only to Atkinson Cycle engines," suggesting that it was appropriate for the NPRM analysis to include turbocharged engines in combination with PHEV and HEV technologies.[1182]

The agencies agree with the underlying issue identified by both CARB and BorgWarner's comments. In both cases a limitation of modeling classification, and not a lack of academic understanding of HEV systems, is the crux of the issue. In the specific case of the 2016 Chevy Malibu, the electrical architecture is a power split, however, the vehicle uses a non-Atkinson, basic direct injection engine. These characteristics put the Malibu HEV in an overlap with the powertrain models used to represent HEV systems in the agencies' analysis. If the system had been classified as a PS HEV system in the analysis fleet, the engine would have incorrectly been modeled as an Atkinson engine, resulting in overestimation of the baseline system's level of efficiency and technology applied. The overestimation of the baseline fleet model would have limited the potential for the baseline system to improve over the timeframe of the analysis. With the system classified as the P2 HEV, the engine can be accurately modeled while still accounting for the benefits of an HEV system. This allowed the platform the full potential for technology and efficiency improvement in the analysis.

The agencies considered the issues identified in comments and reviewed the MY 2017 analysis fleet information to determine what changes could improve the final rule analysis. The agencies determined that expanding the number of electrification technologies would address the CARB and BorgWarner comments, as well as the comments from others that are discussed in Section VI.C.3.a)(1) Electrification Technologies. The agencies increased the number of unique electrification technologies from twelve in the NPRM to eighteen for the final rule analysis. The expanded list enabled greater precision in the assignment of technologies to the MY 2017 analysis fleet, and enabled the agencies to characterize the electrification technologies found in the fleet accurately and realistically. The expanded list also provided more granularity for the application of technologies for the rulemaking analysis. Table VI-102 shows the full list of electrification technologies for the final rule analysis.

This collection of technologies represents the best available information the agencies have, at the time of this action, regarding both currently available electrification technologies and electrification technologies that could be feasible for application to the U.S. fleet during the rulemaking timeframe. The agencies believe this effort has yielded the most accurate analysis fleet utilized for rulemakings to date.

As discussed in the previous section and shown in Figure VI-83, Figure VI-84, and Figure VI-85, electrification may be added to vehicles as shown on the decision tree pathways.

[1181] Comments from CARB, Attachment 2, NHTSA Docket No. NHTSA-2018-0067-11873, at 136.
[1182] Comments from BorgWarner, Attachment 1, Appendix, NHTSA Docket No. NHTSA-2018-0067-11895, at 10.

Further application of electrification technologies to vehicle platforms was dependent on electrification technology already present on vehicles in the MY 2017 analysis fleet. Electrification may also be predicated on whether a vehicle has a dedicated platform that accommodates battery electric capability or whether a platform is designed ("package protected")[1183] to enable the addition of some form(s) of hybridization. The agencies' assessment of each existing platform's capability to adopt electrification technologies is identified in the CAFE model market data input file.[1184]

c) Electrification Adoption Features

In the NPRM and final rule analysis, electrification adoption features were applied in multiple ways. First, when an electrification technology is selected, a path logic is applied that dictates what other technologies are either superseded or mutually exclusive to the applied technology. For a detailed discussion of path logic for the final rule analysis, including technology supersession logic and technology mutual exclusivity logic, please see CAFE model documentation section. Second, application of the more advanced electrification technologies, such as the strong hybrids, plug-in hybrids, and full BEVs, result in major changes to the whole powertrain. The changes to the powertrain include substitution of transmission and engine technologies, and accordingly these technologies can only be applied at a vehicle redesign, as shown in Table VI-102 below. Finally, some of electrification technologies are restricted from application to certain vehicle classifications. These restrictions will be discussed under the specific technology sections.

The fully-electric technologies, BEV technology and FCV technology, qualify as alternative fuel technologies. As a result, these technologies are not considered during portions of the agencies' analysis. Specifically, the exclusion of dedicated alternative fuel technology from NHTSA's analysis of potential fuel economy standards is a result of statutory obligations prescribed under EPCA/EISA.[1185] However, NHTSA performed two fuel economy analyses, a standard-setting analysis that constrained the use of the technologies, and an unconstrained analysis that did not exclude the technologies, which provides an estimation of real-world environmental impacts used as inputs for the Environmental Impact Statement (EIS). The unconstrained analysis included the alternative fuel technologies, and used the adoption features for BEVs and FCVs discussed below. Further, for purposes of analyzing EPA's tailpipe CO_2 emissions rulemaking pursuant to the Clean Air Act, consideration of these technologies is likewise unconstrained. For a detailed discussion of the analysis versions and statutory obligations please refer to Section VI.A Analytical Approach as Applied to Regulatory Alternatives, Overview of Methods and Section VI.A.4 Compliance Simulation.

1183 'Package Protected' is an automotive industry term used to describe the purposeful design of a vehicle to include space and weight allowances for future technology additions.

1184 FRM Market Data central analysis input file.

1185 49 U.S.C. 32902(b)(1). A "dedicated automobile" is defined in 49 U.S.C. 32901 as "an automobile that only operates on alternative fuel."

The exclusion of the BEV and FCV technology from the standard-setting analysis resulted in a comment from ICCT. ICCT stated, "the agencies prevented their fleet compliance model from allowing battery electric vehicles from being applied in their analysis of the Augural standards."[1186] The agencies believe this reflects a misunderstanding of NHTSA's statutory obligation under EPCA/EISA and how the agencies ran the analysis. NHTSA did consider alternative fueled vehicles in the unconstrained analysis—but as discussed further in Section VIII, is prohibited from considering the availability of such technologies when setting maximum feasible standards.

[1186] Comments from ICCT, Attachment 3, Appendix, NPRM Docket No. NHTSA-2018-0067-11741, at I82.

Table VI-102 – CAFE Model Electric Technologies

Technology	**Application Level**	**Application Schedule**	**Description**
EPS	Vehicle	Refresh/Redesign	Electric Power Steering
IACC	Vehicle	Refresh/Redesign	Improved Accessories
SS12V	Vehicle	Redesign Only	12V Micro-Hybrid (Stop-Start)
BISG	Vehicle	Redesign Only	Belt Mounted Integrated Starter/Generator
SHEVP2	Vehicle	Redesign Only	P2 Strong Hybrid/Electric Vehicle
SHEVPS	Vehicle	Redesign Only	Power Split Strong Hybrid/Electric Vehicle
P2HCR0	Vehicle	Redesign Only	[Special] SHEVP2 with HCR0 Engine
P2HCR1	Vehicle	Redesign Only	[Special] SHEVP2 with HCR1 Engine
P2HCR2	Vehicle	Redesign Only	[Special] SHEVP2 with HCR2 Engine
PHEV20	Vehicle	Redesign Only	20-mile Plug-In Hybrid/Electric Vehicle with HCR Engine
PHEV50	Vehicle	Redesign Only	50-mile Plug-In Hybrid/Electric Vehicle with HCR Engine
PHEV20T	Vehicle	Redesign Only	20-mile Plug-In Hybrid/Electric Vehicle with Turbo Engine
PHEV50T	Vehicle	Redesign Only	50-mile Plug-In Hybrid/Electric Vehicle with Turbo Engine
PHEV20H	Vehicle	Redesign Only	[Special] PHEV20 with HCR Engine
PHEV50H	Vehicle	Redesign Only	[Special] PHEV50 with HCR Engine
BEV200	Vehicle	Redesign Only	200-mile Electric Vehicle
BEV300	Vehicle	Redesign Only	300-mile Electric Vehicle
FCV	Vehicle	Redesign Only	Fuel Cell Vehicle

(1) Micro and Mild Hybrid

For the NPRM and final rule analysis, the only adoption features for the SS12V and BISG technologies were functions of path logic. The SS12V and BISG technologies were allowed for consideration in any existing vehicle configuration that did not already have a more advanced electrification technology applied. Per Table VI-102 above, the BISG technology was considered more advanced than the SS12V technology.

Meszler Engineering commented that 48V batteries used in conjunction with 12 volt systems (what are referred to in the analysis as BISG systems) are one example of a "bolt-on" technology that can be added to a vehicle during a product refresh without causing production problems or significantly increasing costs.[1187] Meszler Engineering stated that 48V systems do not require reengineering of the engine and can be added at any time during a model's lifespan, as shown by key suppliers that are expanding production capacity to meet customer demand for the technology.[1188] Meszler Engineering also pointed to examples of vehicles that utilize 48V systems, including high-volume non-luxury vehicles like the Ram pickup truck, Jeep Wrangler, and Ford F-150.[1189]

The agencies disagree with Meszler Engineering's assessment of 48V technology as a "bolt-on" technology. Although BISG systems represent a first step in vehicle electrification, and the number of components involved is fewer than most other types of hybrid systems, a BISG system still requires engineering and packaging of motors, cooling systems, additional wiring harnesses from the 48V battery pack to the motors, control systems, and other components incorporated into the front engine compartment. Further, the addition of a BISG system requires recalibration and validation of numerous engine performance parameters, including emissions controls, balancing torque supply to the transmission between the BISG system and engine, and noise-vibration-harshness controls. In addition, the examples Meszler Engineering provided support the agencies' designation of SS12V and BISG systems as redesign technologies; the BISG system in the MY 2019 Ram pickup and in the MY 2018 Jeep Wrangler were introduced during a product redesign and not during a mid-cycle product refresh.[1190, 1191]

[1191] *See, e.g.*, Tony Quiroga, *The 2018 Jeep Wrangler Hybrid Provides Effortless Thrust, Much Improved Fuel Economy*, Car and Driver (Oct. 15, 2018), available at: https://www.caranddriver.com/reviews/a23746585/2018-jeep-wrangler-unlimited-suv-turbo-four-cylinder-hybrid/ ("Completely redesigned for 2018, the Wrangler is even more like a Power Wheels now that it's available with an electric motor.").

Although Ford has indicated that the F-150 will include hybrid variants,[1192] the agencies do not have information about specific plans for a 48V system on the F-150. In consideration of this information, the agencies maintained the redesign schedule for mild hybrids for the final rule analysis.

(2) Strong Hybrids – SHEVP2, SHEVPS, P2HCR0, P2HCR1, P2HCR2

NPRM adoption features applied to strong hybrid technologies included path logic, powertrain substitution, and vehicle class restrictions. For the NPRM analysis technologies on the Hybrid/Electric path (SHEVP2 and SHEVPS) were defined as stand-alone and mutually exclusive. When the modeling system applies one of those technologies, the other one is immediately disabled from future application. Once a strong hybrid technology is applied it also supersedes lower technologies on the electrification path, allowing future application of technology to consider only more advanced forms of electrification.

In the NPRM when the SHEVP2 technology or the SHEVPS technology were applied, the transmission technology was superseded. Regardless of the transmission technology present when the technology was applied, the transmission technology was replaced by either the AT6 or DCT6. The specific transmission technology selected was based on choosing the best cost versus effectiveness.

During the NPRM analysis when the SHEVP2 technology was selected the engine technology for the platform was maintained. However, the engine technology was locked at the current level and could not be changed. For the SHEVPS technology the existing engine was replaced with an Atkinson cycle engine (Eng26).

The SHEVPS was also constrained from application to particular vehicle technology classes or vehicles with specific performance characteristics in the NPRM. Application of the power-split architecture was restricted from high performance vehicles and vehicles with a high towing capability requirements.[1193] These constraints prevented application to the pick-up and performance pick-up class of vehicles. The constraints also prevented application to any platform with a base horsepower rating greater than 400 HP. Additional platforms determined to be purpose built as performance platforms were also restricted from receiving SHEVPS technology.

Comments from ICCT criticized the manner in which SHEVP2 technology was applied to a platform. ICCT stated "the benefits of level-2 transmission efficiency and TURBO2 over

---

[1192] "Ford to Invest more than $1.45 Billion, Add 3,000 Jobs in S.E. Mich. Plants to Deliver New Pickups, SUVs, EVS, and AVS," Ford Media Center, 17 Dec 2019. https://media.ford.com/content/fordmedia/fna/us/en/news/2019/12/17/ford-invests-adds-jobs-southeast-michigan-plants.html.

TURBO1 are removed when P2 strong hybrid systems (SHEVP2) are selected on the electrification pathway."[1194]

Additional comments regarding the adoption features of the SHEVP2 technology were received from Meszler Engineering and ICCT. Meszler argued that the locking of engine technologies when a manufacturer selects the SHEVP2 technology may preclude the selection of a more cost-effective engine technology.[1195] This concern was echoed by ICCT, who also felt the engine technology lock-in artificially increased cost for effectiveness on the overall SHEVP2 technology packages.[1196] Both commenters specifically wanted an option for a high compression ratio engine technology to be considered in place of any advanced engine technology carried into the SHEVP2 technology pathway.

The agencies agreed with the need for maintaining the benefits of a higher transmission technology, and for the final rule analysis a AT8L2 transmission technology replaced the AT6 or DCT6 transmissions for all hybrid-electric technologies. The AT8L2 was selected as the optimal transmission technology point for HEV systems. The transmission technology point was selected based on observed diminishing returns for applying advanced transmission technologies to advanced engine/powertrains.[1197]

The agencies also reconsidered engine options for SHEVP2 technology, and other strong hybrid-electric technologies. The agencies agreed with Meszler and ICCT's observation and instituted new P2 engine technology options, as discussed above. For the final rule analysis, when a platform considered the SHEVP2 option, the platform also compared maintaining the current engine technology, or selecting an HCR technology. If the SHEVP2 system chooses to apply a HCR engine, the system diverts to the new electrification sub-path of technologies that includes the P2HCR0, P2HCR1, and P2HCR2.

The P2HCR path introduced in the final rule analysis had similar constraints as the SHEVPS. Performance vehicles and vehicles with a high towing requirement were restricted from selection of the P2HCR technology. Restrictions that were applied used the same criteria described for the SHEVPS.

1195 Comments from Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA-2018-0067-11723, at 15-16.

1196 Comments from ICCT, Attachment 3, 15page summary and full comments appendix, NPRM Docket No. NHTSA-2018-0067-11741, at I25-I26.

1197 2015 NAS Report - The National Academy of Science, in their 2015 report, noted that "as engines incorporate new technologies to improve fuel consumption, the benefits of increasing transmission ratios or switching to a CVT diminish."

(3) Plug-in Hybrids—PHEV20/30, PHEV50, PHEV20T, PHEV50T, PHEV20H, PHEV50H

The plug-in hybrid options in the NPRM included PHEV30 and PHEV50 technologies. The plug-in technologies superseded the micro, mild, and strong hybrid electrification technologies and could only be replaced by full electric technologies. The path logic also allowed a PHEV30 to progress to a PHEV50.

In the NPRM, when a platform progressed to the plug-in hybrid technologies the powertrain was automatically modified. The engine technology was replaced by a high compression ratio engine (Eng26) and the transmission was replaced by the AT6 or DCT6 technology.

PHEV30 and PHEV50 were also constrained from application to vehicles with the potential for high towing demands.[1198] This constraint was applied by restricting access to the pickup truck vehicle technology class. Additional specific vehicle platforms were restricted based on engineering judgment.

Comments were received regarding the options for PHEV battery-electric technology. The comments are presented and discussed in Section VI.C.3.e) Electrification Technologies above, and resulted in the creation of additional technology options for plug-in hybrids, as well as a modification of available ranges. Comments were also received regarding the engine and transmission options used in the electrification technologies, these comments are also presented and discussed above in Section VI.C.3.e) Electrification Technologies.

For the final rule analysis, the plug-in hybrid options included PHEV20, PHEV50, PHEV20T, PHEV50T, PHEV20H, and PHEV50H. As with the NPRM, the plug-in technologies superseded the micro, mild, and strong hybrid technologies. For the final rule analysis, plug-in hybrid technologies were also mutually exclusive, and the PHEV20 technologies can progress to the PHEV50 technologies.

When a platform applied plug-in hybrid technologies in the final rule analysis, the engine and transmission technologies are superseded. For all plug-in technologies, an AT8L2 transmission is used. For the PHEV20/50 and PHEV20/50H, the engine is replaced by an Atkinson cycle based engine (Eng26). For the PHEV20/50T, the engine is replaced by the TURBO1 technology engine (Eng12).

The PHEV20/30 and PHEV20/50H path also had similar constraints as the SHEVPS in the final rule analysis. Performance vehicles and vehicles with a high towing requirement were restricted from selection of the PHEV20/30 and PHEV20/50H technologies. Restrictions that were applied used the same criteria described for the SHEVPS.

[1198] Power split or Parallel–selecting the Right Hybrid Architecture: SAE 2017-01-1154. = Kapadia, J., Kok, D., Jennings, M., Kuang, M. et al., "Powersplit or Parallel - Selecting the Right Hybrid Architecture," SAE Int. J. Alt. Power. 6(1):68-76, 2017, https://doi.org/10.4271/2017-01-1154.

(4) Battery Electric Vehicles

For the NPRM analysis, the BEV200 technology was applied as an end-of-path technology. The BEV200 technology was the only battery electric vehicle option. For the final rule analysis, the BEV300 was added as a technology option beyond the BEV200, as discussed in Section VI.C.3.a)(1)(f) Battery Electric Vehicles. BEV200 and BEV300 technology was applied in place of all engine and transmission technologies, and was an end of path technology.

For the final rule analysis, both the BEV 200 and BEV300 had phase-in cap limitations applied based on an analysis of the market availability and cost of batteries.[1199] The BEV200 was limited to a greater extent than the BEV300, accounting for expected limits in market demand for the shorter-range BEV.[1200] The phase-in capacity numbers were determined based on the results of the analysis of the National Energy Model System (NEMS) discussed in Section VI.D.1.b)(1)(b) Macroeconomic assumptions used to analyze economic consequences of the final rule.

(5) Fuel Cell Vehicle

For the NPRM analysis, FCV technology was also applied as an end of path technology. The FCV technology was also applied as end of path technology in the final rule analysis.

For the final rule analysis, a phase-in cap was assigned to FCV technology. The phase-in cap was assigned based on existing market share as well as an analysis of expected infrastructure availability during the time frame of regulation. [1201, 1200]

d) Electrification Effectiveness Modeling and Resulting Effectiveness Values

For this analysis, the agencies considered a range of electrification technologies which, when modeled, resulted in varying levels of effectiveness at reducing fuel consumption. Each technology consists of many different complex sub-systems with unique component efficiencies and operational modes. As discussed further below, the systems that contribute to the effectiveness of an electrified powertrain in the analysis include the vehicle's battery, electric motors, power electronics, and accessory load. Procedures for modeling each of these sub-systems are discussed below, and also in Section VI.B.3 Technology Effectiveness Values and in the FRM Argonne Model Documentation.

The modeled electrification technologies included micro hybrids, mild hybrids, strong hybrids, plug-in hybrids, and full electric vehicles. This section discusses how Autonomie was used to model these technologies' effectiveness. The models for the micro hybrids included a

SS12V system model; mild hybrid models included BISG system models and CISG system models; strong hybrid models included SHEVP2 system models and SHEVPS system models; and finally, electric vehicle models included BEV system models and FCV system models.

(1) Electric Motors, Power Electronics and Accessory Load

Each electrified powertrain type possesses a unique effectiveness for reducing fuel consumption. Autonomie determines the effectiveness of each electrified powertrain type by modeling the basic components, or building blocks, found in each powertrain, and then combining the components modularly to determine the overall efficiency of the entire powertrain. The basic building blocks that comprise an electrified powertrain in the analysis included the battery, electric motors, power electronics, and accessory loads. Autonomie identified which components comprise each electrified powertrain type, and how these components are interlinked within each unique electrified powertrain architecture. This creates a model for each electrified powertrain architecture that simulates how efficiently energy is transferred through each system. For example, Autonomie determines a BEV's overall efficiency by considering the efficiencies of the battery, the electric traction drive system (the electric machine and power electronics) and mechanical power transmission devices. Or, for a SHEVP2, Autonomie combines a very similar set of components to model the electric portion of the hybrid powertrain, and then also includes the combustion engine and related power transmission components.

For the NPRM and this final rule analysis, Autonomie employed a set of electric motor efficiency maps, which originated from two Oak Ridge National Laboratory (ORNL) studies: one for a traction motor and an inverter, the other for a motor/generator and inverter.[1202,1203] Autonomie also used test data validations from technical publications to determine the efficiency of certain electric motors. The electric motor efficiency maps are visual measurements of percent efficiency of power as a function of torque and motor RPM, and were based on representative production vehicles, especially for base and maximum speeds as well as maximum torque curve. The maps were used to determine the efficiency characteristics of the motors, but were scaled such that their peak efficiency value corresponded to the latest state of the art technologies for different electrified powertrains. The maps also included some of the losses due to power transfer through the electric machine.[1204] Table VI-103 details the electric machine efficiency map sources for the different powertrain configurations used for the NPRM.

BEV and FCV[1205]	Nissan Leaf data from ORNL	

For the final rule, the agencies used the same efficiency maps as the NPRM, except for BEVs. The agencies updated the BEV electric motor efficiency for the final rule analysis using data from a more recent technical publication.[1206] The agencies also scaled the maps to have peak efficiencies ranging from 96-98 percent depending on the powertrain type.[1207] Table VI-104 below shows powertrain types and the source of data used for the final rule.

FCV	Nissan Leaf data from ORNL	

Battery performance data (e.g., internal resistance, open circuit voltage) were measured using individual cell testing on a bench using standard test procedures, and BatPaC was used to design battery packs of different capacities and cell counts. The battery utilization (e.g. SOC range) were developed based on numerous vehicle test data.[1208] In addition, as discussed further below, for the NPRM analysis, the agencies resized the battery pack only with the addition of incremental mass reduction technology levels. For this final rule, the agencies updated the modeling to consider battery resizing with the application of all road load reduction technologies. Accordingly, a more appropriately-sized battery pack could result in lower vehicle mass, resulting in potentially improved effectiveness.

Beyond the powertrain components, Autonomie also considered on-board accessory devices that consume energy and affect overall vehicle effectiveness. Some electrical power is consumed by electrical accessories such as headlights, radiator fans, wiper motors, engine control units (ECU), transmission control unit (TCU), cooling systems, and safety systems, in addition to driving the motor and the wheels. In real-world driving, the electrical accessory load on the powertrain varies depending on the how features are used and the condition the vehicle is

operating in, such as for night driving or hot weather driving. However, for regulatory test cycles related to fuel economy, the electrical load is repeatable because the fuel economy and CO_2 regulations control for these factors, as discussed in Section VI.B.3 Technology Effectiveness Values.[1209] Accessory loads during test cycles do vary by powertrain type and vehicle technology class, since distinctly different powertrain components and vehicle masses will consume different amounts of energy.

The baseline fleet consists of hundreds of different vehicle types that vary in the amount of accessory electrical power that they consume. For example, vehicles with different motor and battery sizes will require different capacities of electric cooling pumps and fans to manage component temperatures. Autonomie has built-in models that can simulate these varying sub-system electrical loads. However, for the NPRM and this final rule analysis, the agencies used a fixed (by vehicle technology class and powertrain type), constant power draw to represent the effect of these accessory loads on the powertrain. The agencies intended and expected that fixed accessory load values would, on average, have similar impacts on effectiveness as found on actual manufacturers' systems. This process was in line with the past analyses, such as in the Draft TAR and the EPA Proposed Determination.[1210,1211] For assumptions regarding accessory load modeling for the rulemaking timeframe, the agencies relied on research and development data from DOE's Vehicle Technologies Office and Argonne Advanced Mobility Technology Laboratory, as well as input from automotive manufacturers.[1212,1213,1214]

Table VI-105 below shows the NPRM assumptions for all the vehicle classes and powertrain types for accessory loads.[1215] Data from AMTL D^3 testing were used to designate electric loads for different types of powertrains.[1216]

For the final rule analysis, the agencies updated the electrical load assumptions for many of the powertrain types and classes,[1217] based on further consideration of comments from the Alliance on the 2016 Draft TAR and EPA Proposed Determination.[1218,1219] These assumptions are provided below, in Table VI-106.

Table VI-106 – Final Rule Analysis Accessory Load Assumptions in Watts by Vehicle Class and Powertrain Type

CARB commented on NPRM non-battery component efficiency assumptions in two respects; first by claiming that the agencies relied on outdated data for electric machines and

---

1217 *See* ANL Assumptions Summary, ANL - All Assumptions_Summary_FRM_06172019_FINAL.
1218 Alliance of Automobile Manufacturers Comments on Draft TAR at p. 30. September 26, 2016.
1219 EPA Proposed Determination TSD (November 2016), at p.2-270.

inverter efficiencies across all electrification applications,[1220] and second by claiming that the agencies did not project any efficiency gains in those components over time.[1221] CARB stated that the three vehicles benchmarked in the ORNL studies (MY 2007 Toyota Camry Hybrid, a MY 2011 Hyundai Sonata Hybrid, and MY 2012 Nissan Leaf) were inappropriate for the agencies to use to assess the costs and efficiencies for the same components in MY 2020-2030 vehicles, given the rapid development in the past ten years in automotive electrification. CARB cited the MY 2016 Chevrolet Volt and Bolt, and the MY 2016 Toyota Prius, as examples of vehicles that had undergone electric machine efficiency improvements from one generation to the next; those vehicles generally employed efficiency improvements including reduced electric motor volume and mass, reduced power inverter volume, increased electric motor peak power density, and reduced mechanical losses through friction reduction, among other improvements.

In support of their comments that the agencies did not project any efficiency gains in non-battery components over time, CARB faulted the agencies for not including data from the October 2015 ORNL progress report for electric drive technologies, stating that benchmarking data for a MY 2014 Honda Accord Hybrid inverter and traction motor components could have been used to compare against and update the data from the MY 2007 Toyota Camry Hybrid and MY 2011 Hyundai Sonata Hybrid efficiency maps benchmarked in the older ORNL report. CARB stated that the lack of consideration of this newer data was evidence that the agencies' data selection was biased to support weakening fuel economy standards.

CARB also cited 2017 research from Argonne's Autonomie group as a source of updated data that showed efficiency gains over time for electrification technologies not considered in the agencies' analysis, including increases in high voltage system peak efficiency, increases in high voltage specific power, and decreases in costs.[1222] CARB stated that had the agencies included newer data in the analysis, including from the same data sources from which prior data came, the analysis would have not supported the agencies' proposal.

The agencies agree that there have been improvements in non-battery component efficiency over the past few years, however CARB's characterization of the process used to employ the ORNL benchmarking data in the analysis was incorrect. Autonomie used high-level electric machine characteristics such as base and max motor speed from production vehicles along with generic efficiency map curves for each technology type, with peak efficiencies matching the current state of the art technologies discussed in ORNL reports. Although the source data for the electric machines were from older production vehicles, the peak electric motor and controller efficiencies were updated to reflect the latest available data. Specifically, the NPRM analysis modeled a 92 percent peak efficiency for motors and controllers.[1223]

[1220] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 127.
[1221] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 128.
[1222] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 131. Note that comments on non-battery component costs are addressed in Section VI.C.3.e)(2) Non-Battery Electrification Component Costs.
[1223] *See* the Non_Vehicle_Attribute tab in the NPRM ANL Assumptions_Summary.

That said, the agencies also agreed that the analysis could use updated peak electric and controller efficiencies, and updated those for the final rule. For the final rule analysis, the agencies used 96 percent efficiency for HEVs and PHEVS, and 98 percent peak efficiency for BEVS and FCEVs.[1224] The agencies believe the final rule efficiencies are appropriate for the rulemaking timeframe.

In addition, as discussed above, other changes for the final rule analysis include updating the electric motor sizing as a function of electric power to account for lower electric machine mass, updating the BEV electric machine map to use a newer efficiency map from the Chevy Bolt, updating baseline and reference vehicle mass assumptions to reflect latest machine weight technology development, and updating the electrical accessory loads for vehicle modeling to reflect data from vehicle benchmarking. Changes and updates to the Autonomie analysis are discussed throughout this electrification section and in the FRM Argonne Model Documentation. In addition, for this final rule analysis, the agencies used the latest Argonne BatPaC model to determine the battery pack mass and manufacturing costs for electric vehicle batteries. Updates to non-battery component efficiency were small in comparison to the impact of using updated battery modeling for the final rule analysis. Further discussion on battery modeling can be found in Section VI.C.3.e)(1) Battery Pack Modeling.

(2) Modeling and Simulating Vehicles with Electrified Powertrains in Autonomie

Data from Argonne's AMTL was used to develop the electrified powertrain models in Autonomie. The modeled electrification components were sized based on performance neutrality needs, as discussed further below, and the control algorithms were based on Argonne - collected data.[1225] Detailed discussion about the development of the HEV drivetrains can be found in the Autonomie modeling documentation.[1226] The modeled powertrains are not intended to represent any specific manufacturer's architecture, but are intended to act as surrogates predicting representative levels of effectiveness for each electrification technology.

The agencies also broadly discussed in Section VI.B.3 Technology Effectiveness Values that certain technologies' effectiveness for reducing fuel consumption requires optimization through the appropriate sizing of the powertrain. This analysis iteratively minimizes the size of the powertrain components to maximize efficiency while at the same time enabling the vehicle to meet multiple performance criteria. The Autonomie simulations use a series of resizing algorithms which contain "loops," such as an "Acceleration Performance Loop (0-60 mph)," which automatically adjust the size of certain powertrain components until a criterion, for example 0-60 acceleration time, converges to a target value. As the algorithms examine different performance or operational criteria that must be met, no single criterion is allowed to degrade; once a resizing algorithm completes, all criteria will be met, and some may be exceeded as a necessary consequence of meeting others.

[1224] *See* the Non_Vehicle_Attribute tab in the FRM ANL Assumptions_Summary.
[1225] *See* FRM ANL Model Documentation.
[1226] *See* NPRM ANL Model Documentation at p.92.

Autonomie applies different powertrain sizing algorithms depending on the type of vehicle considered because different types of vehicles not only contain different powertrain components to be optimized, but they must also operate in different driving modes. While the conventional powertrain sizing algorithm must consider only the power of the engine, the more complex algorithm for electrified powertrains must simultaneously consider multiple factors, which could include the engine power, electric machine power, battery power and battery capacity. Also, while the resizing algorithm for all vehicles must satisfy the same performance criteria, the algorithm for some electric powertrains must also allow those electrified vehicles to operate in certain driving cycles without assistance of the combustion engine, and ensure the electric motor/generator and battery can handle the vehicle's regenerative braking power, all-electric mode operation and intended range of travel.

To establish the effectiveness of the technology packages, Autonomie simulated the vehicles performing compliance test cycles, as discussed in Section VI.B.3 Technology Effectiveness Values.[1227, 1228, 1229] For vehicles with conventional powertrains and micro hybrids, Autonomie simulated the vehicles using the 2-cycle test procedures and guidelines.[1230] For mild HEVs, strong HEVs, and FCVs, Autonomie simulated the 2-cycle test, with the addition of repeating the drive cycles until the final state of charge was approximately the same as the initial state of charge, a process described in SAE J1711. For PHEVs and BEVs, Autonomie simulated vehicles performing the test cycles per guidance provided in SAE J1711.[1231] For BEVs, Autonomie simulated vehicles performing the test cycles per guidance provided in SAE J1634.[1232]

A survey of comments about the modeled effectiveness of electrification technologies showed most comments could be sorted in three major categories. The first, and largest category of comments, were concerned with effectiveness values used for the technologies. Specifically, commenters were concerned the values for the modeled effectiveness of the technologies were too low, particularly when compared to past analysis efforts. The second major category of comments were concerned with the size of the electrification components selected in the Autonomie tool, and used to simulate the system performance. Commenters were concerned because oversized components can lead to the system violating performance neutrality constraints and artificially increasing the cost of the technology. The third major category of comments were concerned not enough variety of technologies were represented in the electrification technology models. Specifically, commenters wanted additional engine technologies allowed to couple with electrification technologies.

Each of the comments from the first category will be referenced and addressed under the specific technology sections, below. However, broadly, two factors have led to the comments raised by stakeholders. First, as discussed throughout this document, the agencies avoided using performance values in the analysis that can be traced to specific implementation of a technology type. Thus, when comparing simulated performance to any specific real world vehicle, there will be a deviation. The modeled inputs are meant to represent the typical range of values for a technology—reasonable and realistic values—but are not likely to result in performance outputs that would equal any specific existing vehicle. Second, the modeling approach implemented in the NPRM and final rule analysis succeeds in isolating the effects of individual technologies to a higher degree then previous analysis. Due to the greater use of parametric modeling of full vehicle systems, the specific effects of technologies could be isolated to a higher degree from the amplifying or muting effects of other technologies. This isolation of effect often results in lower predicted effectiveness values for individual technologies than has been observed in previous analysis, where the isolation of effect was not as precise, and often attributed efficiency gains from a combination of technological changes to a single technology.

For the second major group of comments, the agencies mostly agreed with the stakeholder observations. The issues identified were investigated by the agencies and resulted in changes to the sizing algorithms used by the agencies for the final rule analysis. The agencies further investigated the constraints of performance neutrality and ensured those constraints were followed for sizing of electrification components. Further discussion of the changes made, as well as specific answers to comments under each technology section, can be found in the following technology subsections and in Performance Neutrality, Section VI.B.3.a)(6).

The third major group of comments from stakeholders were concerned with allowing more engine technologies to be incorporated in electrification systems. The agencies agreed with these comments and increased the number of technology combinations available. The new combinations are discussed in Section VI.C.3.a)(1) Electrification Technologies, as well as under each technology section below.

(a) Micro and Mild Hybrid Vehicles

The micro and mild hybrid systems modeled in Autonomie represented SS12V and BISG technology (and CISG technology for the NPRM). SS12V and BISG were modeled using a similar approach because both systems have low peak power, low energy storage, and allow stop/start engine idle reduction. The effectiveness improvement from both technologies is attributable to the amount of fuel saved during engine idling period on the 2-cycle test. However, only the BISG system model allowed limited assist to propel the vehicle and limited regenerative braking. For further discussion of these system models, see the FRM Argonne Model Documentation.[1233]

Powertrain resizing was not employed for micro or mild hybrid system application, in either the NPRM or this final rule analysis. These systems have little to no impact on the vehicle performance metrics that would be adjusted by powertrain resizing, and in turn there would be

---

[1233] *See* FRM ANL Model Documentation at chapters 4.6, 4.7 and 4.13.

limited or no benefit in attempting to resize upon application of these systems. For example, the micro hybrid SS12V system allows the engine to be turned off when the vehicle is fully stopped to reduce idle-stop fuel consumption, but the combustion engine size must be retained to maintain performance metrics such as acceleration. The main focus of mild hybrid vehicles is to provide idle-stop and capture some regenerative braking energy, and although they also can provide some assistance to the engine during the initial propelling of the vehicle, this is done to improve efficiency and does not significantly improve the acceleration performance of the vehicle. With BISG mild hybrids, the electric machine is linked to the engine through a belt, and thus the potential power assistance is usually limited. In the NPRM, the BISG system used an 806 Wh capacity battery pack and a 10 kW motor/generator. For the final rule analysis, the 10 kW motor/generator was paired with a 403 Wh battery pack to align with BISG systems emerging in the marketplace.

ICCT commented that the agencies unjustifiably reduced the CO_2 and fuel consumption benefits of SS12V from the Draft TAR, including a reduction in the overall effectiveness benefit when the SS12V system was applied in combination with other technologies.[1234] ICCT stated that the agencies should know the precise effectiveness improvement for SS12V technology based on EPA compliance data, and the agencies should report a full listing of all the baseline 2016 vehicle models with stop-start technology, with their test-cycle, and off-cycle improvement in g/mile and percent effectiveness. ICCT claimed that the agencies either intentionally ignored the full compliance benefits of SS12V technology or "ignored the knowledge and expertise of the EPA engineering and compliance staff," and argued that not reporting the requested data would be "hiding relevant data the agencies have readily available to more rigorously assess existing stop-start technologies and their impact for the rulemaking." ICCT also stated that the agencies did not appropriately include the full regulatory benefit (i.e., inclusion of the additional off-cycle "credit" under EPA's program or fuel consumption improvement value under NHTSA's program) of SS12V technologies due to their off-cycle improvements.[1234]

HDS made a similar observation, noting that the SS12V benefit from the NRPM was similar to the 2012 TSD projection, but lower than the benefit quoted by stakeholders in the Draft TAR.[1235] HDS cited the difference in fuel economy between two vehicles that were produced with and without a SS12V option (the 2015 Ford Fusion 1.5L TGDI and the 2015 Mazda 3 i-ELOOP) which suggested effectiveness values for SS12V of about 3.3 percent for both vehicles. HDS also cited a Bosch presentation that claimed newer SS12V systems could provide effectiveness of up to 6 percent. HDS argued that this actual data and supplier data supported a benefit of at least 3.3 percent, which they stated was double the benefit in the NRPM analysis.

The agencies disagree with ICCT and HDS' comments regarding the effectiveness of the SS12V technology modeled in the NPRM analysis. The implementation of the full vehicle simulation approach used in the NPRM, and carried forward to the final rule analysis, clearly

---

[1234] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-22.
[1235] H-D Systems, Attachment 1, Docket No. NHTSA-2018-0067-11985, at 44.

defines the contribution of individual technologies and separates those contributions from other technologies. The modeling approach also shows when technologies have amplifying or muting interactions. In some cases, this may appear as a reduction in performance compared to previous analysis. The agencies modeled the SS12V system in conjunction with all the IC engine and transmission combinations. The results of this parametric modeling accounted for each engine and transmission combination's unique fuel consumption rate at idle.[1236] The range of effectiveness for the technology in the NPRM analysis is a result of these differences. This range of values will result in some modeled effectiveness values being close to real-world measured values, and some modeled values that will depart from measured values, depending on the level of similarity between the modeled hardware configuration and the real-world hardware configuration. This modeling approach comports with the National Academy of Science 2015 recommendation to use full vehicle modeling supported by application of lumped improvements at the sub-model level.[1237] The approach allows the isolation of technology effects in the analysis supporting an accurate assessment.

For both the NPRM and final rule analysis, the agencies assigned SS12V technology to vehicles in the analysis fleet using compliance data, and used compliance data to assign a vehicle's baseline fuel economy value. The market data file indicated the presence of SS12V on a vehicle, and accordingly, the vehicles reported to include SS12V technology in the analysis fleet were modeled with the technology. For more discussion on how technologies were assigned to the vehicle platforms in the analysis fleet, please see Section VI.B.1 Analysis Fleet. The agencies accounted for the contribution of the SS12V technology in the analysis fleet by using the reported compliance fuel economy values as the baseline fuel economy values for vehicles that included the technology. The analysis fleet fuel economy values were the reported final compliance values for the given vehicle platform and should include the benefits from all technologies on the vehicle platform.[1238] The agencies also captured the off-cycle credits provided to a manufacturer for the existence of the technology in the manufacturer's fleet. For the NPRM and final rule analysis, the manufacturers' fleets are modeled with baseline year compliance-reported off-cycle credits. Further, for the final rule analysis, the agencies increased the application of off-cycle credits in the analysis, as discussed in Section VI.B.2.a) Off-cycle and A/C Efficiency Adjustments to CAFE and Average CO_2 Levels.

Commenters similarly disagreed with the BISG effectiveness presented in the NPRM analysis, suggesting the resulting effectiveness improvement should be at a range of 4 percent to 6 percent.[1239] Such commenters claimed that it was unclear why effectiveness values were so

---

[1236] For example, when idling, a larger eight-cylinder engine has more friction and pumping losses than a smaller four-cylinder engine, and therefore will save more fuel when the engine is shut-off at rest.

much lower than previous effectiveness estimates. More specifically, comments centered on (1) arguing that the agencies' modeling of BISG and CISG systems in Autonomie likely underestimated the resulting effectiveness values; (2) suggesting that the values in prior documents like the Draft TAR and the 2015 NAS report were more accurate; and (3) comparing modeled effectiveness values to claimed values achieved by actual on-road vehicles and mild hybrid systems.

CARB claimed that the agencies failed to disclose the necessary details to conclude why mild hybrid systems were projected to have lower efficiency values than past estimates. CARB also concluded the lack of engine downsizing when adding a BISG/CISG system and the lack of adjusting transmission drive ratios and shift logic were reasons why BISG/CISG effectiveness was underpredicted.[1240] CARB claimed not resizing the engines resulted in a "less than optimized system that does not take full advantage of the mild hybrid system."[1241] CARB argued that the agencies' assumption that manufacturers "would not optimize the engine and transmission when installing a CISG is not realistic and results in improper pairing of advanced gasoline engines and transmissions in the modeling and leads to underestimation of the efficiency benefits." As mentioned above, CARB stated that manufacturers "often are required to make a[n] engine casting change to accommodate the system," and when doing so, "no manufacturer would fail to pair the system with an optimally sized engine and configured transmission to take full advantage of the system's capabilities."[1242]

CARB also inquired into whether the Argonne modeling "took full advantage" of the system, using Daimler's EQ Boost system, that provides temporary boosts for acceleration and enables engine shut-off during coasting events, as an example.[1243] Similarly, CARB noted that CISG systems' ability to provide low end torque makes it an "ideal technology to pair with an engine technology that may have poor low end torque but improved efficiency under other conditions; examples could include an HCR engine sized with minimal low end torque to maximize efficiency improvements in other operating conditions or a turbocharged downsized engine equipped with a larger turbine to reduce backpressure but provide improved efficiency over a larger portion of the engine map."[1244] CARB stated that manufacturers are using such systems to boost engine torque at higher operating speeds so they can keep the engine operating in a more efficient region.

Commenters also cited data from suppliers that produce 48V BISG systems, including data from TULA that showed a 11 percent fuel economy benefit from a 48V system,[1245] data from a Delphi 48V system prototype installed on a Honda Civic that showed a 10 percent

[1245] H-D Systems, Attachment 1, Docket No. NHTSA-2018-0067-11985, at 45.

reduction in CO_2 emissions levels,[1246] and data from Continental showing a 13 percent fuel savings improvement from its BISG system.[1247] ICCT also cited its supplier and technology report on hybrids that estimated the benefit of mild hybrid technology at 12.5 percent, which it characterized as "remarkably similar" to that achieved by the 2019 RAM pickup truck.[1248] HDS noted that even if the effectiveness values from TULA are regarded as optimistic because they are the developers of the technology, EPA's previous modeling results of 8-9 percent effectiveness "appear reasonable in light of what is observed from certification data."[1249] ICCT ultimately recommended the agencies revise the effectiveness value for mild hybrid systems to include a CO_2 effectiveness value of 12.5 percent.[1250]

Commenters also stated that the effectiveness estimates for CISG systems were significantly understated,[1251] with UCS characterizing CISG systems as showing "virtually no benefit whatsoever for CISG over BISG, and in many cases actually show[ing] an increase in fuel consumption."[1252] UCS stated this was a dramatic departure from previous Autonomie results, and with "no explanation whatsoever" given for the decrease in technology effectiveness.

The agencies agree with commenters that the NPRM analysis of mild hybrid technologies could be more representative of production vehicles and vehicles likely to be produced during the rulemaking time period. The agencies further conclude that the NPRM analysis overestimated the costs of such technologies. Thus, for the final rule analysis, the agencies only considered one 48V BISG system in the mild hybrid technology category. The 48V mild hybrid BISG system used the same 10 kW electric motor as the one used in the NPRM analysis, and the 48V BISG battery pack was also reduced in size to 403 W-hr from 806 W-hr to reflect more accurately the size of battery packs available in the market. In addition, the Autonomie model increased the usable battery capacity, increasing the duration of electric motor use by the vehicle before starting the engine. The specifications and assumptions for the 48V BISG system are further discussed in the FRM Argonne Model Documentation and FRM Argonne Assumptions Summary.[1253,1254] The discontinued use of the CISG technology is discussed in Section VI.C.3.a)(1)(c) Electrification Technologies, Mild Hybrids.

The agencies disagree with comments stating incremental effectiveness estimated by Autonomie modeling was incorrect because the effectiveness values deviated from past effectiveness values estimated in the agencies' rulemakings or from real-world values measured

1254 FRM ANL Assumptions Summary (*see* Model Documentation tables in Section VI.A.7 Structure of Model Inputs and Outputs).

on specific vehicles. As discussed in previous sections, the implementation of the full vehicle simulation approach used in the NPRM analysis and carried forward to the final rule analysis clearly defines the contribution of individual technologies through the application of parametric modeling. This approach clearly separated the contributions of each technology. The modeling approach also showed the amplifying or muting interactions between technologies. In some cases, this may appear as reduced performance in comparison to previous analysis. The agencies also strongly disagree that they should use the performance values for any specific vehicle as representative of all mild hybrid systems.

CARB also commented that the agencies' decision to use a fixed final drive ratio and fixed shift logic based on the selected transmission did not allow for efficiency improvements when mated with electrified powertrains, with specific regards to mild hybrid BISG and CISG systems.[1255] CARB stated that based on the information disclosed in the NPRM, "it appears that Argonne did not utilize the system in these manners nor did they allow for changes in gear ratios, final drive ratio, or transmission shift logic to optimize for efficiency improvements when mated with different electrified powertrains."[1256] Roush Industries similarly stated that the analysis under-predicted the potential improvements of employing a BISG system because the engine could operate at a lower RPM with the help of the torque assist of the electric motor/generator, with a change to the final drive ratio and transmission shift logic, but the analysis did not do so.[1257]

The agencies disagree with CARB and Roush Industries' claims about the gear ratio and shift logic used for the NPRM. As discussed in Section VI.C.2.e) Transmission Effectiveness Modeling and Resulting Effectiveness Values, manufacturers commonly maintain the same gear hardware across vehicle platforms and applications, relying on controls and shift strategy to achieve optimization. Autonomie maintained gear hardware but customized the shifting strategy for each unique vehicle system modeled[1258] to reflect real-world manufacturing strategies more accurately.

CARB also commented that the performance modeled by the Autonomie tool in the NPRM analysis failed to remain neutral for over 80 percent of the modeled systems with mild hybrids. CARB felt the over-performance was "indicating some portion of the system capability was improperly modeled to improve performance rather than reduce CO_2 emissions."[1259]

The agencies agree with CARB's observations about the performance of mild hybrid combinations. The mild hybrid configuration exhibited higher performance in comparison to non-mild hybrid configurations in the NPRM analysis. For the final rule analysis, the agencies updated sizing and control of the mild hybrid systems to minimize performance changes and maintain neutrality. As discussed earlier in this chapter, updates include using smaller battery

---

[1255] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 185.

[1259] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 163.

systems, updated algorithms, and updated component weights. For further discussion of performance neutrality for the final rule, see the Performance Neutrality Section VI.B.3.a)(6).

Finally, ICCT commented that the agencies should include off-cycle and "game-changing" pickup truck credits in the effectiveness estimates for hybrid pickup trucks, as "[i]t is the responsibility of the agencies to include all applicable credits with their technology packages calculations and their projections, including any additional credits that will automatically accrue."[1260]

While the agencies included many compliance flexibilities in the modeling for the final rule analysis, hybrid pickup truck credits were not modeled. The referenced pickup truck credit is set to expire for mild HEVs after MY 2021 and strong HEVs after MY 2025,[1261] so in analyzing this comment the agencies considered what technologies manufacturers could apply to pickup trucks during those model years to meet the requirements specified in the regulation. To receive credit in a model year, manufacturers must produce a quantity of improved full size pickup trucks—improvement characterized by including either hybrid technology or improved emissions performance—such that the proportion of production of such vehicles, when compared to the manufacturer's total production of full size pickup trucks, is not less than an amount specified in that model year. The agencies determined that, based on manufacturers' MY 2017 pickup truck offerings characterized in the analysis fleet and with the technology considered in this rule, no pickup truck manufacturer could meet the criteria set by EPA to qualify for the mild credit before the credit is set to expire. For the strong HEV credit, the agencies considered that forcing the application of strong HEV pickups to meet the minimum threshold of 10 percent of the fleet in order to earn the incentive credits would significantly increase the cost for compliance and be less cost-effective than other technology pathways. As the analysis seeks the most cost-effective pathway for compliance, the agencies disagree the analysis should force the application of strong HEV technology to at least 10 percent of full size pickup trucks. However, the agencies did allow and simulated maximum off-cycle and A/C off-cycle FCIVs for all manufacturers in the CAFE model for both the CAFE and CO_2 programs during the rulemaking time frame. So, while the agencies did not model pickup truck credits specifically, the final rule analysis allowed manufacturers to reach the maximum off-cycle credit cap during the rulemaking timeframe.

(b) Strong Hybrid Vehicles

The power-split hybrid (SHEVPS) model in Autonomie included a power-split device, two electric machines and an engine, and allowed various interactions between these components. The SHEVP2 model in Autonomie is based on the pre-transmission (P2) configuration where the electric motor is placed between the engine and transmission for direct flow of power to the wheels. The vehicle can be propelled either by the combustion engine, electric motor, or both simultaneously, but the speed/efficiency region of operation for SHEVP2s under any engine/motor combination is ultimately dictated by the transmission gearing and

[1260] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-25.
[1261] 40 CFR 86.1870–12.

speed. Detailed discussion of SHEVPS and SHEVP2 modeling and validation are provided in the Argonne Model Documentations.[1262] Autonomie full vehicle models representing strong hybrids were based on vehicle test data from vehicle benchmarking.

As discussed previously in this section, power-split hybrids utilize a combustion engine, two electric machines and a planetary gear set along with a battery pack to propel the vehicle. The smaller motor/generator (EM1) is used to control the engine speed and uses the engine to either charge the battery or to supply additional electric power to the second "drive" motor. The more powerful drive motor/generator (EM2) is permanently connected to the vehicle's final drive and always turns with the wheels. The SHEVPS resizing algorithm makes an initial estimate of the size of the engine, battery, and electric motors. The initial estimates for the combustion engine and EM2 sizes are based on the peak power required for acceleration performance and the continuous power required for gradeability performance. The initial estimates for the battery and EM1 powers are based the maximum regenerative braking power. With these initial size estimates, the algorithm computes the vehicle mass, and simulations are run to determine if 0-60 and 50-80 mph acceleration performance is acceptable. If acceleration is not satisfactory (too fast or too slow), the algorithm iteratively adjusts the sizes of the engine, motors, and battery, and runs simulations until a minimum powertrain size is found that meets all requirements. With each iteration, the engine, battery, and motor characteristics were also updated for gradeability performance and regeneration, if necessary. Figure VI-86 below shows the general steps of the SHEVPS sizing algorithm. Detailed descriptions are available in section 8.3 of the FRM Argonne Model Documentation.

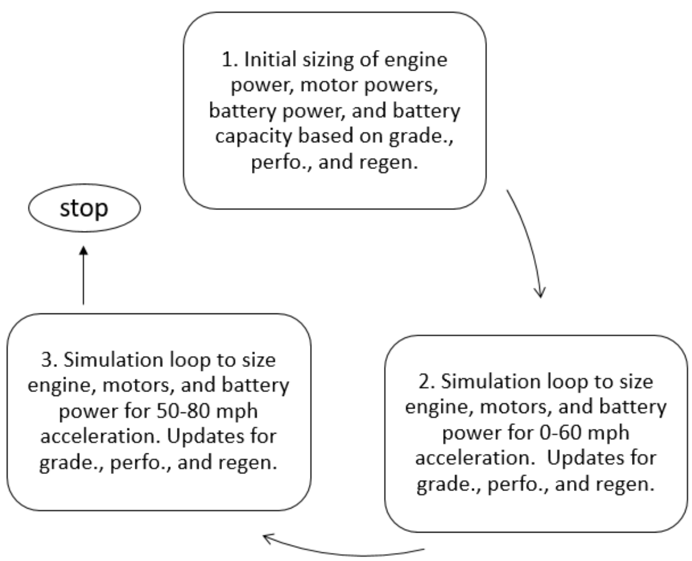

Figure VI-86 – Simplified SHEVPS Sizing Algorithm in Autonomie

A parallel hybrid (SHEVP2) uses a combustion engine and a multi-speed transmission-integrated electric motor (EM1), as discussed previously in this section. As is done with

[1262] FRM ANL Model Documentation, at Chapters 4.13, 4.16 and 6.0.

SHEVPS, the SHEVP2 resizing algorithm creates a starting point by making an initial estimate of the size of the engine, battery, and electric motor based on performance criteria or an estimated regenerative braking power, in turn calculating the associated vehicle mass. The algorithm then uses a simulation loop to find a more precise value of regenerative braking power generated in the UDDS "city driving" cycle, and adjusts the electric motor size and vehicle mass accordingly. Next, the algorithm uses simulation loops to optimize the engine, motor, and battery sizes in relation to acceleration performance criteria. In the event that the acceleration criteria requires downsizing the powertrain, the electric motor size is not reduced as this would not be suitable for the handling of regenerative braking power. If the acceleration criteria cause the electric motor to increase in size, the algorithm then returns to the regenerative braking loop and subsequently all other loops until all components are optimized. Figure VI-87 below shows a simplified sizing algorithm for SHEVP2s.

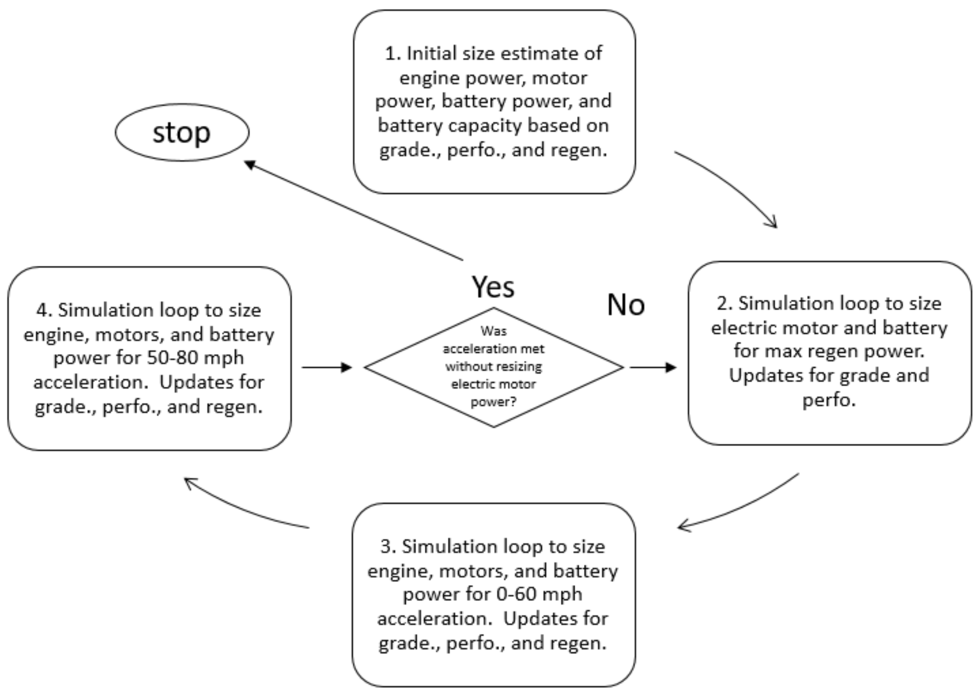

Figure VI-87 – Simplified SHEVP2 Sizing Algorithm in Autonomie

In the NPRM, the acceleration optimization loops in the SHEVP2 algorithm did not resize the powertrain if the resulting acceleration time was less than the target. This strategy was intended to avoid reducing the engine size compared to the conventional vehicle, mimicking an observed marketplace trend in which parallel hybrid models tend to retain similar engine sizes as the non-hybrid models bearing the same nameplate. However, in some cases this resulted in overly aggressive SHEVP2 acceleration times; to further maintain performance neutrality, the final rule sizing algorithm for standard (non-performance) SHEVP2 vehicle powertrains was changed to allow engine downsizing such that acceleration performance could converge toward the target value. This algorithm update is also detailed in Section VI.B.3.a)(6), Performance Neutrality.

CARB, ICCT, Meszler and ACEEE commented that some combinations of advanced engines mated with strong hybrids were illogical and inefficient.[1263,1264,1265,1266] The commenters specifically discussed combinations of SHEVP2 with TURBO2 and CEGR1 technologies that stated the incremental effectiveness resulted in near zero to negative value, but also clarified that not all combinations showed inappropriate effectiveness. CARB further expanded that "[t]hese are not likely combinations utilized by manufacturers as they unnecessarily add both gasoline technology and hybrid technology that negates many of the benefits of the advanced gasoline technology. This error in the Agencies' modeling leads to inflated technology costs on vehicles that are converted into P2HEVs."[1267]

The agencies now conclude that the NPRM included certain engine and strong hybrid pairings that resulted in incremental effectiveness that exceeded a reasonable level of performance neutrality. The agencies also agree that Autonomie should model strong hybrid technology combinations with other engine technologies. In response to these comments, for the final rule analysis the agencies updated the CAFE model to allow the use of HCR engine technologies with strong hybrids, as discussed in Section VI.C.1.c)(5) Engine Maps, HEV Atkinson Cycle Engines, and improved full vehicle modeling of turbocharged engine combinations. These changes were discussed in Section VI.B.3.a)(1) Full-Vehicle Modeling, Simulation Inputs and Data Assumptions and Section VI.C.2.e)(1)(a) Shifting Controller.

In addition, the agencies limited adoption of advanced engine technologies with strong hybrids in cases where the electrification technology would have little effectiveness benefit beyond the benefit of the advanced engine system, but would substantially increase costs. Specifically, the agencies did not model strong hybrid technologies with VCR engines (eng26a) and eBoost engines (eng23c). The agencies believe that manufacturers would not consider these combinations because the combination of electrification and advanced engine technologies are not as cost-effective as other technologies.

(c) Plug-in Hybrid Vehicles

The effectiveness of the PHEV systems in the analysis was dependent on both the vehicle's battery pack size and range, in addition to the other fuel economy-improving technologies on the vehicle (e.g., aerodynamic and mass reduction technologies). For the NPRM analysis, the electrification components were sized to achieve the specified all-electric range (AER) on the combined cycle (UDDS + HWFET) on the basis of adjusted energy values. As mentioned above, the PHEV would provide propulsion energy for a limited range in addition to start-stop or idle-stop. The NPRM analysis classified PHEVs into two levels: (1) PHEV30

[1263] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 155.
[1264] American Council for an Energy-Efficient Economy, ACEEE SAFE NPRM comments, Docket No. NHTSA-2018-0067-12122-22, at 8.
[1265] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-25.
[1266] Comments from Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA-2018-0067-11723, at 14.
[1267] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 186.

indicating a vehicle with an AER of 30 miles; and (2) PHEV50 indicating a vehicle with AER of 50 miles.

The resizing algorithm for plug-in hybrid (PHEV) vehicles, similarly as for SHEVs, considered the power needed for acceleration performance and all-electric mode operation (compared to regenerative braking for SHEVs); the PHEV resizing algorithms used those metrics for an initial estimation of engine, motor(s) and battery powers, and battery capacity. The initial mass of the vehicle was then computed, including weight for a larger battery pack and charging components.[1268] However, since PHEVs offer expanded electric driving capacity, their resizing algorithm must also yield a powertrain with the ability to achieve certain driving cycles and range in electric mode, in which the engine remains off all or the majority of the operation. The analysis sized the PHEV electric motors and battery powers to be capable of completing either the City Cycle (UDDS) or US06 (aggressive, high speed) driving cycle in electric mode, and the battery energy storage capacity to achieve the specified all-electric range on the 2-cycle tests on the basis of adjusted energy values.[1269,1270]

The final rule analysis classified PHEVs into four technology levels, as discussed previously: (1) PHEV20 indicating a vehicle with an AER of 20 miles and powertrain system based on SHEVPS hybrid architecture; (2) PHEV50 indicating a vehicle with an AER of 50 miles and powertrain system based on SHEVPS hybrid architecture; (3) PHEV20T indicating a vehicle with an AER of 20 miles and powertrain system based on SHEVP2 hybrid architecture; and (4) PHEV50T indicating a vehicle with AER of 50 miles and powertrain system based on SHEVP2 hybrid architecture.[1271] The PHEV20, PHEV20T, PHEV50, and PHVE50T resizing algorithms were functionally equal, and differed only in the type of electric mode driving cycle simulated in each one (UDDS for PHEV20/20T, or US06 for PHEV50/50T). These algorithms simulated the driving cycles in an iterative loop to determine the size of the electric motors and the battery required to complete the cycles. In the case of PHEV20 and PHEV20T, the power of the electric motors and battery must be sized to propel the vehicle through the UDDS cycle in "charge-depleting (CD) mode;" in this mode, the electric machine alone propels the vehicle except during high power demands, at which point the engine may turn on and provide propulsion assistance. The PHEV50 and PHEV50T motor(s) and battery must be sized to power the vehicle through the US06 cycle in "electric vehicle (EV) mode," where the engine is off at all times. Then, all PHEV algorithms adjusted the battery capacity, or vehicle range, by ensuring the battery energy content was sufficient to complete a simulated UDDS+HWFET combined driving cycle, based on EPA-adjusted energy consumption. Finally, the engine, electric motor(s), and battery powers were then sized accordingly to meet 0-60 and 50-80 mph acceleration targets. All loops were repeated until the acceleration targets were met without

[1269] Battery sizing and definition of combined 2-cycle tests all-electric range is discussed in detail in ANL Autonomie Model Documentation Chapter 6 Test Procedure and Energy Consumption Calculation.

[1270] ANL has incorporated SAE J1711 standard into Autonomie Modeling. J1711: Society of Automotive Engineers Recommend Practice for Measuring Exhaust Emissions and Fuel Economy of Hybrid-Electric Vehicles, Including Plug-In Hybrid Vehicles.

[1271] As discussed previously, the NPRM analysis included PHEV30 instead of PHEV20. However, the related resizing algorithm is applicable to either.

needing to resize the electric motors, at which point the resizing algorithm finished. Figure VI-88 below shows the general steps of the PHEV sizing algorithm. Detailed steps can be seen in section 8.3 of the FRM Argonne Model Documentation.

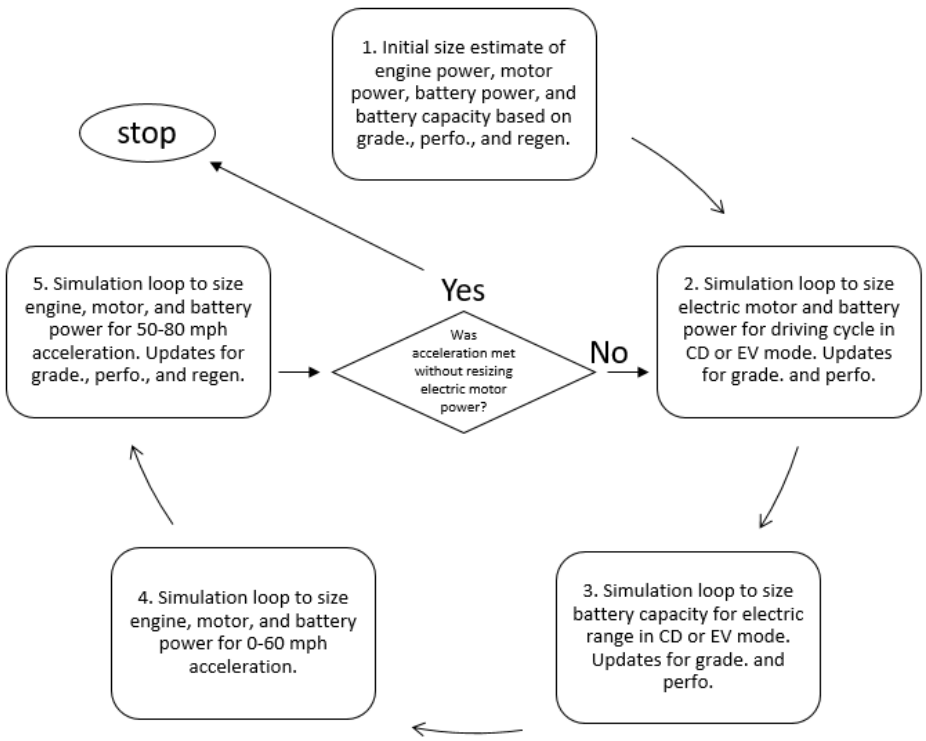

Figure VI-88 – Simplified PHEV Sizing Algorithm in Autonomie

Meszler, CARB, and BorgWarner provided comments on the effectiveness of the PHEV models. The commenters were concerned with underperformance of the technology, sizing of the components, and the variety of PHEV technologies available.

Meszler commented that PHEVs in the 2016 analysis fleet were inappropriately constrained in their future fuel economy potential by the ratio of baseline electric-only fuel economy to baseline engine-on fuel economy; and those vehicles should be allowed to improve that ratio over time, identically to vehicles that adopt PHEV technology during the analysis period.[1272]

The agencies must use the SAE J1711 method for determining the fuel economy for the PHEV systems. The use of SAE J1711 and the underlying duel fuel vehicle fuel economy calculations are defined by statute.[1273] However, it is important to note that PHEVs are not excluded from applying greater range technologies within the PHEV technology paths; that is, a PHEV with a lower AER can progress to become a PHEV with a longer AER.

[1272] Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA-2018-0067-11723 at 32.
[1273] 49 USC 32901(b)(1).

CARB commented that several aspects of the agencies' PHEV modeling contributed to increased PHEV costs. CARB stated that the electric motors were oversized, that all-electric vehicle efficiencies were low, and that the lack of battery resizing for road load reductions other than mass reduction resulted in battery energy capacities much higher than production vehicles.[1274] CARB stated the modeled battery capacity to achieve a given range (kWh/mi) was larger than what exists on several representative production vehicles.

The agencies agreed with CARB's comments that electric motors and batteries may be oversized. As a result, the agencies reviewed the sizing algorithms and methods used in the NPRM analysis and updated the model for the final rule analysis. The updates resulted in smaller motor sizes and battery pack sizes for electrified powertrains, as discussed above. In addition, the review also resulted in a change to the range categories used for the PHEVs in the final rule analysis; the final rule analysis classified PHEVs into two levels: (1) PHEV20 indicating a vehicle with an AER of 20 miles; and (2) PHEV50 indicating a vehicle with AER of 50 miles. For more discussion on the change in classifications see Section VI.C.3.a)(1)(e) Electrification Technologies, Plug-in Hybrids.

BorgWarner commented that "PHEVs and HEVs are complex systems and should be modeled in detail," and further provided, "[t]herefore, modeling should be inclusive of all approaches of PHEV and HEV and not be limited only to Atkinson Cycle engines."[1275] In response, the agencies created additional powertrain options for PHEV technologies for the final rule analysis. The additional PHEV technologies included a plug-in HEV using a turbocharged engine. The additional PHEV paths used in the final rule analysis are described in Section VI.C.3.a)(1)(e) Electrification Technologies, Plug-in Hybrids.

(d) Battery Electric Vehicles

Battery electric vehicles (BEVs) are vehicles with all-electric drive and with vehicle systems powered by energy-optimized batteries charged primarily from grid electricity. The effectiveness of BEV powertrains is dependent on the efficiency of the components that transfer power from the battery to the driven wheels. These components include the battery, electric machine, power electronics, and mechanical gearing. For the analysis, electric machine efficiency was based on efficiency maps derived from actual electrified vehicles, and was scaled such that the peak efficiency value corresponded to the latest state-of-the-art technologies. The range of the battery electric vehicles depends on the vehicle's class and the battery pack size. For the NPRM analysis, manufacturers could apply BEV technology with an AER of 200 miles. As discussed previously, the final rule analysis added a BEV 300 to reflect vehicles in the market for the MY 2017 analysis fleet. For further detailed discussion of how BEV sub-models are simulated in Autonomie see the FRM Argonne model documentation.[1276]

[1274] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 149. Specific comments related to costs are discussed in Section VI.C.3.e) Overview of Electrification Costs, below.
[1275] BorgWarner, BorgWarner NPRM public comments 10-26-2018 Final, Docket No. NHTSA-2018-0067-11895, at 10.
[1276] FRM ANL Model Documentation, at 4.6, 4.7, 4.13, 4.14, and 5.8.

The resizing algorithm for BEVs is functionally the same as the PHEV algorithm; the difference is that BEVs do not use a combustion engine, and thus this component was not included in the BEV algorithm. To begin, initial estimates of motor and battery powers were calculated based on the criteria of acceleration performance, gradeability performance, and vehicle range. Then, the algorithm successively ran four simulation loops to fine tune the powertrain size to ensure that all performance and operational criteria were maintained. First, the BEV motor and battery were sized to power the vehicle through the US06 cycle. Next, the battery capacity was adjusted to ensure the energy content is sufficient to complete a simulated UDDS+HWFET combined driving cycle, based on EPA adjustment factors to represent sticker values, and meet the vehicle range requirement. Finally, the electric motor and battery powers were sized accordingly to meet 0-60 and 50-80 mph acceleration targets. If either acceleration simulation loop resulted in a change to the electric motor size, the algorithm repeated all simulation loops. Once the acceleration targets were met without any resizing of the electric motors, the algorithm finished. Figure VI-89 below shows a simplified sizing algorithm for BEVs.

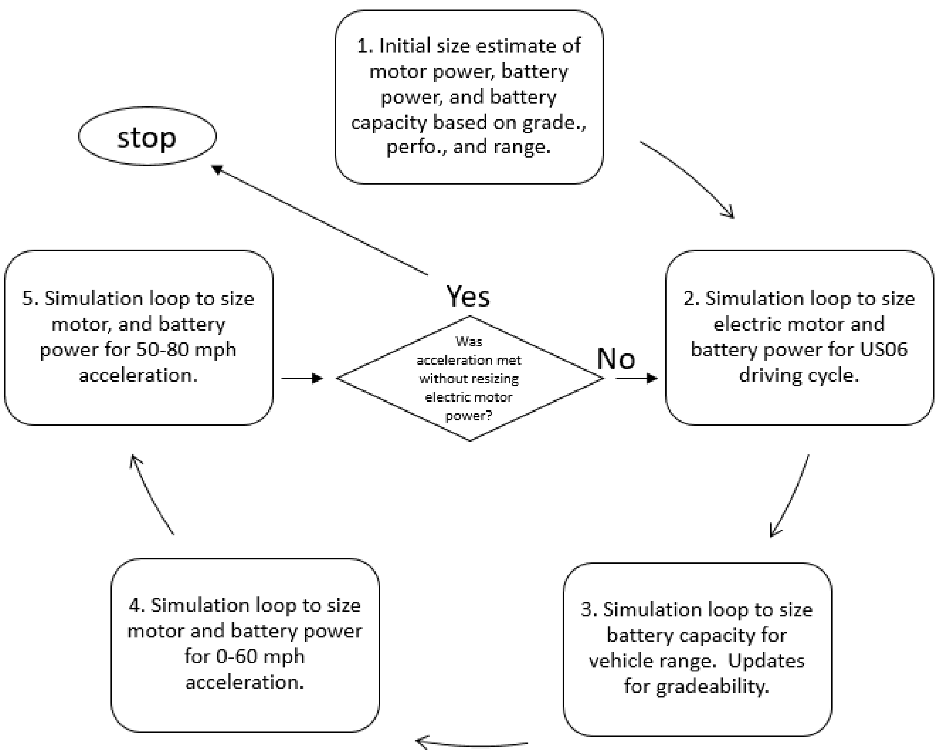

Figure VI-89 – Simplified BEV Sizing Algorithm in Autonomie

Meszler Engineering Services, commenting on behalf of NRDC, argued that the fuel economy for a vehicle adopting BEV technology was inappropriately dependent on the petroleum-based fuel economy of the transforming vehicle.[1277] Meszler reiterated that the fuel economy of the internal combustion engine that BEV technology replaces does not have any

[1277] Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA-2018-0067-11723 at 33.

impact on the efficiency of the resulting BEV, and the electric machine "should not care" whether it replaces a high or low efficiency engine, and should be modeled accordingly.

The agencies agree with Meszler that BEV effectiveness should be independent of the vehicle powertrain it will replace in production. This is, in fact, how the vehicle model and simulation was performed in Autonomie. Autonomie models the capabilities of each unique full vehicle system independently, including BEVs. As BEV technology is adopted by vehicles, the CAFE model uses the Autonomie databases to determine the added incremental efficiency that will bring a specific vehicle up to the appropriate level. Since the CAFE model considers a variety of vehicle types with differing powertrain types, vehicle technology classes, performance criteria, and physical properties (curb weight, etc.), each with a different overall effectiveness, the observed efficiency increment needed to achieve BEV effectiveness will vary with each case. While these increments may differ, the final effectiveness of a BEV is independent of the powertrain it replaced. The effectiveness used in the CAFE model represents the difference between the performance of the full vehicle models—the full vehicle model representing the baseline vehicle and the full vehicle model representing the end-state with all additional fuel economy improving technology applied, as discussed in Section VI.B.3 Technology Effectiveness Values.

ICCT alleged that the agencies did not assess BEV efficiency improvements from road load reductions (i.e., from mass reduction, tire rolling resistance, or aerodynamic improvements) to reduce the battery and power electronic component sizing costs.[1278] CARB similarly commented that battery packs were improperly sized, resulting in underestimation of electrified vehicle effectiveness. CARB stated that the NPRM constraints on battery sizing caused electrified vehicles to end up with oversized, less cost-effective battery packs. CARB further stated that battery designs are more scalable than engines and could thus be adjusted by manufacturers even at incremental technology steps.[1279]

For reference, battery resizing in the NPRM was constrained in the same manner as other powertrain components, such as the combustion engine. Resizing would typically be associated with a major vehicle or engine redesign, which in turn would justify the high costs of changing the powertrain. In the NPRM, the battery pack and other powertrain components were not resized for other improvements in incremental technologies such as AERO and ROLL. The agencies agree that battery packs, due to their modularity, should be capable of being resized at relatively lower cost and complexity, and thus should not be subject to the same resizing restrictions applied to other powertrain components such as conventional combustion engines. In consideration of CARB and ICCT's comments on battery pack resizing, for the final rule, the agencies allowed SHEV, PHEV, and BEV battery packs to be resized at all incremental technology steps, including for road load reduction technology improvements (aerodynamics, rolling resistance reduction, and low levels of mass reduction). This avoided the additional cost and range associated with oversized battery packs on BEVs and other electrified vehicles.

[1278] International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-82.
[1279] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 145.

CARB commented that the NPRM analysis oversized battery packs that targeted 200-mile label range, resulting in exaggerated battery pack costs. CARB also stated that some MY 2016-2018 BEVs exist that have a higher efficiency than simulated for BEV200s in Autonomie. They further argued that although these vehicles were assigned BEV200s, their actual range was greater than 200 miles.[1280]

We agree with CARB that the NPRM modeled and simulated battery packs were oversized and that the AERs for BEVs did not match the current and expected future vehicle AERs. In response to these comments, for the final rule analysis, the agencies removed certain constraints from the Autonomie battery sizing algorithm, allowing batteries to be sized as function of all road load reduction technologies. As discussed earlier, this additional battery sizing is feasible due to the modularity of battery pack construction. This update allowed the battery pack cost and mass to better reflect the actual required energy capacity and power, and improved the efficiency of modeled BEVs. The agencies also updated the modeling of electric machines used in BEVs to reflect improvements in efficiency. Furthermore, the agencies added the BEV300 (with an AER of 300 miles) to the final rule analysis, providing a better representation of production BEVs with more than 200 miles of range. For more discussion on BEV300 and electrification efficiency improvements, see Sections VI.C.3.a)(1) Electrification technologies and VI.C.3.d)(1) Electric Motors, Power Electronics and Accessory Load.

(e) Fuel Cell Vehicles

The fuel-cell system in the analysis was modeled to represent hydrogen consumption as a function of the produced power, assuming normal-temperature operating conditions with a peak system efficiency of 60 percent, including the balance of plant.[1281] The system's specific power is 650 W/kg. The hydrogen storage technology selected was a high-pressure tank with a specific weight of 0.04 kg H2/kg, sized to provide a 320-mile range on the 2-cycle tests on the basis of adjusted energy values.

The sizing algorithm for FCVs was similar to PHEVs and BEVs, but adapted to size the specific components of a FCV powertrain: the electric motor, fuel-cell, hydrogen (H_2) fuel tank, and battery pack. The electric motor drives the wheels needed to propel the vehicle. During very low power operation, the battery pack alone powers the motor/wheels, depleting the battery charge. At moderate driving loads, the fuel-cell provides electrical power (generated by consuming stored H_2) to the motor and also to charge the battery. Under heavy loads, both the fuel cell and battery deliver electric power to the motor. To begin, initial estimates of motor, fuel cell, and battery powers are calculated based on criteria for acceleration performance, gradeability performance, and vehicle range. Then, the algorithm successively runs four simulation loops to finetune powertrain size, ensuring that all performance and operational criteria are maintained. First, the FCV motor and battery are sized to power the vehicle through the US06 cycle. Next, the on-board mass of H2 fuel, as well as the fuel tank mass are adjusted to

[1280] California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 147.

[1281] Power needed for supporting components and auxiliary systems. The balance of plant in a fuel cell system is the auxiliary equipment required to ensure the fuel cell operates as a reliable power source. This may include fuel reformers and pumps, for example.

ensure the vehicle can complete a simulated 2-cycle test and meet the range requirement. Finally, the electric motor and fuel cell powers are sized accordingly to meet 0-60 and 50-80 mph acceleration targets. If either acceleration simulation loop results in a change to the electric motor size, the algorithm repeats all simulation loops. Once the acceleration targets can be met without any resizing of the electric motor, the algorithm completes. Figure VI-90 below shows a simplified sizing algorithm for FCVs.

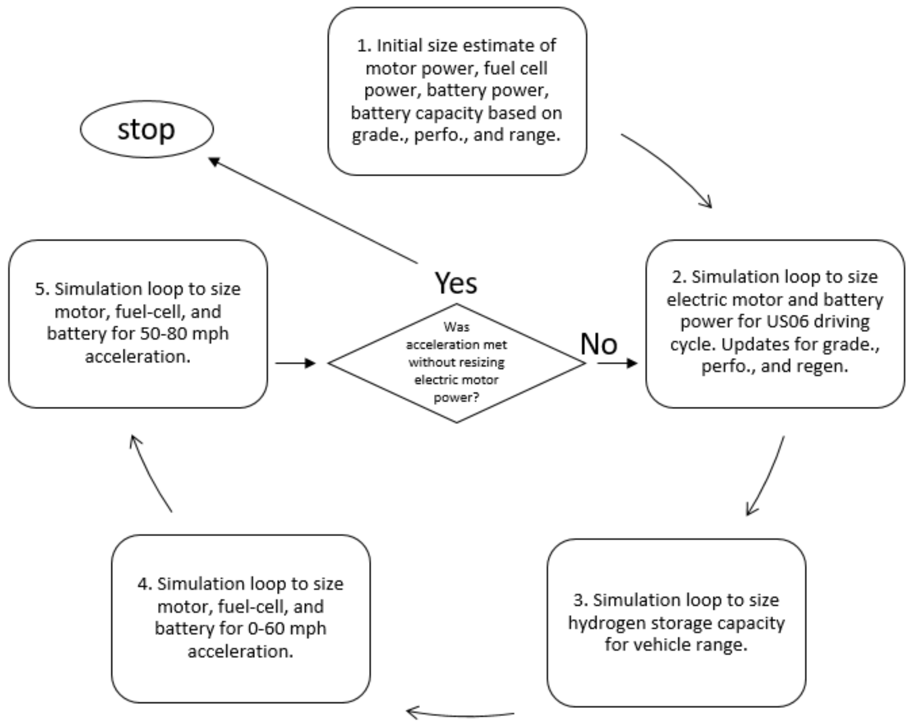

Figure VI-90 – Simplified Fuel Cell Vehicle Sizing Algorithm

The agencies did not receive comments on FCV modeling in Autonomie. For the final rule analysis, the agencies used the same FCV model and simulations to estimated effectiveness values.

e) Electrification Costs

The primary factors that influence the cost and effectiveness of hybrid or battery electric vehicles are the cost and efficiency of the energy storage components and electric machines. Energy storage components include battery cells, battery management systems, and thermal management systems. The electric machine components include electric motors, power electronics, controllers, and other devices that support thermal management.

Charging infrastructure is an essential component for PHEVs and BEVs, and may add to the total cost of ownership of the vehicle. However, most households are equipped with a 110-volt outlet for level 1 charging, for which no additional cost is incurred. Installing a level 2 charging outlet (220-volt) will add cost to the total ownership of the vehicle but decreases charging time. The price of level 2 residential charging equipment varies, but typically ranges from $500 to $2,000 before installation and state or utility incentives.[1282]

For this final rule analysis, the agencies used Argonne's BatPaC modeling tool to develop battery pack manufacturing costs as well as weight.[1283] Battery packs were sized in terms of the vehicle's energy and power requirement and costs were estimate for each of the simulated technology combinations. The Argonne team used BatPaC to create a "lookup table" with battery pack size (energy and power) and cost as well as weight data for the full vehicle simulations to "reference," to avoid the need for conducting a full BatPaC simulation for each unique vehicle modeled in the analysis. The table included cost data for each technology key and vehicle technology classes. As discussed below, Autonomie runs linearly interpolate between points in the lookup tables when deriving final values from BatPaC, the differences between using BatPaC for each configuration and the interpolation using the lookup table was insignificant.

The agencies used the cost of electric machines from U.S. DRIVE's October 2017 report, "Electrical and Electronics Technical Team Roadmap." In industry, manufacturers use different types of electric machines resulting in a range of actual costs for the systems. To capture this range, the agencies considered a single type of high efficiency electric machine, representative of the range of technology available in the rulemaking timeframe, uniquely sized for each of the simulated combinations. For the final rule analysis, the cost of the electric machine was determined using a dollar-per-kilowatt metric. The agencies sized the electric machines using the method discussed in Section VI.C.3.d) Electric Effectiveness Modeling and Resulting Effectiveness Values.

The following sections discuss the method used for modeling battery and non-battery component costs, the learning curves applied to those costs, and the total costs for each type of electrification technology considered in this final rule analysis.

(1) Battery Pack Modeling

BatPaC is a software designed for policymakers and researchers interested in estimating the manufacturing cost of lithium-ion batteries for electric drive vehicles.[1284] BatPaC is used to estimate the cost of manufacturing lithium-ion batteries and examine trade-offs that result from different battery performance specifications such as power and energy capacity. BatPaC includes a library of lithium ion electrode combinations and inputs for all the parameters associated with materials and manufacturing operations in a factory.

Specifically, BatPaC models stiff-pouch, laminated prismatic format cells, placed in double-seamed, rigid modules. The model supports liquid- and air-cooling, accounting for the

---

[1282] U.S. Department of Energy Office of Energy Efficiency and Renewable Energy, Charging at Home, https://www.energy.gov/eere/electricvehicles/charging-home (last visited March 20, 2020).
[1283] The agencies used BatPaC version 3.0 (released in 2015) for the NPRM and BatPaC version 3.1 (June 2018) for the final rule.
[1284] BatPaC: Battery Manufacturing Cost Estimation, Argonne National Laboratory, https://www.anl.gov/tcp/batpac-battery-manufacturing-cost-estimation.

resultant structure, volume, cost, and heat rejection capacity. The model considers cost of capital equipment, plant area and labor for each step in the manufacturing process. The model places relevant limits on electrode coating thickness, and considers limits applicable to current and near-term manufacturing processes. The model also considers annual pack production volumes and economies of scale for high-volume production.

BatPaC calculations are based on a generic pack designs that reasonably represents the weight and manufacturing cost of batteries deployed commercially. The advantage of using this approach is the ability to model wide range of commercial design specifications for the various classes of vehicles. This modeling approach is particularly advantageous because the data from commercially available battery packs is limited and varies widely with respect to the underlying specifications (power and energy) and constraints (mass, volume, dimensions, durability) set by the manufacturer.

BatPaC is a Microsoft Office Excel spreadsheets-based model. The data needed to design and build a battery pack, such as dimensions of the cell, estimate of materials, and manufacturing cost, are provided in the model, with the manufacturing costs for the designed battery based on a "baseline plant" designed for a battery of intermediate size and production scale so as to establish a center-point for other designs. BatPaC can be configured with alternative chemistries, charging constraints, battery configurations, production volumes, and cost factors for other battery designs by customizing these parameters in the modeling tool.

For this analysis, running individual BatPaC simulations for each full vehicle simulation requiring an electrified powertrain would have been computationally intensive and impractical, given that approximately 750,000 simulated vehicles out of the 1.2 million total simulated vehicles had an electrified powertrain. Accordingly, staff at Argonne built "lookup tables" with BatPaC to provide battery pack manufacturing costs, battery pack weights, and battery pack cell capacities for vehicles modeled in the large-scale simulation runs.

To build the lookup tables, Argonne staff selected a range of minimum and maximum values for battery pack power (kW) and battery pack energy (kWh) for each vehicle powertrain based on a combination of market analysis and analysis of the Autonomie simulations that were run for the NPRM and final rule. The performance requirements (vehicle acceleration times, EV range, etc.) were defined from set assumptions and validated from existing vehicles.[1285] The range, as well as the number of power and energy points considered to generate each lookup table, varies across powertrains. The minimum and maximum power and energy values have been selected to encompass current designs. For example, one end of the spectrum is representative of the MY 2016-2017 Tesla Model S 100D (100 kWh total battery energy, 335-mile range), while the other end of the spectrum is representative of the 2017 Mitsubishi iMiEV (16 kWh total battery energy, 62-mile range). The components were then sized in Autonomie across all vehicle classes to define the minimum and maximum values to be considered, as shown in Table VI-107.

[1285] *See* Final Rule Argonne Model Documentation Section 5.9, Battery Performance and Cost Model (BatPaC).

Table VI-107 - Power and Energy Ranges for the Vehicle Classes Defined with Autonomie

Vehicle Powertrain	**Battery Pack Power (kW)**		**Battery Pack Energy (kWh)**	
	Min Value	Max Value	Min Value	Max Value
Split HEV	23.5	67.1	1.0	2.8
Split PHEV20	37.9	73.2	7.1	14.4
EREV PHEV50	86.8	148.4	16.5	32.5
BEV200	103.1	295.4	45.2	104.7
BEV300	138.9	323.6	70.9	162.4

Figure VI-91 illustrates the inputs generated in Autonomie to create the BatPaC-based lookup tables, and the outputs characterized in the BatPaC-based lookup tables that are used to provide estimates referenced in the agencies' analysis. A linear interpolation was then performed in MATLAB to determine the associated values for battery pack manufacturing cost, weight, and cell capacity.

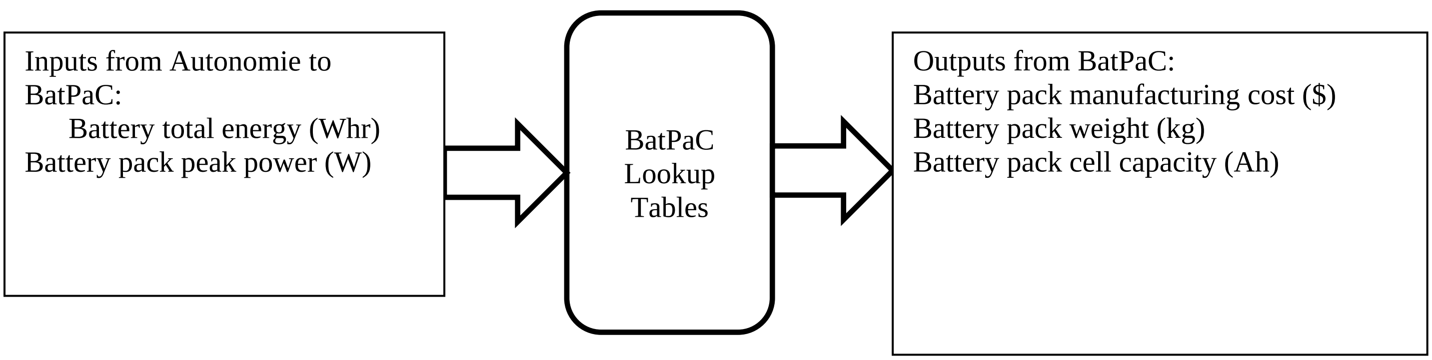

Figure VI-91 – Flowchart Showing How Autonomie Calls BatPaC Look-up Tables

Figure VI-92 shows the linear relationship between cost, power, and weight used to generate the compact passenger car BEV200 technology class lookup table presented in Figure VI-93. As seen from the figures below, the energy values produced by BatPaC consist of a fairly linear relationship with respect to power and energy for a vehicle class. Since Autonomie runs would linearly interpolate between the points in the lookup tables when deriving the final values from BatPaC, the differences between using BatPaC for each configuration and the interpolation using the lookup table were insignificant.

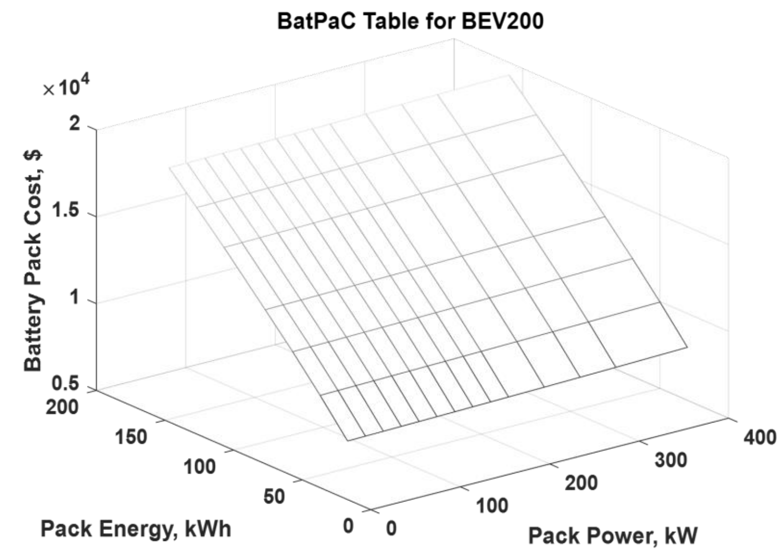

Figure VI-92 – Table Used to Generate Look-Up Table for BEV200 Compact Car Class

Figure VI-93 details the estimates of $ per kWh at the pack level generated from the lookup table for BEV200 compact cars used in the final rule analysis. As discussed further below, the specific battery costs for each simulated vehicle were presented for the NPRM (and now for the final rule) in the docketed Argonne assumptions files and in the vehicle simulation database included in the CAFE model.

	BEV200		Energy, kWh			
			30.0	50.0	70.0	90.0
$/kWh at Pack Level (Total Energy)	Power, kW	20.0	$ 255	$ 192	$ 163	$ 146
		40.0	$ 256	$ 192	$ 164	$ 146
		60.0	$ 257	$ 193	$ 164	$ 147
		80.0	$ 257	$ 193	$ 164	$ 147
		100.0	$ 258	$ 193	$ 164	$ 147
		120.0	$ 258	$ 194	$ 165	$ 147
		140.0	$ 259	$ 194	$ 165	$ 147
		160.0	$ 260	$ 195	$ 165	$ 148
		180.0	$ 260	$ 195	$ 165	$ 148
		200.0	$ 261	$ 195	$ 166	$ 148
		240.0	$ 262	$ 196	$ 166	$ 148
		280.0	$ 264	$ 197	$ 167	$ 149
		320.0	$ 265	$ 198	$ 167	$ 149
		400.0	$ 268	$ 199	$ 168	$ 150

Figure VI-93 - BEV200 (Compact) $ per kWh Look-up Table for the Final Rule Analysis

During the Autonomie large-scale simulation runs, calling the BatPaC model for each individual simulation would have been computationally intensive. Using the MATLAB lookup tables reduced the time to run the approximately 750,000 simulations significantly, which in turn reduced the total simulation run time for all of the technology combinations by several days with insignificant impact on the analytical results.

(a) BatPaC Inputs and Assumptions

The Argonne documentation describing the analysis performed for the NPRM, "A Detailed Vehicle Simulation Process To Support CAFE Standards," detailed the specific assumptions that Argonne's experts used to simulate batteries and their associated costs for the full vehicle simulation modeling.[1286] In addition, detail on the NPRM electrification analysis was presented in the PRIA.[1287] While the Argonne Summary of Main Component Assumptions Excel file correctly identified the chemistry used in the NPRM analysis as NMC333,[1288] the PRIA inadvertently described that NMC441 was used. The agencies presented selected lookup table battery cost values in the Argonne Summary of Main Component Assumptions Excel file,[1289] as shown above, and the specific battery costs for each simulated vehicle were presented for the NPRM and final rule in the vehicle simulation database included in the CAFE model.

Several commenters claimed that costs for electrification technologies were too high, especially regarding battery costs (note that comments on non-battery component costs are addressed separately in Section VI.C.3.e)(2) Non-battery Electrification Component Costs, below).[1290] Several commenters pointed to text in interagency review documents that stated the NPRM battery modeling costs were higher than what EPA recommended,[1291] and higher than what EPA had obtained from the most recent version of the BatPaC model.[1292]

CARB commented that the agencies incorrectly identified and assessed existing technologies, improperly oversized components and batteries for the modeled vehicle classes, and underestimated technology efficiency through improper modeling.[1293] CARB also submitted supplemental comments (discussed further, below) stating that the PRIA and the underlying modeling were inconsistent regarding which exact battery chemistries were modeled for every electrified model in the fleet, which CARB argued was crucial for understanding the battery compositions and thus their production costs.[1294]

ICCT stated that the agencies misrepresented the leading research on both battery and electric vehicle costs, with the result being that electric vehicles were so costly that they were modeled to remain at approximately the same penetration in 2025 with the Augural 2025 fuel economy and adopted 2025 CO_2 standards, as they were in mid-2018 (i.e., between 1.5 percent

and 2 percent of new vehicle sales).[1295] ICCT stated that the agencies' inputs failed to reflect the latest industry data on future potential electric vehicle cost parity with combustion vehicles. ICCT commented that through a combination of incorrectly high electric vehicle prices (which, they argue, do not reflect Argonne or other leading battery research groups' work), and modeling restrictions on electric vehicles, the agencies unduly inflated technology costs of electric vehicles to comply with the standards. ICCT argued that although the agencies purported to use state-of-the-art tools like the BatPaC model for battery costs, the cost calculations erroneously pushed up electric vehicles' incremental costs above $10,000 per vehicle. ICCT claimed that the agencies introduced errors that artificially pushed up the battery costs higher than indicated by BatPaC and other experts in the field.

NCAT noted that the PRIA described some ways in which the modeling increased battery costs, namely, that the battery pack costs were adjusted upwards, the cost of the battery management system increased, and a cost for a battery automatic and manual disconnect unit was added.[1296] Regardless, NCAT stated that the agencies analysis was not sufficiently transparent, and argued that the battery costs were significantly overestimated in the modeling supporting the NPRM. Boulder County Public Health and other Colorado municipal organizations claimed that overstated battery costs had the effect of mischaracterizing and downplaying the benefits of increased numbers of electric vehicles as part of the vehicle fleet.[1297] Commenters also argued that discrepancies existed between battery costs used in the rulemaking documents and battery costs found in the Argonne database, referring specifically to BISG and CISG costs (discussed further below).[1298]

In addition to comments claiming that the agencies' battery cost projections were incorrect or difficult to interpret, many commenters submitted general information about the state of battery technology and cost advances now and as projected into the future. For example, NCAT stated that battery technology has improved and battery costs have fallen dramatically, due in part to reduced material costs, manufacturing improvements, and higher manufacturing volumes.[1299] In compliment, NCAT asserted that the demand for EVs is growing "dramatically."

ICCT stated that the agencies' analysis of electric vehicle costs and the resulting extremely low penetration levels was not in line with automakers' announcements, which included statements that they would produce far greater numbers of electric vehicles to comply with standards around the world.

ICCT summarized projections of electric vehicle battery costs for 2020-2030, and stated that the agencies did not analyze the studies and automaker announcements they cited to understand the potential for cost-effective electric drive technology.[1300] ICCT stated the data

[1299] National Coalition for Advanced Transportation, NHTSA-2018-0067-11969. NCAT also stated that the increase in mass manufacturing of lithium-ion storage is expected to continue to reduce battery prices.
[1300] International Council on Clean Transportation, NHTSA-2018-0067-11741.

they reviewed included a variety of different technologies, production volumes, and cost elements, and although there were differences in methods for each, "they generally include in some variation of material, process, overhead, depreciation, warranty, and profit costs." ICCT summarized the results of their review, projecting that battery pack costs will decline to $150/kWh by 2020-2023 and then to about $120-$135/kWh by 2025, with the exception of Tesla, which reports costs of $150 kWh in 2018 and projected costs of $100/kWh by 2022. ICCT stated that the results of this review were corroborated in the aforementioned EPA interagency comments on battery costs used in the proposal.

NCAT stated that the average price of a battery pack dropped from $1,000/kWh in 2010 to $209/kWh in 2017, demonstrating a decrease of 79 percent in seven years.[1301] NCAT stated Tesla is on track to achieve $100/kWh by the end of 2018, and Audi has been buying batteries at $114/kWh, according to trade press reports.[1302] NCAT also cited BNEF analyses showing that battery costs are projected to continue to decline substantially,[1303] specifically projecting a decrease in battery cost of 77 percent between 2016 and 2030. Accordingly, NCAT stated that EVs will be less expensive to buy than conventional gasoline vehicles by 2025 in the United States.[1304] Workhorse similarly echoed the assertion that EV costs will reach parity with conventional vehicle costs before 2025.[1305]

NCAT also cited the ICCT Efficiency Technology and Cost Assessment, which concluded that, primarily because of rapid developments in battery pack technologies, EV costs will be reduced by $4,300-$5,300 per vehicle by 2025 compared to EPA's prior estimates in support of the MY 2017-2025 standards.[1306] In that report, ICCT concluded that battery costs of $140/kWh is a realistic estimated value by 2025, as compared with EPA estimates in the 2016 Mid-Term Evaluation (MTE) analysis of $180-200/kWh.[1307]

[1307] *Id*.

NCAT also cited improvements in manufacturing techniques, specifically by Tesla, as an example of how batteries are being manufactured in large volumes with high quality at low cost.[1308] NCAT stated that in mid-2018, Tesla was producing batteries at its Gigafactory 1 facility at an annualized rate of roughly 20 GWh, making it the highest-volume battery plant in the world.[1309] NCAT and other commenters also cited Bloomberg's New Energy Finance research stating that the average energy density of EV batteries is improving at around 5-7 percent per year.

Finally, Workhorse commented that they have more than ten years of experience in the field of designing and assembling battery packs, and their business plans are predicated on battery costs much lower than assumed by the agencies.[1310]

As explained above, the agencies consulted with and relied on Argonne battery experts to develop inputs to the BatPaC model and generate the battery cost lookup tables used as references for the Autonomie full-vehicle simulations, as detailed in Argonne's documentation supporting the NPRM analysis.[1311] As explained further below, the agencies also directed CARB to information about the NPRM battery cost analysis available in the public docket in response to their FOIA request.

Commenters are correct that the EPA Draft TAR and Proposed Determination estimates for battery sizing and cost were different than the NPRM analysis. For the Draft TAR and in the Proposed Determination, a separate battery and motor sizing spreadsheet was built to determine the energy and power requirements for PHEVs and BEVs at different curb weights, and then BatPaC was used to determine specific energy (kWh/kg) and the battery pack cost estimate.[1312] For this NPRM and final rule, the energy requirements for PHEVs and BEVs were determined using Autonomie simulations with the integrated BatPaC lookup table to select the appropriate battery pack size, cost, and weight. As discussed in Sections VI.B.3.a)(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation and VI.B.3.a)(6) Performance Neutrality, the Autonomie full-vehicle simulation modeling assessed metrics to ensure performance requirements were met for every modeled vehicle. Appropriately accounting for vehicle metrics and individual vehicle power and weight requirements resulted in some of the differences observed between the Draft TAR and Proposed Determination estimates and the estimates presented in the NPRM and this final rule.

For the final rule, the agencies considered these public comments, market observations, literature, industry reports, and additional research. In addition, as described further below and in the Argonne documentation accompanying this final rule, Argonne consulted the A2Mac1

database for additional data points on batteries that were used to inform the final rule battery cost modeling.

As discussed above, BatPaC version 3.0 was used for the NPRM analysis because that was the most up-to-date version of BatPaC available at the time the NPRM analysis was being conducted. BatPaC version 3.1, released after the NPRM analysis was completed, was used for this final rule because that was the most up-to-date version of BatPaC available at the time the final rule analysis was being conducted.

The agencies note that BatPaC version 4.0 has been released since the analysis was completed for this final rule. Specifically, that version was released on January 14, 2020, after the rule had been submitted for interagency review. The default battery chemistry in BatPaC version 4.0 continues to be NMC622, which as discussed further in Section (i) below, reflects the reasonable assumption this chemistry will likely continue to be used in the rulemaking timeframe based on its commercial application and market trends towards higher-nickel, lower-cobalt content chemistries.[1313] As explained in this section, and further in Section (c) below, the agencies' modeled costs for battery packs aligns with current industry estimates and closely tracks future projections of battery pack costs from the Department of Energy's Vehicle Technology Office (DOE VTO) lab targets.[1314,1315]

In addition to using BatPaC version 3.1 for this final rule, BatPaC assumptions were updated to reflect what the Argonne battery experts and the agencies believed would be representative and attainable of battery manufacturing trends in the rulemaking timeframe. Section (ii) provides additional information on BatPaC inputs and assumptions that were updated for the final rule based on public comments and the agencies own market observations and additional research. In addition, as discussed further below, for the final rule, the calculated battery pack weight and manufacturing cost was compared with the battery pack cost and weight data obtained through various benchmarking studies. The agencies believe that the Argonne methodology for producing the hundreds of thousands of battery pack cost estimates required for the full-vehicle modeling and simulation resulted in reasonable estimates of battery pack costs. The following sections provide additional context and response to comments on specific BatPaC inputs and assumptions used in the NPRM and final rule.

(i) Chemistry

The choice of chemistry for battery cells depends on the application and consideration of cost, energy density, and safety, among other factors. The PRIA described the battery pack cell chemistry used for different powertrain types modeled in the NPRM analysis.[1316] For Micro HEVs, BISG HEVs, CISG HEVs, and Full HEVs, the agencies used LFP-G, rather than LMO-G,

---

[1313] The agencies note that BatPaC version 4.0 provides a new option to build battery packs with NMC811.
[1314] Freyermuth, Vincent. Rousseau, Aymeric. "Impact of Vehicle Technologies Office Targets on Battery Requirements." ANL/ESD-16/22. Energy Systems Division, Argonne National Laboratory (2016).
[1315] Hummel et al., UBS Evidence Lab Electric Car Teardown – Disruption Ahead?, UBS (May 18, 2017), https://neo.ubs.com/shared/d1ZTxnvF2k/.
[1316] PRIA at 373.

because the latter has a limited lifespan which is expected to degrade functionality over a vehicle's lifetime, and has greater limitations on available ranges of battery charge and discharge rates. As described above, for PHEVs and BEVs, the Argonne "Summary of Main Component Performance Assumptions" file correctly stated that NMC333 was used, however the PRIA misstated that NMC441 was used.

Both UCS and CARB commented on the agencies' choice of battery chemistry, with UCS noting that this choice can have a large impact on performance and materials costs, and therefore on the modeled cost of drivetrain electrification.

First, both commenters stated that the NPRM documentation was inconsistent and unclear. UCS noted the discrepancy between the PRIA and Argonne model documentation, and also that the rulemaking documents stated the most recent version of Argonne's BatPaC model was used to estimate battery costs, but the default lithium ion chemistry in the current BatPaC model is NMC622. UCS stated the choice of NMC variant effects battery costs, as NMC622 replaces more expensive cobalt with nickel. UCS further stated it was not possible to determine the magnitude of the cost error in the PHEV and BEV battery pack costs, only that the costs were likely higher than current battery cost data supported.

CARB stated that the agencies' selected battery chemistries represented a step backward from previous analysis done for the Draft TAR. CARB claimed that the biggest lithium-ion production companies have indicated that they will use NMC811 for BEVs, and therefore NMC441 or NMC333 would not represent current technology going into BEVs or near-future BEV battery technology. CARB stated that NMC811 technology was expected to come to market in 2019, which is far sooner than anticipated, even in the agencies' prior analyses.

Commenters also noted that the chemistry chosen for mild and strong hybrids differed from what is used in current and announced HEVs. UCS stated that all non-plug-in hybrids in the proposed rule analysis used lithium iron phosphate (LFP) chemistry, but in practice, most hybrids on the road did not use this chemistry. UCS referenced the Toyota Prius and the new RAM 1500 pickup as examples of vehicles that do not use LFP chemistry. CARB similarly stated that the NPRM battery chemistry selection for PHEV and strong hybrid batteries does not represent many of the batteries that are being deployed in the market, nor have been, for several years now, but did not provide an alternative chemistry they believed to be better represented in the market. CARB stated that this resulted in a "misappropriation of higher costs for electrification technologies in the Agencies' analysis, and further highlights the Agencies' sudden lack of knowledge about electrification, despite the far more directionally correct projections in previous analysis for the 2016 Draft TAR and EPA's Proposed Determination."

Similarly, UCS pointed to a discrepancy in strong hybrid battery costs between the proposed rule estimates (greater than $1,200, even for the small car classes) and an estimate from Argonne in 2017 ($614), to argue that the lack of detailed information made it impossible to determine if the choice of battery chemistry was responsible for the discrepancy.

The agencies carefully considered these comments. As stated above, the agencies disagree that the discrepancy in the Argonne Summary of Main Component Performance Assumptions file and the PRIA over the use of NMC333 for the NPRM analysis limited commenters ability to comment on battery chemistry, as both UCS and CARB communicated a belief that the agencies choice of battery chemistry contributed to the overstated battery costs in the NPRM. The agencies understand how the choice of chemistry impacts battery costs, and many of the commenters' concerns intertwined the NPRM choice of battery chemistry with the NPRM battery costs. Here, the agencies respond to comments on the choice of chemistries. The agencies will also discuss costs below.

As stated earlier, although manufacturers use different battery chemistries in various HEV, PHEV, and BEV applications, the choice of chemistry for a given application depends on several factors including safety, stability, and functional requirements (high power or high energy requirements for performance) of the battery pack. In determining whether to select one battery chemistry over another, the agencies concluded that using commercially proven technologies that represented the current cost of production was more reasonable than assuming additional technologies would come to fruition during the rulemaking timeframe, and attempting to project the cost and effectiveness of such technologies. While there is ongoing research and development in battery chemistry and in other battery related technologies that have the potential to reduce costs and increase battery capacity, these technologies have yet to be proven viable for commercial use.[1317]

In addition, as discussed throughout this document, the agencies considered technologies that manufacturers could use to comply with standards in the rulemaking timeframe that reasonably represented the state of technology across the industry. While the battery chemistries used in commercial vehicles are largely confidential business information, proprietary teardown reports are one source of information used to learn more about the chemistries actually employed in the market. For both the NPRM and final rule, the agencies consulted Argonne's battery experts to determine the chemistries that should be modeled in the BatPaC analysis. Argonne consulted A2Mac1 battery pack teardown reports, which confirmed that indeed, manufacturers use a range of chemistries across the electrified vehicle types. Selecting battery chemistries that can reasonably represent the range employed in the market ensured that the analysis better captured the average of costs across the industry.

For example, in addition to the reasons listed in the NPRM, LFP has been proven in commercial use, as identified in literature and battery teardown reports.[1318] This presented a basis for using LFP, as the chemistry was reasonably representative of chemistries used in mild and strong hybrids at the time of the analysis. The agencies also considered that LFP's lower cost compared to other potential HEV battery chemistries (contrary to commenters' statements)

[1317] Recent Advances in Energy Chemical Engineering of Next-Generation Lithium Batteries, Engineering, Volume 4, Issue 6 (December 2018), at 831-847. Available at https://www.sciencedirect.com/science/article/pii/S2095809918312177. Some examples include lithium-sulfur battery cell chemistry and solid-state electrolyte battery cells.

[1318] Details of cell chemistry and battery cooling system are described in Nelson, Paul A., Gallagher, Kevin G., Bloom, Ira D., and Dees, Dennis W. *Modeling the Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles - SECOND EDITION* (2012), available at https://publications.anl.gov/anlpubs/2015/05/75574.pdf.

made it more attractive for vehicles with tight cost constraints, even with the associated lower energy density.

Similarly, although EPA selected NMC622 as the modeled battery chemistry for the Draft TAR, manufacturers were also using other NMC chemistries in hybrid and BEV applications in that timeframe depending on the required application. The chemistry selected for the NPRM, NMC333, was selected based on proprietary teardown reports that demonstrated the chemistry's commercial use: a survey of twelve MY 2013 to MY 2018 HEVs, PHEV, and BEVs showed that NMC333 was used in eleven of those vehicles, and NMC622 was only used in one.[1319]

Accordingly, the agencies believe that assuming LFP-G as the modeled cell chemistry for HEVs and NMC333 as the modeled PHEV and BEV chemistry for the NPRM analysis of battery costs was not unreasonable, based on their demonstrated commercial use in a range of electric vehicle applications. However, employing BatPaC version 3.1 for the final rule analysis also presented the opportunity to update the modeled battery chemistry used to assess battery costs.

The agencies similarly consulted Argonne battery experts on battery chemistry and trends to inform the final rule analysis. Argonne staff used the A2Mac1 database to determine real-world battery chemistry and configurations in different electric vehicle applications. As shown in the Argonne Full Vehicle Modeling documentation for the final rule, the A2Mac1 battery pack teardown analysis provided an array of data points on battery chemistries for different electric vehicle applications, among other relevant battery pack data, that informed the final rule battery analysis.[1320]

In determining which of these chemistries would best represent the range of chemistries demonstrated in the market, the agencies considered several issues. Due to the increasing manufacturing volume of battery packs with NMC, it is expected that NMC battery cells will continue to be used in battery packs across different electric vehicle applications in the future. The agencies considered concerns about NMC formulations with varying cobalt content, and issues including the current and future cost of cobalt,[1321] and the cobalt supply chain.[1322] These

[1320] *Id*.

[1321] *See, e.g.*, MIT Energy Initiative. 2019. Insights into Future Mobility, at 78. Cambridge, MA: MIT Energy Initiative ("…significant uncertainty remains about the steady-state price of cobalt in the future as demand and supply continues to increase [internal citation omitted]. Under our base case scenario, global demand for cobalt in 2030 from new EV sales (even if all EVs use batteries with the high nickel content of NMC811) would reach approximately 80% of the world's total cobalt output in 2016. Considering that only 15% of the worldwide demand for cobalt in 2017 was used in EV batteries (Jackson 2019), an increase in demand of this magnitude might result in higher prices for cobalt. Thus, automakers may need to move to different battery chemistries that are less reliant on cobalt to avoid raw materials shortages and price volatility.").

[1322] *See, e.g.*, Todd C. Frankel, *The Cobalt Pipeline: Tracing the path from deadly hand-dug mines in Congo to consumers' phones and laptops*, Washington Post (Sept. 30, 2016), https://www.washingtonpost.com/graphics/business/batteries/congo-cobalt-mining-for-lithium-ion-concerns, among others, have led to the market shift towards cathode active materials with a higher fraction of nickel and less cobalt.[1323] Manufacturers have demonstrated the use of NMC622, which contains more nickel and less cobalt than NMC333, in different electric vehicle applications. In addition, as CARB noted and has been reported in the news for some time, the expected next step in battery chemistries using even less cobalt is NMC811. However, the shift to higher-nickel-content chemistries is not without challenges; increasing nickel content results in lower thermal stability, leading to safety concerns.[1324]

For the final rule analysis, based on these considerations, the agencies in consult with Argonne determined that it was reasonable to model HEV, PHEV, and BEV batteries using NMC622 as the cathode active material, as shown in Table VI-108 below.

Table VI-108 – Battery Chemistry Applications in the NPRM and Final Rule

Battery Chemistry Application		
	BatPaC version 3.0	BatPaC version 3.1
	NPRM	Final Rule
Micro HEV	LFP	LFP
Mild HEV	LFP	LFP
HEV	LFP	NMC622
PHEV	NMC333	NMC622
BEV	NMC333	NMC622

The agencies recognize that there will be advancements in battery chemistries during the rulemaking timeframe. As discussed further in Section (3), below, the analysis accounts for the potential that battery costs will decrease, but in a technology-agnostic manner. The agencies used BatPaC to model battery costs for the analysis by modeling battery prices in a specific year—in this case, MY 2020—and then used learning curves to reduce the cost of batteries over time. The learning curves act as a proxy for potential future improvements in battery chemistry and other battery-related advancements that would reduce costs. Using the learning curves in

this way makes it unnecessary to make inherently uncertain projections of potential future improvements in battery chemistry over time.

BatPaC version 4.0, which contains NMC811 as a chemistry option, was released after the analysis for this rule was completed. However, the cost estimates generated in BatPaC version 3.1 using NMC622, with discussed learning curves applied, resulted in estimated $/kWh battery pack costs during the rule making time frame within a reasonable range of other estimated projections that considered NMC811 as the predominant battery chemistry. As discussed further in Section (3), a significant shift in battery chemistry alone is only one factor required to significantly lower battery costs; other developments like increases in battery pack production quantities and cell yield (plant efficiencies) would be required to reach the commonly-cited $100/kWh target.

The agencies recognize that the specific chemistries manufacturers may choose for future model years may or may not be the same as the chemistries selected by the agencies for the analysis. However, this approach mirrors the approach taken to modeling technology effectiveness and cost used across the analysis; the modeled technology effectiveness and cost represents a level of performance representative of the typical range of performance across industry. If the agencies modeled pre-production battery chemistries unlikely to be widely adopted by the industry for several years, the analysis would likely under-predict the actual cost and effectiveness of electrification technology application. Accordingly, the agencies determined that using LFP-G as the modeled chemistry of choice for mild hybrids and NMC622 as the modeled chemistry of choice for strong HEVs, PHEVs, and BEVs was reasonable.

(ii) Other Updated Inputs and Assumptions for the Final Rule

The agencies also refined other inputs and assumptions used for modeling battery costs in BatPaC, based on a review of public comments and subsequent review of market research, technical publications, and other information.

Argonne continuously studies the battery pack designs of existing electrified vehicles in the market, using, among other information, detailed battery pack teardown analysis reports spanning a range of electrified vehicle types and vehicle classes produced over a range of MYs. For the final rule, Argonne utilized detailed battery pack teardown analysis reports for 10 MY 2013 to MY 2018 vehicles from A2mac1,[1325] as shown in the Table VI-109 – below.

[1325] Argonne Vehicle Modeling for Safer Affordable Fuel Efficient (SAFE) Vehicles Final Rulemaking, Section 5.9 Battery Performance and Cost Model (BatPaC), referencing A2Mac1 Automotive Benchmarking, https://a2mac1.com.

Table VI-109 – Vehicles Used to Evaluate Final Rule BatPaC Assumptions

Full HEV	**PHEV20**	**PHEV50**	**BEV200**	**BEV300**
2016 Toyota Prius	2016 Prius Prime	2016 Chevrolet Volt	2017 Chevrolet Bolt	2018 Hyundai Kona
2013 Ford Fusion	2016 Mercedes-Benz GLE 550e PHEV			
2014 Honda Civic	2016 BMW X5 xDrive40e PHEV			
2014 VW Jetta				

The teardown analysis reports were used to evaluate different battery pack design criteria, including battery pack power, battery pack energy, battery pack configuration, total number of cells per module, number of modules per pack, battery pack mass, energy density (cell/pack), cell voltage, battery pack voltage, cathode chemistry, cell capacity, and pack capacity. The metrics data collected from teardown analysis were used to estimate the battery pack manufacturing cost and mass (energy density – Wh/kg) in BatPaC for these exemplar vehicles from the A2Mac1 database. The data collected was also used to validate the battery pack design assumptions in BatPaC for the final rule. The four metrics that BatPaC provides are: battery pack manufacturing cost, battery pack weight (energy density – Wh/kg), battery pack capacity (Ah) and nominal battery pack voltage. Since the A2mac1 teardown reports do not avail the manufacturing costs of these battery packs, the analyses and comparisons were limited to the scope of the other three criteria.

For the NPRM, Argonne used the U.S. Department of Energy VTO targets for battery energy density (Wh/kg) for high energy and power density (W/kg) for high powered batteries.[1326] As a result of the analysis discussed above Argonne updated the method of estimating battery pack weight for each battery pack design in the final rule analysis. The analysis revealed greater influences on battery pack design by usable energy density characteristics then was initially assumed for the NPRM. For the final rule analysis BatPaC was used for battery pack weight estimates along with manufacturing cost estimates.

As discussed further in Section VI.C.3.e)(1)(c) Battery Pack Costs, the number of cells per pack influenced total battery pack costs for the final rule. As result of the analysis discussed above Argonne updated the number of cells in each battery. For the final rule analysis battery cell counts increased or decreased for some battery pack designs, while battery counts for some designs remained the same. Argonne's process for evaluating different design criteria for electrified vehicles is detailed further in the Argonne model documentation.[1327]

The agencies also updated other BatPaC inputs and assumptions based on additional market information or research. For the NPRM, the agencies modeled battery packs in BatPaC

[1326] Modeling the Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles, ANL/CSE-19/2.
[1327] A Detailed Vehicle Simulation Process To Support CAFE and CO2 Standards for the MY 2021 - 2026 Final Rule Analysis, Section 5.9 Battery Performance and Cost Model (BatPaC).

using the default values associated with the baseline manufacturing plant, including an annual production rate of 100,000 batteries.[1328]

The estimate for battery pack costs incorporates an assumption of the battery pack production volume. Both BatPaC version 3.0, used in the NPRM, and BatPaC version 3.1, used in the final rule, include a default value assumption of 100,000 battery pack units manufactured per year per manufacturing plant as well as the plant efficiency (cell yield) of 95 percent. For the final rule, the agencies adjusted the production volume assumption used in BatPaC version 3.1 to 25,000 battery pack units, based on the analysis presented below.

As described in the BatPaC model documentation, the BatPaC models the differences in pack designs and how they affect the costs of one or more steps in the battery production process and the physical plant layout.[1329] For example, increasing the power of the battery packs without increasing the number of cells, or cell capacity, results in the model increasing the area of the cells and decreasing the electrode coating thickness. This results in an increased cost of the coating equipment, the floor area occupied by the equipment, and the direct labor for the process.[1330,1331] The agencies are aware that each manufacturer (not brand) has a unique battery pack design that differs from other manufacturers. Accordingly, it is likely that each manufacturer's BEV models had distinct characteristics, such as unique battery packaging space, energy requirements, thermal control systems, and safety systems, which cause battery pack designs to vary between each manufacturer.

Thus, the agencies determined that even though one battery manufacturer might manufacture batteries for multiple vehicle manufacturers, the default BatPaC assumption of 100,000 battery pack units manufactured per plant likely did not account for all of the cost differences in pack designs between manufacturers. Therefore, the agencies assumed the production volume of each battery pack type was reasonably represented by the BEV production volume for each manufacturer. The agencies also assumed that battery pack manufacturing plants operated at reasonable capacity during that timeframe, which would produce the lowest cost assumption.

The agencies analyzed BEV sales for MYs 2016-2019, referencing data collected by the Department of Energy.[1332] Table VI-110 shows that individual manufacturer U.S. BEV sales are substantially below 100,000 units per year except for Tesla, beginning in MY 2018 Tesla is a

vertically integrated battery and BEV manufacturer, which is not the model the remainder of the industry has implemented, or intends to, based on the agencies current understanding. More specifically, Tesla sold more BEVs than all manufacturers combined in MYs 2016, 2018, and 2019. 2017 was the only year in which all other manufacturers *combined* sold more BEVs than Tesla. Ultimately, in selecting a battery pack volume estimates for an industry-wide assessment, the agencies sought to accurately account for both the representative production volumes and representative practices applicable to the industry. As such, the agencies evaluated the average per manufacturer volumes, less the outlying and vertically integrated volumes of Tesla (shown in Table VI-111). As depicted in Table VI-110 and Table VI-111, the data show that the average annual sales of BEVs for individual manufacturers, excluding Tesla, is just 5% of the default battery pack production volume in BatPaC.

Table VI-110 – BEV Sales in the U.S. from 2016 to 2019

U.S. BEV Sales by Model in Order of Market Introduction						
Vehicle	Type	2016	2017	2018	2019	Total
Nissan Leaf	EV	14,006	11,230	14,715	12,365	52,316

Table VI-111 - Individual Manufacturer Average Annual BEV Sales in the U.S. from 2016 to 2019

Vehicle	Number of Manufacturers	Type	2016	2017	2018	2019
All Manufacturers[1333]	11	EV	7885	9499	21,711	21,992
Total (all Tesla Models)	1	EV	49,800	49,970	191,627	189,355
Total (all Non-Tesla Models)	10	EV	3693	5452	4719	5255

In consideration of this data, when estimating the production volume in the final rule analysis, the agencies selected a value of 25,000 units per year per manufacturer as a reasonable estimate for the average industry for MY 2020, which is the base model year for estimated battery pack costs using BatPaC version 3.1. As discussed in Section VI.C.3.e)(3) Electrification Learning Curves, other model year battery pack costs are estimated using cost learning. Using the default production volume of 100,000 units per year per manufacturer, the agencies would have underestimated the actual cost of battery pack production for MY 2020, as the model assumes that production costs decrease as production volumes increase. By selecting the value of 25,000 units per year per manufacturing plant, the battery cost estimate from the BatPaC model better aligned with the cost estimate published in industry- recognized reports such as the UBS MY 2016 Chevy teardown report.[1334,1335,1336]

The agencies performed a sensitivity study for production volume using BatPaC version 3.1. The cost of the battery pack dropped by 15 percent on average when the production volume was changed from 25,000 to 100,000 units per year. The sensitivity analysis showed that manufacturing plant volume has a significant impact on battery pack costs and therefore it is important to use realistic production volume estimates for the battery pack cost analysis.

Manufacturing plant efficiency is another parameter important to estimate battery pack costs. BatPaC version 3.1 defines manufacturing plant efficiency in terms of cell yield, or the number of cells that are usable out of the total number of cells that the plant produced.[1337] Since battery pack technology and battery pack manufacturing processes are proprietary, the data on plant efficiencies are not widely reported. While BatPaC uses a default cell yield (plant efficiency) value of 95 percent, Argonne battery experts have used an 85 percent cell yield value

---

[1333] Note, for the assessment, Nissan and Mitsubishi are considered a single manufacturer.
[1334] Proposed Determination TSD at 2-127.
[1335] Based on the battery cell to battery pack ratio of 1.3 to 1.5, the 2015-2019 cell-level figure of $145 per kWh used in the MY 2016 Chevy Bolt would translate to approximately $190 to $220 per kWh on a pack level.
[1336] Hummel et al., UBS Evidence Lab Electric Car Teardown – Disruption Ahead?, UBS (May 18, 2017), https://neo.ubs.com/shared/d1ZTxnvF2k/.
[1337] Cells might not be usable because of, for example, manufacturing defects, among other reasons.

to represent the current production yield for internal DOE studies.[1338] By selecting an 85 percent cell yield value for the final rule analysis, the agencies aligned the cell yield value assumption with internal DOE studies.

In addition, as discussed in detail above, the final rule analysis was performed using BatPaC version 3.1, with NMC622 assumed as the battery chemistry for HEVs, PHEVs, and BEVs. Separate from the inputs and assumptions discussed here, the Argonne battery experts made a number of changes to BatPaC version 3.1, and these are extensively documented in the BatPaC manual,[1339] as well as in Argonne model documentation for final rule.

(b) Comments on Information Availability

In addition to comments that the agencies' battery pack costs were too high, the agencies received comments that the analysis for battery pack costs was unclear and not well documented. ICCT stated that the agencies largely obscured the BEV cost sources and calculations, which made it "nearly impossible for even very interested researchers to understand how all the BatPaC costs translate into BEV costs that can be compared with other full-BEV costs in the literature."[1340] ICCT stated that to enable meaningful public comments, the sources and cost calculations must be made explicit and the agencies must provide an additional public comment opportunity.[1341]

CARB claimed that it could not comment meaningfully on the battery modeling for the NPRM analysis without extensive additional information.[1342] As such, CARB submitted a letter to the agencies' NPRM docket posing, under FOIA, a number of questions pertaining to battery assumptions used for the modeling. This requested information concerned what version of BatPaC was used in the NPRM analysis, inputs incorporated into the BatPaC model; and information about how battery costs were generated for the analysis.

Specifically, CARB's initial comments alleged that the agencies had not disclosed the exact version of BatPaC used, and had simply claimed to use the "most up-to-date" version of BatPaC, and further that the agencies had not disclosed "the BatPaC modeling files that were used, clear statements about what version of the model was used, or thorough descriptions of the inputs to those modeling runs." CARB claimed that without that information, "there is no way to know what assumptions were made for raw material pricing, battery cell yields, pack electrical connection topology, battery production volume assumptions, or if any additional parameters

[1340] International Council on Clean Transportation, NHTSA-2018-0067-11741.
[1341] *Id*.
[1342] California Air Resources Board, NHTSA-2018-0067-11873.

were modeled, like rapid charging capability." CARB argued that these pieces were critical to understanding whether the BatPaC model was estimating proper battery pack cost values.

In a subsequent docketed comment submitted as an administrative appeal to NHTSA's FOIA response, CARB reasserted that, in fact, the "most recent version" of BatPaC had not been used, because the FOIA response stated clearly that version 3.0 had been used and Argonne had updated to version 3.1 in October 2017, which was the last version released before the NPRM was published. CARB further argued that NHTSA was "choosing to withhold information about battery pack configurations," and that the agencies had not posted the BatPaC model version and files used for the NPRM to the agencies' dockets, inhibiting meaningful comment.

The majority of information sought by CARB's comment was already published in supporting documents and materials posted to the agencies' dockets and online websites for the NPRM. Nevertheless, in an effort to answer CARB's specific questions, NHTSA also processed the initial comment as a FOIA request and provided a written response directly to CARB within the comment period. This response both pointed CARB to the locations where the sought material could be located among the published NPRM materials, and expressly answered several of CARB's questions for clarification, such as identifying the specific version of BatPaC utilized in the NPRM analysis. For example, although the Argonne model documentation describing the battery modeling for the NPRM was included in the docket, the agencies' response directed CARB to the precise location in the docket where it could be found.

The agencies believe that the NPRM docket contained enough information for stakeholders to comment meaningfully. This is apparent from the voluminous comments the agencies received regarding the NPRM's electrification analysis—including from CARB. For example, as discussed above, CARB submitted extensive comments on each element of the battery cost modeling that CARB claimed the agencies did not adequately explain. As discussed above, CARB stated that the agencies' selected battery chemistries represented a step backward from previous analysis done for the Draft TAR. CARB noted that regardless of whether NMC441 or NMC333 was chosen for PHEVs and BEVs in the NPRM analysis, the biggest lithium-ion production companies have indicated that they will use NMC811 for BEVs, and therefore neither NMC441 nor NMC333 would represent current technology going into BEVs or near-future BEV battery technology. CARB stated that NMC811 technology is expected to come to market in 2019, which, the agencies note, is far sooner than anticipated, even in the agencies' prior analyses. CARB was accordingly able to communicate its opinion that NMC881 should have been used to model battery chemistries for the NPRM analysis, and that NMC441 or NMC333 should not be used.

As these comments demonstrate, in addition to the extensive comments listed above, the expansive information, data, and documentation concerning the Argonne BatPaC modeling analysis for the NPRM sufficiently enabled commenters to submit voluminous technical analysis regarding the electrification analysis. Moreover, while the docketed and published NPRM materials themselves afforded sufficient notice on these topics, the agencies even undertook the additional step of directly responding to CARB in writing in an attempt to address specific questions raised by CARB. This written correspondence both directed CARB to specific locations on the rulemaking dockets and agencies' websites where information CARB was seeking could be accessed, and even directly answered several of CARB's questions through narrative responses. Both CARB and other commenters submitted subsequent comments, which referenced the material described in this written response. Accordingly, the agencies consider the information provided with the NPRM sufficient to enable meaningful comment, which is underscored by the voluminous technical comments received on the electrification issues.

For this final rule, the BatPaC model version 3.1 (June 2018) model documentation has been included in the docket for this rulemaking.[1343] Furthermore, Argonne's detailed documentation describing the modeling process used to support this final rule provides information and specific assumptions that Argonne's experts used to simulate batteries and their associated costs for the full vehicle simulation modeling.[1344] These resources, in addition to the detailed description of the battery cost modeling process provided here and in the FRIA provide interested stakeholders the necessary tools to understand the battery cost modeling analysis.

(c) Final Rule Battery Pack Costs

As discussed above, based on comments and additional research, the agencies updated the battery cost analysis for the final rule by relying on BatPaC version 3.1.[1345] In addition, as outlined above and explained in more detail in the Argonne Model Documentation for this final rule, several inputs and assumptions were updated based on public comments, market research, and additional literature review. The agencies computed the average battery pack cost across all road load combinations for electrification technologies that could be reasonably compared between the NPRM and final rule.[1346]

Table VI-112 to Table VI-116 show the differences between battery pack costs presented in the NPRM and final rule.[1347] The tables show absolute cost differences between battery packs, which can vary for battery packs with different energy and power combinations. For example, as shown in Table VI-113, the cost difference between the NPRM and final rule for a Mild HEV battery pack with a 1kWh energy and 10kW power rating is -28 percent. Similarly, the cost difference in an HEV battery pack with a 1kWh battery energy and 40kW power rating is 5 percent. In summary, the percentage increase or decrease in the table represents the absolute cost differences between the battery packs used in NPRM and in final rule.

Figure VI-94 to Figure VI-96 shows the average battery pack costs across all road load combinations for each applicable vehicle technology class for SHEVPS, PHEV50, and BEV200s

---

[1343] Nelson, Paul A., Ahmed, Shabbir, Gallagher, Kevin G., and Dees, Dennis W. Modeling the Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles, Third Edition (ANL/CSE-19/2), available at https://publications.anl.gov/anlpubs/2019/03/150624.pdf.
[1344] A Detailed Vehicle Simulation Process To Support CAFE and CO2 Standards for the MY 2021 - 2026 Final Rule Analysis.
[1345] Modeling the Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles, Third Edition (ANL/CSE-19/2) provides a complete list of changes and assumptions incorporated in BatPaC version 3.1.
[1346] Costs data is from the CAFE Model core file Battery_Costs.csv.
[1347] The absolute cost differences shown here is by comparing the cost of battery pack with similar number of cells in the NPRM to the final rule cost lookup tables for compact and medium car. The cost differences between the NPRM and the final rule cost lookup tables for small SUV, medium SUV and Pickup trucks will be different from the table shown here.

between the NPRM and final rule.[1348] Since the battery pack size varies for different road load combinations, the battery pack cost across different road load combinations varies as well. For example, there are 105 combinations of different mass reduction, aerodynamic improvements and rolling resistance improvements. The battery pack size for an initial road load condition that includes MR0, AERO0 and ROLL0 is larger, and therefore, the cost of the battery pack is higher as well. The battery pack size is smaller for the highest level of road load reduction such as in MR6, AERO20 and ROLL20, and the cost of battery pack is less as well.

Table VI-112 shows the cost difference in Micro HEV battery packs. The cost reduction is from the reduced number of cells in the battery pack.

Table VI-112 – Percentage Cost Differences for Micro HEV Battery Packs

Micro HEV			**Energy, kWh**				
			0.6	0.8	1.0	1.2	1.4
BatPac Cost	**Power, kW**	0.5	-60%	-56%	-54%	-52%	-50%
		1.1	-60%	-56%	-54%	-52%	-50%
		1.5	-60%	-56%	-54%	-52%	-50%
		2.0	-60%	-56%	-54%	-52%	-50%
		2.5	-60%	-56%	-54%	-52%	-50%
		3.0	-60%	-56%	-54%	-52%	-50%

Table VI-113 shows percentage cost differences for mild hybrid (BISG) battery packs. The cost difference is due, in part, to accounting for BISG-related hardware costs, such as the battery management system, as part of the electric machine costs in this final rule.[1349]

[1348] The agencies did not simulate SHEVPS and BEV200 powertrain architectures on pickup trucks in the NPRM, so those are not included in the comparison.
[1349] In the NPRM, additional hardware component costs were included as part of the battery pack cost.

Table VI-113 – Percentage Cost Differences for Mild Hybrid (BISG) Battery Packs

Mild BISG			**Energy, kWh**					
			0.30	0.40	0.60	0.81	1.00	1.20
BatPac Cost	**Power, kW**	5.00			-29%	-28%	-27%	-27%
		6.00			-29%	-28%	-27%	-27%
		7.69			-29%	-28%	-27%	-27%
		8.00			-29%	-28%	-28%	-27%
		9.00			-30%	-29%	-28%	-27%
		10.00			-30%	-29%	-28%	-27%

Table VI-114 shows the percentage cost differences for HEV battery packs. Even as the battery chemistry changed to NMC622, the cost increase is from the different battery pack production volume and plant efficiency assumptions used in the final rule.

Table VI-114 – Percentage Cost Differences for SHEVPS Battery Packs

HEV			**Energy, kWh**					
			0.9	1.0	1.2	1.4	1.6	1.8
BatPac Cost	**Power, kW**	10.0						
		20.0		14%	13%	13%	14%	14%
		30.0		11%	10%	9%	8%	9%
		40.0		10%	8%	7%	6%	5%

Figure VI-94 shows the difference in battery pack costs for SHEVPS applications between the NPRM and final rule. Power-split hybrids could not be used in pickup trucks due to their unique power and towing requirements, so those technology classes are not shown. In general, the cost of the battery pack in the final rule analysis increased due to the updated battery pack production volume and plant efficiency assumptions.

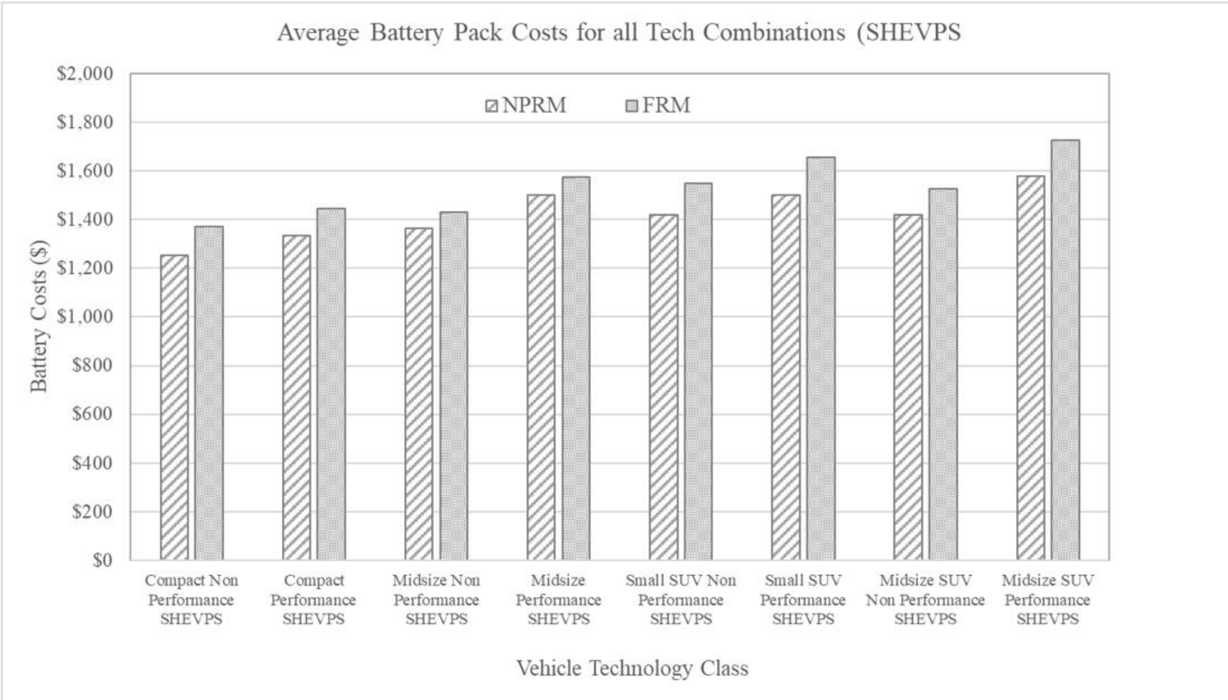

Figure VI-94 – Comparing SHEVPS Average Battery Costs
(Costs do not include RPE or Learning Curve Adjustment)

Table VI-115 shows the percentage cost differences between the NPRM and final rule for PHEV50 battery packs. The cost increase in the PHEV50 battery pack shown here is mainly due to the increase in number of cells per pack as well as the other updated BatPaC assumptions.

Table VI-115 – Percentage Cost Differences for PHEV50 Battery Packs

PHEV50			**Energy, kWh**					
			10.0	20.0	30.0	40.0	50.0	60.0
BatPac Cost	**Power, kW**	60.0	26%	17%	11%	6%	3%	1%
		80.0	26%	17%	11%	6%	3%	1%
		100.0	20%	17%	11%	7%	3%	1%
		120.0	14%	17%	11%	7%	3%	1%
		140.0	8%	15%	11%	7%	3%	1%

Table VI-111 shows the difference in average PHEV50 battery pack costs between the NPRM and final rule for all technology combinations.

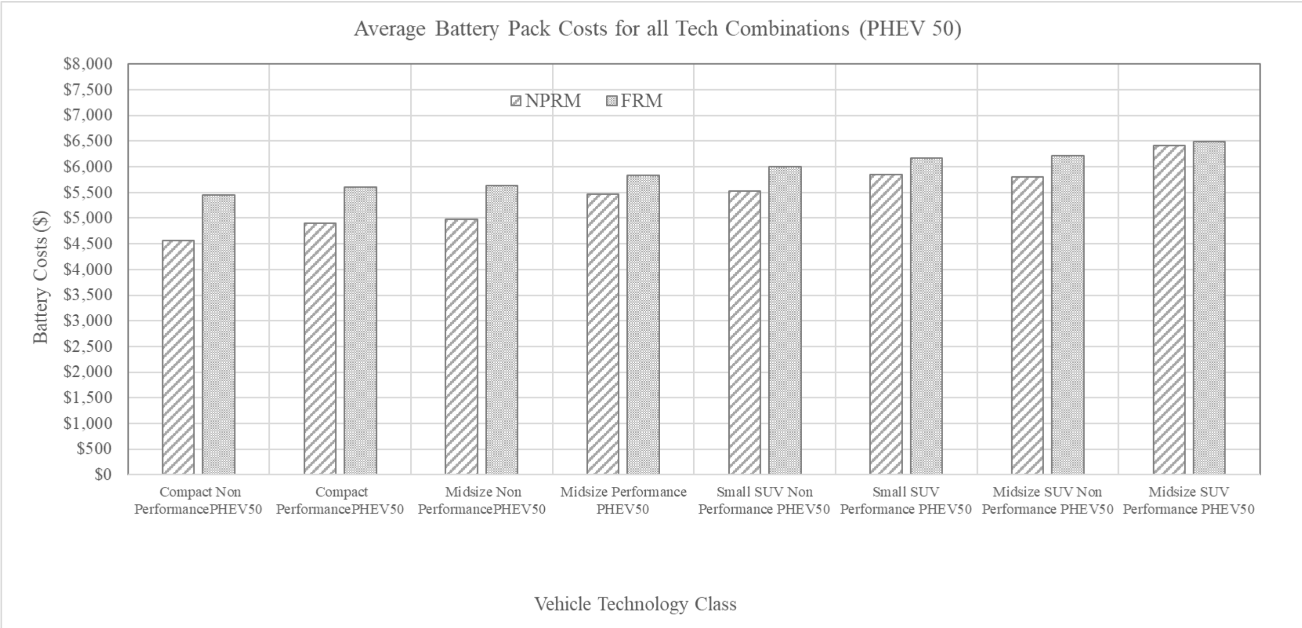

Figure VI-95 - Comparing PHEV50 Average Battery Costs
(Costs do not include RPE or Learning Curve Adjustment)

Table VI-116 shows the percentage cost differences for BEV battery packs. In the example shown in Table VI-116, the agencies compared the cost lookup table from the NPRM with 300 cells to the cost lookup table in the final rule analysis with 320 cells. The cost increase in the higher energy packs is due to the different battery pack production volume and plant efficiency value assumptions, along with the different battery chemistry assumption.

Table VI-116 – Percentage cost differences in BEV200

BEV200			**Energy, kWh**		
			50.0	70.0	90.0
BatPac Cost	**Power, kW**	60.0	2%	2%	2%
		80.0	3%	3%	3%
		100.0	3%	3%	3%
		120.0	3%	3%	3%
		140.0	3%	3%	3%
		160.0	3%	3%	3%

Figure VI-96 shows the average cost of BEV200 battery packs across all technology combinations for technology classes that could be compared between the NPRM and final rule. As shown, for the final rule analysis, the average cost of a BEV200 battery pack is lower than the average cost of the NPRM BEV200 battery pack. For the final rule analysis, the agencies updated the motor efficiency map for BEVs (as explained in Section VI.C.3.d) Electrification Technology Effectiveness) and updated the glider share of the vehicles from 50 percent of the curb weight to 71 percent of the vehicle curb weight (as explained in Section VI.C.4 Mass

Reduction). In addition, the updated motor weight resulted in further reduced vehicle weights. This combination of improved vehicle assumptions resulted in reduced energy and power requirements in BEVs.

The agencies also observed that even as the number of cells in the battery pack increased from 300 to 320, and changes in production volume and plant efficiency values resulted in marginal cost increases for higher energy packs, the overall battery capacity requirement went down due to overall reduction in power and energy demand from electric vehicles.[1350] A reduction in battery capacity leads to reduced cell size in a pack with number of cells and voltage. A reduction in cell size leads to cost reductions at the cell level and at the pack level. In general, a higher capacity battery pack is more expensive than a lower capacity battery pack due to the increase in cell size for a given number of cells and voltage.[1351,1352]

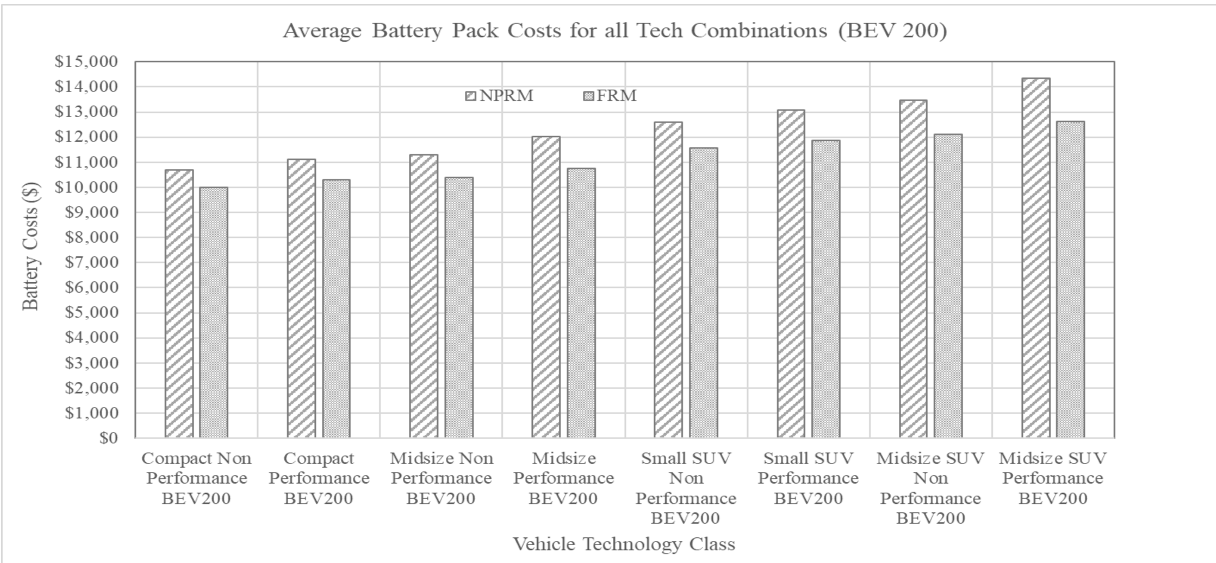

Figure VI-96 – Comparing BEV200 Average Battery Costs
(Costs do not include RPE or Learning Curve Adjustment)

The graphs demonstrate the range of cost changes observed, with the other electrification technologies falling somewhere in between the extremes. In summary, the agencies observed that the BEV200 technology showed a cost reduction in battery packs across all vehicle platforms with the largest reductions occurring for the largest battery packs. In contrast the

---

[1350] As explained above, the energy density values in the NPRM were kept constant. For the final rule analysis, the power density varied to meet different power and energy requirements, as was observed through market research.
[1351] Nelson, Paul A., Ahmed, Shabbir, Gallagher, Kevin G., and Dees, Dennis W. Modeling the Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles, Third Edition (ANL/CSE-19/2), at 15 (battery design worksheet). Available at https://publications.anl.gov/anlpubs/2019/03/150624.pdf.
[1352] The amount of electrode materials and electrode area of the cells are determining cost factors in the battery. Higher capacity battery packs require additional manufacturing steps to increase the energy density of the pack.

PHEV50 technology showed a cost increase in battery packs across all vehicle platforms with the smallest increase for the largest battery packs and the largest increase for the smallest battery packs. It is worth noting the cost decreases seen across the technologies are generally larger than the cost increases.

For the final rule, when possible, the calculated battery pack weight and manufacturing cost was also compared with the battery pack cost and weight data obtained through various benchmarking studies. For example, UBS reported a battery pack manufacturing cost of $12,500 from its 2017 Chevrolet Bolt teardown analysis.[1353] Using a production volume of 25,000 packs per year per plant and similar battery pack design, BatPaC estimated a manufacturing cost of $10,680.[1354] These comparisons were used to verify the different assumptions used in BatPaC and helps represent the battery packs for electrified vehicles used in representative market volume. Table VI-117 shows a comparison of specifications estimates for 60 kWh and 160 kW battery packs from the 2016 DOE VTO report[1355,1356] and BatPaC version 3.1 (June 2018), and the Chevrolet Bolt. The comparison shows modeled and actual battery packs are in close agreement.

Table VI-117 – Chevrolet Bolt Battery Pack Weight and Configuration Analysis Comparison of BatPaC and A2mac1/TBC

	A2Mac1	**Chevrolet Bolt**	**BatPaC**
Electrode Chemistry	NMC622	NMC/LMO	NMC622
Energy Capacity, kWh	60	60	60
Power, kW	160	160	160
Pack Specific Energy, Wh/kg	140.6	139.5	169
Pack Mass, kg	427	430	355
Cell Specific Energy, Wh/kg	264	244	215
Cell Mass, kg	-	-	279
No. of Cells	288	-	300
Cell Configuration	8 x 10S3P 2 x 8S3P	-	10 x 10S3P
Pack Voltage, V	355	-	365

In addition, the agencies compared the battery pack cost estimates generated using BatPaC to other current studies or studies cited by commenters. Table VI-118 summarizes battery pack estimates from selected studies in MYs for which that information was available.

Table VI-118 - Battery Pack Cost Estimates from Other Sources - $/kWh[1357]

	2018-2020[1358]	**2025**	**2030**	**2045**
UBS[1359]	$188	$136		
BCG[1360]		$137	$117	
ICCT[1361]	$175-177	$104	$64-73	
BNEF EV Outlook 2019[1362]	$176[1363]	$87	$62	
MIT[1364]	$193	$146	$130	
DOE VTO[1365] – based on usable energy	$170	$125	$98	$80
NHTSA/EPA from BatPaC version 3.1 (2018)	$178	$141	$112	$77

As shown in the table above, there are a range of cost estimates for battery packs. Each individual cost estimate is derived based on certain set of assumptions to arrive at a rate of cost reduction. Among all the different cost estimates, Bloomberg New Energy Finance (BNEF) has

---

1357 Not each study distinguished a DMC source year, so these values vary slightly based on inflation.
1358 Sources generally provided estimates for 2018 or 2020.

the most aggressive year-over-year cost reductions, based on the historical learning rate of 18% and their battery demand forecast.[1366] Similar to other sources of cost estimates BNEF assumes improved battery chemistry and battery density increasing greater than 200Wh/kg by 2030. In order for the battery manufacturer to achieve economies of scale, BNEF assumes a global battery manufacturing facility capable of producing battery packs for both stationary energy storage and vehicle applications.

A recent report from the Massachusetts Institute of Technology (MIT), the MIT Energy Initiative's Insights into Future Mobility, has the most conservative estimate among all the cost sources listed the Table VI-118. The authors use a more rigorous two-stage method of estimating composite battery learning curves independently for (a) battery material synthesis and minerals costs, and (b) battery pack production processes. The learning rates are defined as the cost reduction that results from cumulative volume doubling, and produce separate cost learning rates for the two stages of 3.5 percent and 16.5 percent, respectively. The study argues that there are greater opportunities for cost learning in the production stage than the chemical synthesis stage, which is more mature. These cost estimates produce global EV fleet penetration rates that may not be as aggressive as other estimates, reaching only 33 percent by 2050. This study also assumes NMC811 will be available by 2030.

The cost estimates from other sources referenced above also include assumptions about higher levels of battery pack production and higher density battery cells. Most cost estimates assume improved battery chemistry, such as NMC811. As discussed above, the agencies determined that modeling assuming NMC622 was reasonable, based on current production vehicles, the relative uncertainty surrounding large-scale NMC811 deployment in the rulemaking timeframe, and the ability to account for lower battery pack costs over time with cost learning. The agencies also believe that, based on the market analysis and from the teardown analysis, improvements in battery chemistry may be slow to be applied in a widespread manner, and therefore the economies of scale required to achieve considerable cost reductions solely from improvements in chemistry may remain effusive during the rulemaking timeframe.

For these reasons, the agencies believe that the BatPaC-generated battery cost estimates using the updated inputs and assumptions are reasonable.

(2) Non-battery Electrification Component Costs

Battery components are the biggest driver of the cost of electrification, however, non-battery electrification components also add to the total cost required to electrify a vehicle. In this analysis, the agencies accounted for the following non-battery component costs: electric motor(s), inverter, and other power electronics including a bi-directional DC/DC converter, a voltage step down DC/DC converter, and an on-board charger. Collectively, these components (except for the on-board charger) are referred to as the electric traction drive systems (ETDS), or the electric machine. Non-plug-in hybrid electric vehicles include all of the listed components

[1366] Logan Goldie-Scot, A Behind the Scenes Take on Lithium-ion Battery Prices, Bloomberg New Energy Finance (March 5, 2019), https://about.bnef.com/blog/behind-scenes-take-lithium-ion-battery-prices/.

except for an on-board charger; PHEVs include all of the listed components; and BEVs include all of the listed components except, in some cases, a second motor.

For the NPRM, the agencies accounted for battery pack costs and ETDS costs independently.[1367] The Alliance commented broadly in support of separating electrification hardware costs and battery costs, and stated that it was a positive change to the modeling.[1368] The Alliance correctly noted that the separation allowed for separate learning rates and cost differentiation between the two distinct pieces of electrification technologies.

As stated in the PRIA,[1369] the agencies derived the cost values for the EDTS using Argonne National Laboratory's "Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies" report.[1370] Generally, the agencies referred to this report in the PRIA as the DOE VTO report, as it was a report that reviewed results of the DOE VTO. Some commenters seemed confused by this alternative reference—even questioning why the agencies didn't rely on recent Argonne National Laboratory reports.[1371] To clarify, this report was written by Argonne National Laboratory, and to avoid further confusion it is referred to using the full title throughout this rule.

CARB expressed concerns with non-battery component effectiveness values, arguing that the agencies inappropriately relied on outdated data for electric machines and inverter efficiencies across all electrification applications, and further claiming that the agencies did not project any efficiency gains in those components over time.[1372] Broadly, as these comments on effectiveness related to the NPRM non-battery component cost estimates, CARB claimed that the agencies failed to consider new data, including the 2015 ORNL Annual Progress Report for the Power Electronics and Electric Motors Program, and two Argonne studies, which rendered the analysis unrepresentative of actual technology costs.

CARB also commented that the agencies did not provide any substantive discussion or documentation of how non-battery component costs were developed for the NPRM analysis. CARB claimed that dissonance existed between the PRIA description of voltage systems and associated costs needed for different performance classes, the Autonomie files, and the technologies input file, and that this served as an example of how the agencies failed to include information regarding how costs and cost differences were derived, or any component changes from previous analyses.

[1372] California Air Resources Board, NHTSA-2018-0067-11973, at 130.

CARB also commented that the lack of disclosure of non-battery cost development information was an issue for other electrification technologies. CARB cited the increase in parallel (P2) and power-split (PS) hybrid systems costs relative to costs used in past agency analyses, noting that there was no discussion on what changed from the past analyses. CARB referenced a 2010 FEV teardown (Light Duty Technology Cost Analysis, Power-Split and P2 HEV Case Studies, EPA-420-R-11-015) study that the agencies had previously relied on for component costs, noting that not only did the agencies ignore that study in the NPRM, but that ICCT had commented 2010 FEV report overstated strong hybrid costs at the time of the study, making it likely that costs are likely to be lower now and even more so in the future. CARB claimed that the agencies provided no justification or rationale for the increases in strong hybrid modeled costs for the proposal, and that there was no meaningful way to comment on the exact components or cost changes that the agencies relied upon. Similarly, CARB cited EPA's 2016 Proposed Determination and associated public comments from Ford and Tesla on the Draft TAR for the proposition that non-battery costs, which were lower in the Draft TAR than the NPRM, were conservative and not overly optimistic.

Finally, in addition to the ORNL and Autonomie group studies that CARB referenced as examples of sources that provided updated data on non-battery component effectiveness and costs, CARB claimed that newer data existed from a UBS Global Research report that examined the component costs of a MY 2016 Chevrolet Bolt, and the agencies did not discuss why the newer data was not used in the NPRM analysis. CARB stated the significant upward adjustment in non-battery costs from previous analyses was not supported by industry input, analysis conducted by other outside sources, or by the agencies' previous analyses.

As explained above, for the NPRM the agencies relied on Argonne's "Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies" for EDTS costs. In turn, the Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies report referenced electric machine data provided by OEMs, suppliers, and Oak Ridge National Laboratory.[1373] Regarding CARB's assertion that the agencies did not refer to the UBS Global Research report on the MY 2016 Chevy Bolt teardown for the NPRM, the agencies agree. The UBS Global Research report was not available at the time the CAFE model inputs were finalized for the NPRM analysis. That study, among others, was considered for the final rule.

For the final rule analysis, the agencies carefully considered comments and the referenced studies, as well as other studies. The agencies determined the cost and component efficiency estimates from U.S. DRIVE's October 2017 report, Electrical and Electronics Technical Team (EETT) Roadmap,[1374] provided reasonable estimates to use in the final rule. The EETT Roadmap report reflected considerable work by the DOE VTO collaboratively with

---

[1373] Moawad, Ayman, Kim, Namdoo, Shidore, Neeraj, and Rousseau, Aymeric. Assessment of Vehicle Sizing, Energy Consumption and Cost Through Large Scale Simulation of Advanced Vehicle Technologies (ANL/ESD-15/28), at 32.
[1374] U.S. DRIVE, Electrical and Electronics Technical Team Roadmap (Oct. 2017), available at https://www.energy.gov/sites/prod/files/2017/11/f39/EETT%20Roadmap%2010-27-17.pdf.

U.S. DRIVE, a government-industry partnership. The EETT Roadmap report estimated the 2017 manufacturing cost of a commercial on-road 100kW ETDS consisting of a single electric traction motor and inverter. The reported costs were approximately $1,800, with the cost of the electric motor accounting for $800, and approximately $1,000 for the inverter, equaling $18/kW for the ETDS.

The agencies also referenced the UBS MY 2016 Chevy Bolt teardown report to compare the cost of the ETDS.[1375] To compare the costs, the agencies applied the $18/kW metric for ETDS as determined by EETT Roadmap report to the 150kW ETDS used in the MY 2016 Chevy Bolt ($18kW x 150kW = $2700). As shown in Table VI-119, the cost estimate from the above computation aligned with UBS MY 2016 Chevy Bolt teardown cost estimate. As a result, the agencies determined that it was appropriate to use $18/kW to estimate the cost of the ETDS for all hybrid and electric vehicle architectures for the final rule.

The EETT Roadmap report did not explicitly estimate the cost of other electrical equipment present in PHEVs and BEVs, such as on-board chargers, DC to DC converters, and charging cables, but recommended cost targets for the years 2020 and 2025. As a consequence, the agencies relied on the UBS MY 2016 Chevy Bolt teardown report to estimate the cost of on-board chargers, DC to DC converters, and charging cables. Table VI-119 shows the cost estimate for the ETDS from the EETT Roadmap report and from the UBS MY 2016 Chevy Bolt teardown report, and the cost estimate for other electrical equipment from the same UBS report.

[1375] Hummel et al., UBS Evidence Lab Electric Car Teardown – Disruption Ahead?, UBS (May 18, 2017), https://neo.ubs.com/shared/d1ZTxnvF2k/.

Table VI-119 – Cost Estimates from the EETT Roadmap Report and UBS MY 2016 Chevy Bolt Teardown

	EETT Roadmap Report	UBS MY 2016 Chevy Bolt Teardown
ETDS	$18/kW	$17.76/kW
On-Board Charger	-	$85/kW
DC to DC Converter	-	$90/kW
High Voltage Cables	-	$450

Table VI-120 – Final Rule Non-Battery Electrification Component Costs Assumptions (2017$)

Electric Propulsion Systems	Cost metric	Application assumption
Traction Motor + Inverter + Bi-Directional Converter	$18/kW	Calculated for Peak motor power
Generator Motor + Inverter + Bi-Directional Converter	$18/kW	Calculated for Continuous motor power
On-board charger for BEV	$85/kW	Calculated for 7kW required for BEV
On-board charger for PHEV	$85/kW	Calculated for 2kW required for PHEV
DC/DC Converter	$90/kW	For all electric and hybrid vehicles
High voltage cables, charging cord & connectors	$450	For all electric and hybrid vehicles

While the EETT Roadmap report estimated the cost of the ETDS at the system level, the report did not itemize the cost of individual components in electric motor and inverter in 2017. However, the EETT Roadmap report provided target cost estimates for the motor and inverter system for the year 2025. As shown in Table VI-121, the EETT Roadmap report estimated a cost reduction of 73 percent for the inverter and 59 percent for the motor relative to 2017. Using the percentage cost reductions from 2025 to the on-road status as defined in the EETT Roadmap report, the agencies developed an estimated motor and inverter component cost for 2017. The resulting cost estimate for 2017 using the scaling factor matches the $18/kW for motor and inverter ($10/kW for Inverter + $8/kW for motor). Since the motor and inverter component costs are developed based on a $/kW basis, the agencies applied the same $/kW metric for all hybrid and electric vehicle applications for the final rule analysis.

Table VI-121 – Cost Targets Published in the EETT Roadmap Report (2017$)

	Cost in 2017 (2017$)	Cost Target in 2025 (2017$)	Cost Reduction
Power Electronics[1376]	10	2.7	73%
Electric Motor[1377]	8	3.3	59%
Average Cost Reduction[1378]	18	6	66%

Table VI-122 – Inverter Costs Estimates

Inverter Component Cost	2017 Estimated Component Cost	2025 Component Cost Target from EETT Roadmap[1379]
Power Module	$219	$59
DC Bus Capacitor	$141	$38
Control Board	$137	$37
Gate Drive	$222	$60
Bus Bars/Terminal Block	$96	$26
Current Sensors	$41	$11
Miscellaneous	$144	$39
Total	$1,000	$270
$/kW	$10	$2.7

Table VI-123 – Motor Costs Estimates

Electric Motor Component Cost (100kW)	2017 Estimated Component Cost	2025 Component Cost Target from EETT Roadmap[1380]
Stator	$373	$154
Rotor	$189	$78
Magnet	$32	$13
Miscellaneous	$206	$85
Total	$800	$330
$/kW	$8	$3

In addition, the EETT Roadmap report provided notably newer data than the 2010 FEV teardown study referenced by commenters. Based on these considerations, the agencies

[1376] U.S. DRIVE, Electrical and Electronics Technical Team Roadmap, at 12 (Oct. 2017), available at https://www.energy.gov/sites/prod/files/2017/11/f39/EETT%20Roadmap%2010-27-17.pdf.
[1377] U.S. DRIVE, Electrical and Electronics Technical Team Roadmap, at 12 (Oct. 2017), available at https://www.energy.gov/sites/prod/files/2017/11/f39/EETT%20Roadmap%2010-27-17.pdf.

determined that the EETT Roadmap report provided reasonable costs to estimate the cost of EDTS components in the rulemaking timeframe.

(3) Electrification Learning Curves

The total incremental costs of electrification powertrain technologies are comprised of the DMC as modified by the learning curves for each individual powertrain component, which include batteries, non-battery components, and IC engines and transmissions (for hybrids and PHEVs). The PRIA showed the learning curves for battery and non-battery electrification technologies,[1381] and listed the sources used to develop those curves, including the 2015 NAS report, Wright-based learning curves,[1382] and Argonne's 2016 Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies.[1383] Learning rates for batteries were also derived using Argonne's BatPaC model.

For the NPRM, to develop the learning curves for non-battery components, the agencies consulted Argonne's 2016 Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies report. The report provided estimated cost projections from the 2010 lab year to the 2045 lab year for individual vehicle components.[1384,1385] The agencies considered the component costs used in electrified vehicles, and determined the learning curve by evaluating the year over year cost change for those components.

The agencies used BatPaC version 3.0 to develop the NPRM learning curves for batteries. As discussed above, BatPaC calculations are based on generic pack design for a given set of inputs that could reasonably represent potential current and future designs. Because BatPaC does not simulate battery costs as a function of time, the agencies modified the battery volume inputs for MY 2015, MY 2020, MY 2025 to show costs in each of those MYs. Like the non-battery component analysis, a learning curve was developed from the year over year cost change, and this rate was used to develop the learning curves used in the NPRM.

1385 DOE's lab year equates to five years after a model year, *e.g.*, DOE's 2010 lab year equates to MY 2015.

CARB stated that publicly available data supported lower costs in the near term than what the applied learning curve rates would do to the battery costs developed by the agencies, and the agencies failed to consider new information or data to adjust battery costs.[1386] CARB stated that considering the substantial volume of publicly available information and public input to the agencies' previous analysis, projected battery costs should have been adjusted even further downward for the NPRM. CARB stated that instead, the agencies moved costs upward without sufficient justification, and in contrast, the analysis for the Proposed Determination and 2016 Draft TAR provided far more justification for those modeled battery costs.

As discussed in Section VI.B.4.d) Cost Learning, above, ICCT commented broadly on the change in approach to learning curves since the Draft TAR, stating that this change in approach led to lower decreases in costs over time in the NPRM than the Draft TAR analysis. ICCT compared EPA's Draft TAR learning curves and NPRM learning curves for batteries in MYs 2016-2025, concluding that there was a 29% reduction in learning for batteries from EPA's Draft TAR analysis to the NPRM analysis.

The agencies considered an array of both present and future cost estimates from various public and private sector organizations to validate the rate at which battery pack costs declined over time. These estimates, in addition to estimates submitted by commenters as discussed in BatPaC Inputs and Assumptions and Final Rule Battery Pack Costs are shown in Table VI-118. In addition, the agencies had to consider how to project learning rates out through 2050, as discussed in Section VI.B.4.d) Cost Learning and Section VI.C.3.e)(3) Electrification Learning Curves.

The agencies also assessed and reviewed literature evaluating more recent battery technology development.[1387,1388] The NPRM analysis used a three percent learning rate per year from MY 2033 to MY 2050. Learning rate forecasts from MY 2033 to MY 2050 for this final rule analysis were scaled down in steps from the previous analysis based on literature, market research, and Wright's learning curve assumptions.

It is difficult to predict which battery chemistry and production processes will be prevalent for electrified vehicles in MY 2030, let alone for MY 2050. The agencies reviewed potential battery chemistries that could come into readiness for adoption at different timeframes, such as MY 2030s to MY 2039, and MY 2040 to MY 2050.[1389] It is possible that costs based on other lithium-ion based chemistries will learn at the same rate as lithium-ion NMC development. However, the same learning effect in battery production may not be additive across different chemistries, especially in learning effects related to battery production. Accordingly, the

learning rates applied between MY 2030 to MY 2039 considered development and increased volume for the same or similar battery chemistries as an NMC battery platform.[1390] Learning curves beyond MY 2040 were flattened further to ensure that the cost of batteries did not lower beyond the projected price of the raw materials. Further, new chemistries introduced in later years may learn at different rates than the curve identified for NMC-based chemistries. The battery pack cost learning rate that resulted from this exercise produced the schedule that appears in Table VI-113, which shows this final rule analysis battery pack cost reduction as function of time. By MY 2040, the pack cost has reduced by 54 percent. Accordingly, the estimated battery pack cost between MY 2040 and MY 2050 as shown in Figure VI-97 below shows flatter curve.

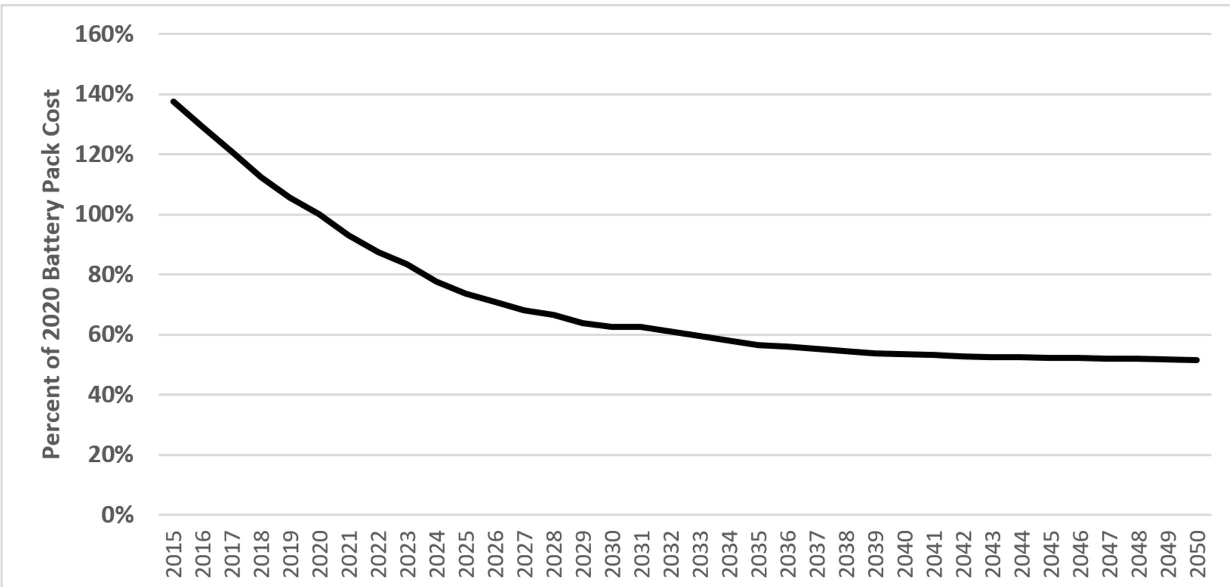

Figure VI-97 – Battery Pack Cost Learning in Final Rule

The reference cost is defined for MY 2020 vehicles, and vehicles produced in subsequent years (as well as earlier years) use a per kWh cost that is a percentage of the 2020 cost. As the figure shows, the cost reduction is rapid through MY 2030, after which cost reductions slow considerably. As discussed above, the cost projections assumed different battery chemistries and different rates of cost learning.

The agencies expect there will be incremental improvements in battery chemistry, energy density, plant efficiency, and production volume over the timeframe modeled in the analysis. While each of these factors may have an impact on the rate at which battery costs decline over time, the agencies determined that using the same cost learning projection method from the NPRM to project learning rates out through 2050 provided a reasonable method for accounting for something that is inherently uncertain. Accordingly, the learning curve used in the NPRM and in the final rule represent a composite learning curve irrespective of the type of battery

[1390] For example, an NMC lithium-ion-based platform could move from a cathode composition of NMC622 to NMC811.

chemistry, the production volume necessary to achieve economies of scale, or energy density of the battery pack. For the final rule, the agencies have performed sensitivity analyses varying the battery pack learning rate, and these analyses are presented in FRIA VII.E.

(4) Electrified Powertrain Costs

For the NPRM analysis and carried forward for the final rule analysis, the total electrified powertrain costs were developed by summing individual component costs. The costs associated with the IC engine, transmissions, electric machines, and battery packs were combined to create a full-system cost, per Section VI.C.3.e)(2) Non-battery Electrification Component Costs, Section VI.C.3.e)(1) Battery Pack Modeling, Section VI.C.1.g) Engine Costs, and VI.C.2.f) Transmissions Costs. This approach assured all technologies appropriately contributed to the total system cost.

The Alliance commented in support of the agencies' accounting separately for the subsystems' costs and benefits for CISG, BISG, P2 hybrid, power split hybrid (PS), and PHEV technologies.[1391] The Alliance noted that these distinctions are important to capture the differences between various technologies, which can have separate packaging requirements, efficiency potentials, and vehicle applications. Ford echoed the Alliance comments on the modeling of electric vehicles in the NPRM, stating they supported the use of separate cost and benefits modeling for P2 and power split strong hybrid technologies.[1392] Additionally, Ford commented that the modeling "better reflects market realities by recognizing that manufacturers cannot simply pass on the entire incremental costs of hybrid, plug-in hybrid, and battery electric vehicles to the customers."

Comments from other stakeholders generally stated that the NPRM powertrain sizing approach resulted in costs for complete powertrains that were too high compared to other studies or market observations. In addition, as discussed in Section VI.C.1.g) Engine Costs, CARB also commented that the costs associated with IC engines were not excluded from the final costs of BEV vehicles.[1393] CARB continued, stating that "the final costs of BEV vehicles are higher due to the inclusion of the base absolute costs, to which the assigned BEV incremental cost would be added." The agencies agreed with CARB that inclusion of IC engine costs in the BEV cost was an error in the analysis.

In response to this comment, the agencies developed absolute costs for baseline engines for the CAFE Model so the absolute costs for IC engines could be removed from BEVs. In the final rule analysis, when a vehicle adopted BEV technology, the costs associated with IC powertrain systems were removed. As the vehicle walks through the technology tree, becoming a battery electric vehicle, the motor and inverter (ETDS) costs replaced the internal IC engine costs. Since the cost of the ETDS accounted for significant portion of the total cost of electrification, it was important to accurately characterize the motor size (motor rating). To do

For SHEVPS and SHEVP2 vehicles, as explained further in Section VI.C.3.e)(4)(c) Strong Hybrid Costs, the agencies computed the average rating for traction and generator motors across all road load combinations using Autonomie simulation runs. Since motor sizing varies based on road load levels, the average motor sizes acted as a mid-range representation for motor ratings across all road load combinations. The full range of motor sizes are driven by road load limits; the motor size for initial road load levels (MR0, AERO0 and ROLL0) would be larger compared to the motor size for highest level of road load reduction (MR6, AERO20 and ROLL20). After calculating the average motor size, the agencies applied the $18/kW metric (derived from the EETT Roadmap report) for both traction motors and generator motors. As discussed earlier, the agencies also used the cost of the CVTL2 as proxy to represent the cost of the eCVT used in power-split hybrid vehicle systems, and used the cost of the AT8L2 as proxy for the cost of the planetary gear set used in the P2 parallel hybrid system. The total cost of electrification for power-split hybrid vehicles includes the cost of the eCVT transmission, and the total cost of electrification for the P2 parallel hybrid vehicles includes the cost of the planetary gear set transmission. The cost shown in the following tables has been updated to 2018$ dollars.

Par PHEV50 (PHEV50T)	139	0	$2,568	$184	$174	$460	$3,386	$1,690	$5,076	$7,614

CARB also submitted supplemental comments attempting a cost walk for electrified powertrain technologies, stating that inconsistencies in the model files and PRIA and lack of documentation about how the costs were derived "[left] the public without the ability to understand why the costs are what they are and what should be applied."[1394] Accordingly, a cost walk for a vehicle adopting an electrified powertrain is shown below. Additional comments on electrified powertrain costs are discussed in each individual technology section below, along with a discussion of changes made for the final rule in response to these comments.

For the final rule analysis, the agencies have updated several electrification inputs and assumptions in response to these comments, as discussed in the previous sections. An example of how the costs are applied to a simulated vehicle platform's technology cost is discussed here, to assist CARB and other stakeholders in assessing electrification technology costs for the final rule analysis. The example shows the costs for a vehicle with conventional engine and transmission technology as it adds electrification technology.

[1394] California Air Resources Board, NHTSA-2018-0067-12428, at 25.

The application of the electrification costs to an existing platform follows the same basic process for each technology on the electrification path. All technology costs used are for the model year of the electrification technology application. The first step is the process is the removal of the costs associated with the conventional drivetrain technologies. The next step is the application of the costs associated with the electrification technology. The costs include the cost of the engine, if applicable, transmission, non-battery components, and the battery pack. After the electrification costs are applied, other technology costs, such as aerodynamic or rolling resistance technologies are applied.

The specific example is the Toyota Rav4 LE AWD/XLE AWD simulated platform. The platform data were used from the reference run CAFE model standard setting vehicle_report.csv result file, augural standards results. The change in technology for the simulated platform was between MY 2023 and MY 2024. Table VI-127 shows the costing change between the MYs.

Table VI-127 – Cost Difference Between MY 2023 and MY 2024 Toyota Rav4 LE AWD/XLE AWD Simulated Platform.

MY	Tech Key	Tech Cost (2018$)
2023	HCR1; AT8; IACC; CONV; SAX; ROLL20; AERO15; MR0	1,596.51
2024	IACC; PHEV20; LDB; SAX; ROLL20; AERO20; MR1	10,122.64
	Cost Difference	8,526.13

Table VI-128 shows the costs, and where to find them, for the drivetrain components subtracted from the MY 2023 version of the platform. The costs for current engine and transmission were subtracted. To properly cost the engine it is important to note the engine was designated as a 4C1B engine, or, 4 cylinder 1 bank engine type. For more information about engine geometry designation in the technology input file please see Section VI.A.7 Structure of Model Inputs and Outputs.

Table VI-128 – Costs Removed During Electrification Cost Integration for Rav 4 example

Technology	Designation	Data location	MY 2024 value (2018$)
Engine	HCR1 / 4C1B	Technologies Input file (‘4C1B’ Tab, ‘HCR1’ Row)	5,835.32
Transmission	AT8	Technologies Input file (‘SmallSUV’ Tab, ‘AT8’ Row)	2,195.21

The costs for the new electrification technology were then applied. For the specific example the simulated vehicle platform is being converted to a PHEV20 powertrain. For all the technologies in the electrification path two major component groups were always added, the battery pack and the non-battery components. Hybrid electric technologies will also include the cost for an engine. Table VI-129 shows the costing data for the non-battery pack electrification technology components, and where the cost data can be found.

Table VI-129 – Costs added for the Non-Battery Pack Electrification Technology Components for Rav4 example

Technology	Application Note	Data location	MY 2024 value (2018$)
Engine	Per application features the PHEV20 technology has a specific engine applied	Technologies Input file (‘4C1B Tab’, ‘PHEV20’ row)	5804.24
PHEV20 Equipment	The non-battery components of the system	Technologies Input file (‘SmallSUV’ Tab, ‘PHEV20’ row)	6049.74

The battery pack is cost is determined by multiplying the baseline battery pack cost by the learn curve factor. Table VI-130 shows the calculation of the battery pack costs. The baseline battery costs are determined per discussions in Section VI.C.3.e)(1) Battery Pack Modeling.

Table VI-130 – Battery Pack Cost for Rav 4 Example

	Application Note	Data Location	(2018$)
Learning Factor	Value in MY 2024 = 1.24	Technologies Input file (‘SmallSUV’ Tab, ‘PHEV20’ row)	
Base Cost	$3590 (2018$)	Battery_Costs.csv file, a core CAFE model file.	
		Resultant Battery Pack Cost	4,451.6

Table VI-131 shows a summary of the total cost application for the technology transition of the Rav4 example platform. The added costs of the addition of the LDB technology, improvement from AERO15 to AERO20, improvement from MR0 to MR1 are summarized. However, the costing data for these technologies can be found in the Technology Input file on the ‘SmallSUV’ tab under each technology’s respective rows.

Table VI-131 – Summary of Technology Cost Change for Rav4 Example

MY	Technology Removed	Technology added	MY 2024 Cost (2018$)	Technology Cost (2018$)
2023				1596.51
	Engine (HCR1)		(5,835.32)	-4,238.81
	Transmission (AT8)		(2,195.21)	-6,434.02
		PHEV20 Engine	5804.24	-629.78
		PHEV20 Components	6049.74	5,419.96
		PHEV20 Battery Pack	4,451.60	9,871.56

MY	Technology Removed	Technology added	MY 2024 Cost (2018$)	Technology Cost (2018$)
		MR1, AERO20 and LDB	251.08	10,122.64
2024			8526.13	10,122.64

The following sections discuss specific electrification component cost comments on the NPRM, responses, and any relevant assumptions for the final rule analysis.

(a) Micro Hybrid Cost

As stated in PRIA, the cost of SS12V in NPRM included the cost of the battery, learning rate and retail price equivalent.[1395] The assumed direct manufacturing cost (DMC) was the same as was used for the Draft TAR and the Proposed Determination,[1396] but adjusted for learning and updated from 2013 to 2016 dollars. Cost learning made the cost of SS12V presented in the NPRM slightly lower than the Proposed Determination.

ICCT compared the agencies' NPRM cost effectiveness estimate for SS12V with EPA's Proposed and Final Determination analyses, and concluded that the latter analyses found SS12V cost nearly $100 less than the agencies found in the NPRM, with a higher effectiveness benefit.[1397] ICCT noted its difficulty in evaluating whether SS12V technology was actually cost-effective, since the NPRM CAFE model added the incremental cost of BISG over SS12V. ICCT stated that because SS12V is not as cost effective as other technologies in the electrification technology pathway, such as BISG, the analysis' estimate of SS12V costs was exaggerated and resulted in an unrealistic increase in compliance costs.

While BISG is more expensive than the SS12V, BISG provides additional benefits such as smoother start-stop (reduced vibration during each start-stop event), launch assist and/or torque assist (during certain sudden acceleration while passing or load at low speed for short burst of time). Therefore, the effectiveness of SS12V should not be compared to BISG. The agencies have always considered BISG as a separate technology. Also, the effectiveness of SS12V in the Proposed Determination was determined using ALPHA modeling. A peer reviewer noted that "[a]ccording to the documentation review, ALPHA's stop/start modeling appears to be very simplistic."[1398] As discussed in Section VI.B.3 Autonomie model, the Autonomie tool simulates the technology as part of the full vehicle system, accounting for interactions with other technologies, and therefore the agencies believe the full-vehicle simulations provide more realistic effectiveness estimates than the value from the Proposed Determination. For these reasons, the agencies disagree with ICCT's assertions. For SS12V, the

agencies continued to use the costs from the NPRM, which are consistent with the Draft TAR and Proposed Determination. The ETDS costs presented in the final rule do not include the cost of the battery.

(b) Mild Hybrid Cost

The belt integrated starter generator (BISG) and crank integrated starter generator (CISG), sometimes referred to as mild hybrid systems, provide idle-stop capability and use a higher voltage battery with increased energy capacity over typical automotive batteries. The higher voltage allows the use of a smaller, more powerful and efficient electric motor/generator which replaces the standard alternator. For the NPRM the agencies developed the costs for the mild hybrid systems assuming the use of a 115V system. The battery, motor, and supporting components were sized and costed based on this voltage level.

Many commenters asserted that the costs presented in the NPRM analysis for BISG and CISG systems were inflated or incorrect.[1399] ICCT noted that because mild hybrid systems were widely adopted by the fleet under the augural standards, the high cost of those systems had a significant impact on the costs of the standards.[1400]

Meszler Engineering Services noted that the NPRM documentation presented BISG/CISG battery costs that were "not unreasonable," and that the CAFE model database of battery costs used for NPRM analysis included estimates for those electrification technologies that were $259 higher than those presented in the NPRM documentation.[1401] Meszler surmised that it initially appeared as if the model may have been applying a redundant RPE factor to BISG/CISG costs, but noted that the determination that the costs differed from those documented by a constant absolute offset made that assumption an unlikely possibility.

ICCT and UCS both noted the discrepancy between the reported battery costs in the PRIA and costs reported in the NPRM Autonomie simulation databases.[1402] ICCT disagreed with the agencies' approach to modeling batteries in the NPRM analysis, stating that "[n]ot only is [the Argonne] database exceedingly difficult to access to modify battery costs (as battery costs should be a user input), but it makes it much harder to see how battery costs affect mild hybrid costs over time."[1403] Claimed difficulties aside, ICCT concluded that the battery costs were outdated and grossly overstated, based on the tables in section 6.3.9.12 of the PRIA and the outputs of the low battery cost sensitivity case, which ICCT stated were more closely aligned

with EPA and other research on battery costs. ICCT presented its own best estimate of NPRM BISG costs, stating that they were not able to make the PRIA and datafile costs match up.

Several commenters noted that the costs of BISG/CISG systems were higher for Small Cars/SUVs and Medium Cars than for Medium SUVs and Pickup trucks, which the Alliance and FCA described as "implausible" and "misaligned with industry understanding," and which ICCT described as "contrary to basic engineering logic, which holds that a system which would be smaller and have lower energy and power requirements would be less expensive, not more."[1404] Both ICCT and UCS stated that regardless of alleged errors in costs between technology classes, even the lower of the values presented in the PRIA overestimated the cost of mild hybrid batteries.[1405]

The Alliance and FCA urged the agencies to update the CAFE model to address this issue so that the cost of compliance was properly reflected in the results. To estimate the impact of the error, the Alliance and FCA modified the technology input file so that the Medium SUV and Pickup truck electrification costs were changed to be identical to the Small Car/SUV and Medium Car costs for SS12V, BISG, and CISG, and re-ran the CAFE model to show an estimated $13 billion increase in compliance costs under the augural standards with the error corrected.[1406]

Conversely, CARB modified the fuel consumption improvement estimates for BISG systems to match those predicted by Argonne in a recent report after calculating the smallest modified improvement from MYs 2015-2025 for five vehicle classes, resulting in efficiency improvements of 8.5-11 percent.[1407] CARB also reduced the non-battery costs for Small Car/SUVs to match the non-battery costs for Medium SUV and Pickup trucks, which CARB stated still reflected higher costs than those previously used by EPA in the Proposed Determination. CARB did not modify the battery costs, but did comment that they were overstated by approximately 50 percent "due to the erroneous oversizing of the battery." CARB's modified run decreased average vehicle technology costs by a range of $300-$500 per year, "reflecting an approximate 25 percent drop in 2029 model year incremental technology costs to meet the existing standards relative to the rollback standards."

[1406] Fiat Chrysler Automobiles, NHTSA-2018-0067-11943; Alliance of Automobile Manufacturers, NHTSA-2018-0067-12073.
[1407] California Air Resources Board, NHTSA-2018-0067-11873 ("Specifically, the fuel consumption improvements modeled by ANL in the most recent report for DOE were utilized in place of the assumptions used for the Agencies' analysis. As noted above, ANL, via Autonomie modeling, identified efficiencies between 8.5 percent to 12.7 percent for mild hybrids, relative to both gasoline spark ignited and relative to turbocharged gasoline spark ignited across five different vehicle classes. Using approximately the smallest modeled improvement across the 2015 to 2025 model years for each of the five classes, improvements of 8.5 percent-11 percent were utilized for a modified CAFE Model run.").

Commenters also pointed to prior agency analyses, studies, and applications of BISG systems to provide examples of what they believed BISG system costs should be, with ICCT arguing that the agencies' cost values for BISG/CISG systems were contrary to the research and evidence.[1408] HDS noted that the 2018 PRIA estimate was approximately double the estimate from the 2016 Draft TAR, that the difference in battery costs between those two analyses did not explain the difference, and that there was no discussion in the PRIA that did so.[1409]

UCS stated that BISG system costs have already reached that which was predicted in EPA's first Final Determination, published in 2017, for 2025, and would decline further because of continued volume-based learning.[1410] UCS also cited a 2018 Argonne report that estimated the battery component cost for a mild hybrid system to be $159.35, and a Chevrolet Malibu eAssist teardown study that estimated total battery subsystem direct costs at $166, and battery modules, power distribution, and covers at $120 in direct manufacturing costs.[1411] UCS summarized that the aforementioned costs are less than half the costs listed in the PRIA and approximately one quarter of the "BatPaCCost" value given in the Argonne input files. UCS also cited cost estimates from the 2015 NAS report and two EPA reports, and concluded that the agencies did not sufficiently explain why the NPRM cost data differed so substantially from this other available information.

ICCT cited its own 2016 study of supplier costs with estimates for 48V mild hybrid systems, estimating the system cost at $600-$1,000 (with costs on the lower side for cars and the higher side for light trucks) in the 2025 timeframe.[1412] ICCT pointed to the RAM 1500 pickup truck as an example of a vehicle with a BISG system that "has already validated the ICCT figures in 2019." ICCT noted that the BISG system, branded as eTorque, was first offered as a "free standing" option on the RAM 1500 truck for $800, and that price was recently raised to $1,450. ICCT stated that even with the higher price, applying the agencies' RPE of 1.5 means that the direct manufacturing cost is less than $1,000, which is less than the $1,616 direct manufacturing cost estimate in the NPRM for 2016 pickup trucks.[1413] Similarly, UCS cited the $500 premium that General Motors charged for the technology on its Chevrolet Silverado pickup trucks with eAssist.[1414]

The agencies reviewed all of the comments and information provided. It appears there may have been confusion about what costs were used for the Draft TAR and NPRM. For the Draft TAR, non-battery BISG costs, including learning and RPE, were $1,701 compared to

[1412] International Council on Clean Transportation, NHTSA-2018-0067-11741.
[1413] ICCT also stated that the eTorque system offered improved performance and driveability and contributes to higher payload and towing ratings for 2019 compared with 2018, and noted that the agencies "have completely failed to account for the consumer value of the utility benefits" from the system. The agencies' approach to simulating performance neutrality and the consumer benefit of increased performance are discussed in Section VI.B.3.a)(6) Performance Neutrality.
[1414] Union of Concerned Scientists, NHTSA-2018-0067-12039.

$1,186 for the NPRM (both costs in 2018 dollars). Therefore, the costs for the NPRM were lower than for the Draft TAR when cost accounting is on an equivalent basis.

Table VI-132 – Absolute BISG costs, without Batteries, Includes Learning and Retail Price Equivalent for MY 2017 in 2018$

Draft TAR[1415]	**NPRM**[1416]	**Final Rule**[1417]
$1,701	$1,186	$847

The agencies also determined the cost presented by EPA in Draft TAR (see Table 5.131 in Draft TAR) was the direct manufacturing cost of the BISG system, and not the retail price equivalent. The Draft TAR cost estimate in Table VI-132 includes the RPE and costs updated from 2013 to 2018 dollars. The agencies agree with the commenters about the discrepancy in the cost of the battery pack for the BISG system presented in PRIA and in CAFE model. To avoid any confusion, Table VI-132 shows the *non-battery* costs of the BISG system.

After considering the comments and reviewing the approach used in the NPRM, the agencies agreed updating the cost of the BISG system was appropriate for the final rule analysis. Adjustments were based on using a 48V BISG system instead of the 115V system used for the NPRM. For the final rule, the agencies considered several cost sources, including the EPA-sponsored FEV report titled: Light-Duty Vehicle Technology Cost Analysis on 2013 Chevrolet Malibu ECO with eAssist BAS Technology Study.[1418] Based on the teardown study, EPA estimated the direct manufacturing cost of the BISG system (without batteries) to be $1,045 in 2013 dollars. This included a cost adjustment for reduced voltage insulation. The agencies also considered the 2019 Dodge Ram eTorque system retail price. A cost of $1,195 for water-cooled system and $1,450 for air-cooled system in 2018 dollars was deduced from the retail price of eTorque assist (BISG) system. The 2015 NAS report estimated the cost range of BISG technology at $888 to $1,164 in 2010 dollars in 2025.[1419] This is equivalent to a range of $1,020 to $1,337.27 in 2018 dollars in 2025. The agencies also reviewed confidential business information on BISG cost and mass estimates provided by manufacturers.

For the final rule analysis, the agencies used the A2Mac1 database to develop a bill of materials for BISG systems. The agencies sourced cost estimates for the motor, inverter and

[1415] Table 5.131 in Draft TAR ($1,045 x1.5 = $1567.5 in 2013$. (Absolute cost, without batteries. This includes learning and Retail Price Equivalent).
[1416] Table 6-32 in PRIA (Absolute Electrification Cost without batteries. This includes learning and Retail Price Equivalent).

DC-DC converter from the 2017 EETT roadmap report.[1420] The agencies used BatPaC model version 3.1 to perform a standalone analysis determining the cost of a battery pack for the 48V system.[1421,1422] Table VI-133 shows the cost and mass estimates for BISG components used in the final rule.

Table VI-133 – Cost and Mass Estimate of BISG components (2018 dollars)

Components	**DMC**	**RPE**
Motor, Inverter & cooling system (10kW)	$184	$276
DC to DC converter (2kW)	$184	$276
Battery Pack (0.43kWh)	$405	$608
Water Pump	$43	$65
Wiring harness	$29	$44
Connecters	$10	$16
Belt pulley modifications to A/C compressor	$10	$15
Auxillary electric oil pump to transmission	$46	$69
Modifications to auxillary brake pump	$43	$65
Brackerts for motor and battery attachment	$15	$23
Total	$970	$1,455

The agencies compared the cost estimates in the 2017 EETT roadmap report and found they aligned well with cost estimates from sources cited by commenters. For reference, Table VI-133 above showed the cost estimate for BISG system (without the battery) used in Draft TAR, NPRM and in Final Rule. Furthermore, the agencies considered the Alliance and FCA analysis, provided in their respective comments, recommending the use of the same BISG system cost for both cars and trucks.[1423,1424] This analysis, supplemented with CBI data, demonstrated that the costs for implementing BISG systems on different vehicle classes was not appreciably different. The agencies agree with this assessment. For the final rule analysis, the cost of the BISG system is the same for cars, SUVs, and pickups.

(c) Strong Hybrid Cost

In the NPRM and this final rule analysis, the total cost for strong hybrids (SHEVP2 and SHEVPS) included the electric machine, battery pack, IC engine, and transmission. Discussed earlier in Section VI.C.3.d) Electrification Effectiveness Modeling, each strong hybrid powertrain is optimized for the given vehicle class by appropriate sizing of the electric machine, IC engine and battery pack. Accordingly, the costs represent the optimized system. For the NPRM, the agencies referred to the "*Assessment of vehicle sizing, energy consumption, and cost through large-scale simulation of advanced engine technologies"* report to estimate the cost and effectiveness for different hybrid systems for the NPRM.[1425] For the final rule, as discussed in Section (2) and further below, the agencies sourced cost estimates from the October 2017 U.S. DRIVE report, *"Electrical and Electronics Technical Team Roadmap."*[1426]

SHEVP2 and SHEVPS have different characteristics and in turn have different costs, as reflected in both the NPRM and this final rule analysis. The cost for engines and transmissions for SHEVP2s are based on estimates discussed further in Sections VI.C.1 Engine Path and VI.C.2 Transmission Path, respectively. The cost for SHEVP2 electric machines and battery packs were dependent on their sizes, which were optimized by the Autonomie sizing algorithm. SHEVPS total powertrain costs includes the optimized battery pack, electric machine, an Atkinson engine, and the CVT.

Many commenters generally stated that the costs of hybrid technology were overestimated in comparison to prior agency estimates and other publicly available sources, and that the agencies' documentation of hybrid system costs was unclear.

Meszler Engineering Services commented that the net costs of vehicles that apply SHEVP2 technology were in error, resulting from the way that the CAFE model applied HCR, CEGR and TURBO technology in combination with the SHEVP2 strong hybrid system.[1427]

HDS claimed that cost estimates for both SHEVP2 and SHEVPS were significantly higher than the Draft TAR estimates, differing by a factor of about 2 for SHEVP2 and by a factor of 2.5 for SHEVPS, with no justification given for the increase in costs.[1428] HDS noted that the SHEVPS cost estimates were particularly surprising since the costs have been investigated extensively since that technology was introduced to the market over a decade ago. HDS stated

[1428] H-D Systems, NHTSA-2018-0067-11985.

that the 2016 TAR estimates were in line with other analyses like the NAS estimate, and consistent with actual retail price increments observed in the market.

HDS also pointed to cost estimates based on teardown studies sponsored by EPA and the European Union,[1429] public cost data disclosed by suppliers of hybrid systems, and the retail prices of available hybrid vehicles as estimates that contradict the agencies' NPRM cost estimates. HDS compared the European Vehicle Market Phase 1 FEV cost analysis to the costs published by EPA in the TAR, concluding that the EU costs "even at [levels adjusted for the strength of the Euro] are quite similar to EPA estimates of $2,650 to $3,300 (depending on vehicle size) published in the TAR for the P2 hybrid, and also shows that the PS hybrid is just 7 percent more expensive than the P2 hybrid." HDS stated that battery costs have also certainly decreased since 2012 when the report was written, so current costs are estimated to be approximately $400 less than the values cited above.

HDS also cited a methodology to estimate costs from retail price increments in the market,[1430] stating that a typical cost-to-retail price ratio is 1.5. Applying this methodology, the cost of the SHEVPS hybrid as used by Ford and Toyota would be in the $2,500 to $3,000 range, the cost of a SHEVP2 as used by Hyundai Kia would be $2,250, and the cost of a low volume and/or luxury model system would be estimated at $3,300 for a SHEVP2.

Similarly, ICCT stated that the agencies failed to analyze properly the dozens of hybrid vehicles in the marketplace, their costs which were lower than the agencies assumed, and their rapid improvements from automakers and suppliers competitively developing lower cost components for those vehicles.[1431] ICCT observed an incremental price increase in the analysis for hybrid vehicles under the augural standards of approximately $6,600 per hybrid vehicle in 2017 and $4,800 in 2025, and concluded that this was not a plausible result considering hybrid component costs and full-vehicle prices in the marketplace in 2016 as well as the technology improvement that continues to enter the fleet. ICCT stated that the agencies must set a maximum cost premium for full hybrids of $2,500 in 2017, declining linearly to $1,400 by 2025 for mid-size cars and crossovers, with cost components likely scaling by vehicle power requirements (up for pickups, down for smaller cars), which it stated the agencies must also account for in the modeling.

ICCT stated that the agencies must disclose the basis for the "unrealistically high" hybrid system cost estimates, such that the public can clearly connect the bottom-up cost components to full vehicle costs for all vehicle models that have hybrid cost applied.[1432] ICCT stated that hybrid system cost estimates are "one of the most important technology cost estimations to assess the Augural standards' compliance cost, as the NPRM projects that 22 percent of vehicles

---

[1431] International Council on Clean Transportation, NHTSA-2018-0067-11741.
[1432] International Council on Clean Transportation, NHTSA-2018-0067-11741.

will need full hybrid systems to meet the augural standards," and accordingly after disclosing those costs, the agencies must provide another opportunity for public comment. Similarly, CARB stated that it was unable to decipher the hybrid cost components, and without that information could only guess as to why the costs increased relative to costs in the Draft TAR and EPA's Proposed Determination.[1433] As such, CARB stated they could not make a conclusion as to whether improper battery resizing, incorrectly modeled batteries, or oversized electric motors contributed to the overestimation of costs for strong hybrid systems.

The agencies believe comparing the retail price of P2 or PS hybrid to conventional vehicles could be misleading. Even though hybrid vehicles may have higher direct manufacturing costs, manufacturers may choose not to price it higher than the conventional version of the vehicle. In other words, manufacturers may choose to subsidize the cost of hybrid technologies to gain overall credit for fleetwide compliance. Therefore, the agencies believe that comparing retail price between hybrid and conventional vehicles should be done only when other sources of information are available to corroborate the differences in retail price.

The agencies also referred to an EPA-sponsored teardown and cost estimate report as suggested by HDS. Table VI-134 shows the absolute cost of P2 and PS hybrid systems as estimated in the EPA sponsored teardown report and the absolute cost estimated in the final rule in 2018$. As indicated above, the absolute cost in the final rule includes the cost of transmissions for the PS and P2 hybrid systems. The EPA teardown cost estimate includes the cost of the eCVT for the PS hybrid systems only. The P2 hybrid system costs do not include the cost of engine and transmission in the table below.

Although ICCT suggested that the agencies cap the maximum cost premium for full hybrids of $2,500 in 2017 and linearly decrease the cost to $1,400 by 2025, ICCT did not provide any supporting material to suggest that maximum upper limit of $2,500 for full hybrid is economically feasible, nor did they provide an example of an existing full hybrid vehicle in the marketplace with a technology increase of $2,500 in 2017. ICCT also did not make it clear if the costs suggested would be applicable to P2 or PS hybrid architecture.

Based on the comments, the agencies reassessed SHEVP2 and SHEVPS cost estimates for the final rule. As discussed above, the agencies referred to U.S. DRIVE's October 2017 report, "Electrical and Electronics Technical Team Roadmap"[1434] to estimate the cost of motors and inverters. The agencies also agreed with commenters and referenced the MY 2016 Chevrolet teardown report by UBS to estimate the cost of other hybrid components such as wiring harness, cables, voltage-step-down DC to DC converters, and on-board chargers. Per Section VI.C.3.e)(2) Non-battery Electrification Component Costs, for the final rule, the cost of non-battery hybrid system components includes the cost of traction motor, motor/generators, high voltage cables and connectors, charging cord, and on-board chargers. The cost of the planetary gear set is also included in the cost of non-battery components. Per Section VI.B.4 Technology Costs, for the final rule, the cost of hybrid systems is presented as absolute cost, and

---

[1433] California Air Resources Board, NHTSA-2018-0067-11873.
[1434] U.S. DRIVE, Electrical and Electronics Technical Team Roadmap (October 2017), https://www.energy.gov/sites/prod/files/2017/11/f39/EETT%20Roadmap%2010-27-17.pdf.

not as an incremental to some previous technology (absolute cost includes the retail price equivalent). The agencies used the cost of the AT8L2 transmission as a cost proxy for the planetary gear set in P2 hybrid systems, and used the cost of CVTL2 transmission as a cost proxy for planetary gear set for PS hybrid systems. It should also be noted the costs shown here do not include the cost of engine coupled to the hybrid system.

The agencies reviewed the FEV 2010 Ford Fusion HEV teardown report, Light Duty Technology Cost Analysis, Power-Split and P2 HEV Case Studies.[1435] In a Split-HEV architecture, there are two motors; one motor provides torque while the other motor act as a generator to recapture the energy during regenerative braking. The report does not capture the cost of motor-generator and the cost of the DC to DC converter. The report did not include an extensive teardown of a P2 hybrid vehicle, but rather made a cost adjustment for the PS motor and inverter to reflect additional cost. Table VI-134 shows the breakdown of cost estimates for the electric machine in the 2010 Ford Fusion HEV.[1436] Since the costs were developed in 2009$, the cost estimates for the same components are presented in 2018$. Table VI-135 shows the cost estimate for electric machines for a midsize passenger car for MY 2017 in 2018$.[1437] The cost is estimated using the EETT Roadmap report as explained earlier. Since EPA uses indirect cost multiplier (ICM) to determine the final retail price, and ICMs vary for different technologies, the agencies compared the direct manufacturing cost from report to the direct cost estimate in the final rule.

The direct manufacturing cost estimated in the Light Duty Technology Cost Analysis, Power-Split and P2 HEV Case Studies published for EPA is $3,689.28 in 2018$, and direct manufacturing cost estimated for electric machines in this final rule is $4,355.82. As mentioned before, the cost of the motor-generator and the cost of the DC to DC converter is not captured in that report.

Table VI-134 – Absolute Cost of P2 and PS Hybrid Systems in FEV Report and Final Rule

2010 Ford Fusion HEV (not including battery pack)	2009$ DMC	2018$ DMC
Transmission System (eCVT and Motor)	$2,216.43	$2576.34
Electrical Power Supply System (Inverter)	$755.96	$878.42
Electrical Distribution and Control System (Cables)	$201.5	$234.22
Total of HEVPS in FEV report	$3,173.89	$3,689.28

[1435] Light Duty Technology Cost Analysis, Power-Split and P2 HEV Case Studies, EPA-420-R-11-015 (November 2011), available at https://nepis.epa.gov/Exe/ZyPDF.cgi/P100EG1R.PDF?Dockey=P100EG1R.PDF.
[1436] Table D-4 (components considered are transmission, power distribution cables and Inverter). The cost of inverter is from Table D-11.
[1437] Average peak power for the traction motor used in this final rule is 72kW, and 37kW continuous power for the generation motor.

Table VI-135 – Direct Manufacturing Cost Estimate for a Midsize Non-performance Car for MY 2017 (2018$)

Cost of Electric Machine in Final Rule (not including battery pack)	MY 2017	MY 2017
Midsize Non-Performance Car (MY2017)	DMC	RPE
Motor + Inverter +DC Converter + Cables	$2666.44	$3999.66
CVT	$1689.37	$2534.06
Total Cost of SHEVPS in final rule	$4355.82	$6533.73

(d) PHEV Cost

Plug-in hybrid vehicles' costs were developed similar to strong hybrids for the NPRM analysis and the final rule analysis. The plug-in-hybrid system components were optimized, per Section VI.C.3.d)(2) Modeling and Simulating Vehicles with Electrified Powertrains in Autonomie and the resultant systems were used to determine costs, per Battery Pack Modeling and Non-battery Electrification Component Costs. Per Section VI.C.3.c) Electrification Adoption Features, the agencies used one engine technology and one transmission technology per plug-in hybrid architecture type.

For PHEVs following SHEVP2 on the hybrid/electric architecture path, per Section VI.C.3.a)(1) Electrification technologies, the total cost of the technology package was determined from summing the costs of the TURBO1 engine, the AT8L2 transmission, and the battery and non-battery electrification technology components. For PHEVs following SHEVPS on the hybrid/electric architecture path, per Section VI.C.3.a)(1) Electrification technologies, the total cost of the technology package was determined from summing the costs of the Atkinson engine, the CVT transmission, and the battery and non-battery electrification technology components.

CARB provided observations about non-battery component costs for PHEVs, arguing that what the agencies asserted for the incremental costs of a PHEV over a strong hybrid vehicle are not supported in the market.[1438] CARB cited the Toyota Prius Prime and Hyundai Sonata as examples of vehicles that share most of their components with their non-plug-in hybrid counterparts, with components like the on-board charger and higher voltage, larger energy capacity battery pack excepted. CARB stated the agencies' lack of discussion about how non-battery component costs were developed made it "virtually impossible to understand what the drivers are for the increases in costs relative to the Agencies' previous analysis for the 2016 Draft TAR and EPA's Proposed Determination." CARB concluded that the available PHEV market offerings do not support the higher costs relative to the Draft TAR and EPA's Proposed Determination analyses, and no justification was provided for the change.

The agencies agree with CARB that the incremental costs of PHEV over strong hybrid costs were too high, and that values were not supported by the market. In response to this

[1438] California Air Resources Board, NHTSA-2018-0067-11873.

comment, the agencies updated the non-battery component costs as well as the battery costs to better reflect the market values. In addition, the agencies have optimized the Autonomie modeling in a way to maintain the same engine, transmission and other components from a SHEVP2 or SHEVPS moving to a PHEV20/50 or PHEV20T/50T.[1439] For further discussions on PHEV modeling and updates, see Section VI.C.3.a)(1) Electrification technologies and Section VI.C.3.d) Modeling and Simulating Vehicles with Electrified Powertrains in Autonomie. The updates discussed here and applied to the final analysis resulted in values that more accurately represented PHEV technology costs.

(e) BEV Cost

For the NPRM and this final rule analysis, the total costs of BEVs included optimized battery pack and electric machine costs. Like the other electrified powertrains, Autonomie optimized both the size of the battery pack and electric machine to fulfill the performance neutrality requirements for each vehicle. Further discussion on electrification technology component sizing and optimization is provided in Section VI.C.3.d) Modeling and Simulating Vehicles with Electrified Powertrains in Autonomie. Discussion on electrification component costing is provided in Battery Pack Modeling and Non-battery Electrification Component Costs. When computing the total cost of a vehicle, the agencies remove the costs of the IC engines and transmission when a conventional or hybridized powertrain adopts BEV technologies. In Section VI.C.1 Engines Path and Section VI.C.22 Transmission, the agencies discussed the absolute costs used for engine and transmission technologies in the final rule analysis.

ICCT stated that if the agencies had considered BEV battery and other component costs correctly, cost parity would be reached with conventional combustion vehicles in the 2025-2027 timeframe.[1440] ICCT went on to allege that if the agencies removed all constraints on electric vehicles,[1441] they would appropriately realize that the 2025 standards are more cost-effective if electric vehicles are included.

The agencies disagree with ICCT's statement that BEVs would reach parity to IC engines by the 2025-2027 timeframe. For this final rule analysis, the agencies have updated the battery pack costs, electric machine costs, and excluded costs of IC engines and transmission when a vehicle was converted to a BEV. However, the costs still did not reach parity within the rulemaking time frame. Furthermore, NHTSA notes that the decision to exclude BEV technology from the CAFE program standard-setting analysis is not a choice made by the agency, but a statutory requirement.[1442]

[1439] *I.e.*, a SHEVP2 with a turbocharged engine may adopt PHEV20T or PHEV50T technology, but a SHEVPS will only ever adopt PHEV20 or PHEV50 technology, as the SHEVPS do not use turbocharged engines.
[1440] International Council on Clean Transportation, NHTSA-2018-0067-11741.
[1441] As discussed above, the agencies believe that ICCT misunderstood the agencies' statutory obligations and the differences between the standard setting modeling scenario and the "real-world" modeling scenario. The agencies did not apply additional constraints on BEVs in the NPRM analysis.
[1442] *See* 49 U.S.C. 32902(h).

(f) FCV Cost

For the NPRM and the final rule analysis the agencies considered fuel cell vehicle technology advancements in hydrogen storage tanks, sensors and control systems, and market penetration.[1443] The agencies are also considered the availability of hydrogen refueling stations across the country and cost of compressed hydrogen.[1444, 1445] Although the agencies did not receive any comments on the cost of fuel cell vehicles, the agencies updated the cost of hydrogen storage tanks and fuel cells based on a cost analysis from Department of Energy (DOE), Office of Energy Efficiency and Renewable Energy (EERE), Fuel Cell Technologies Office.[1446]

The DOE estimates that the cost of a compressed gas storage system is around $28/kWh (assumed rate of production of 10,000 units per year). The hydrogen fuel price ranges from $12.85 to $16 per kilogram, which translates to approximately $5.60 per gallon on an equivalent energy basis.[1447]

Table VI-136 shows the evolution of the fuel cell vehicle costs from the Draft TAR to final rule (costs include the fuel cell, control systems, motors, inverters, hydrogen storage tanks, wiring harness, hydrogen fuel sending lines, safety systems, sensors and hardware for mounting and installation). The cost of the battery pack and battery management system is not included in the cost of the fuel cell vehicle.

Table VI-136 – Cost of Fuel Cell Technologies (2018$)

Draft TAR	NPRM	Final Rule
$20,346.54	$17,381.97	$20,512.00

4. Mass Reduction

Mass reduction is a relatively cost-effective means of improving fuel economy and reducing CO_2 emissions, and vehicle manufacturers are expected to apply various mass reduction technologies to meet fuel economy and CO_2 standards. Reducing vehicle mass can be accomplished through several different techniques, such as modifying and optimizing vehicle component and system designs, part consolidation, and adopting lighter weight materials (advanced high strength steel, aluminum, magnesium, and plastics including carbon fiber reinforced plastics). The cost for mass reduction depends on the type and amount of materials

---

used, the manufacturing and assembly processes required, and the degree to which changes to plants and new manufacturing and assembly equipment is needed. In addition, manufacturers may develop expertise and invest in certain mass reduction strategies that may affect the approaches for mass reduction they consider and the associated costs. Manufacturers may also consider vehicle attributes like noise-vibration-harshness (NVH), ride quality, handling, and various acceleration metrics when considering how to implement any mass reduction strategy. See Section VI.B.3.a)(5) Maintaining Vehicle Attributes for more details.

The automotive industry uses different metrics to measure vehicle weight. Some commonly used measurements are vehicle curb weight,[1448] gross vehicle weight (GVW),[1449] gross vehicle weight rating (GVWR),[1450] gross combined weight (GCVW),[1451] and equivalent test weight (ETW),[1452] among others.

The vehicle curb weight is the most commonly used measurement when comparing vehicles. A vehicle's curb weight is the weight of the vehicle including fluids, but without a driver, passengers, and cargo.

A vehicle's glider weight, which is vehicle curb weight minus the powertrain weight, is used to track the potential opportunities for weight reduction not including the powertrain. A glider's subsystems may consist of the vehicle body, chassis, interior, steering, electrical accessory, brake, and wheels systems. However, as noted in the PRIA, the definition of a glider may vary from study to study (or even simulation to simulation).

Each of the subsystems presents an opportunity for weight reduction; however, some weight reduction is dependent on the weight reduction of other subsystems. The agencies characterize mass reduction as either primary mass reduction or secondary mass reduction. Primary mass reduction involves reducing mass of components that can occur independent from the mass of other components. For example, reducing the mass of a hood (e.g., replacing a steel hood with an aluminum hood) or reducing the mass of a seat are examples of primary mass reduction because each can be implemented independently. Other components and systems that may contribute to primary mass reduction include the vehicle body, chassis, and interior components.

When significant primary mass reduction occurs, other components designed based on the mass of primary components may be redesigned as well. An example of a subsystem where

---

[1448] This is the weight of the vehicle with all fluids and components but without the drivers, passengers, and cargo.
[1449] This weight includes all cargo, extra added equipment, and passengers aboard.
[1450] This is the maximum total weight of the vehicle, passengers, and cargo to avoid damaging the vehicle or compromising safety.
[1451] This weight includes the vehicle and a trailer attached to the vehicle, if used.
[1452] For the EPA two-cycle regulatory test on a dynamometer, an additional weight of 300 lbs. is added to the vehicle curb weight. This additional 300 lbs. represents the weight of the driver, passenger, and luggage. Depending on the final test weight of the vehicle (vehicle curb weight plus 300 lbs.), a test weight category is identified using the table published by EPA according to 40 CFR 1066.805. This test weight category is called "Equivalent Test Weight" (ETW).

secondary mass reduction can be applied is the brake system. If the mass of primary components is reduced sufficiently, the resulting lighter weight vehicle could safely maintain braking performance and attributes with a lighter weight brake system. Other examples of components where secondary mass reduction can be applied are wheels and tires.

For this analysis, the agencies consider mass reduction opportunities from the glider subsystems of a vehicle first, and then consider associated opportunities to downsize the powertrain, which are accounted for separately.[1453] As explained later, in the Autonomie simulations, the glider system includes both primary and secondary systems from which a percentage of mass is reduced for different glider weight reduction levels; specifically, the glider includes the body, chassis, interior, electrical accessories, steering, brakes and wheels. The model sizes the powertrain based on the glider weight and the mass of some of the powertrain components in an iterative process. The mass of the powertrain depends on the powertrain size. Therefore, the weight of the glider impacts the weight of the powertrain.[1454] See Section VI.B.3.a)(3) Vehicle models for Autonomie and Section VI.B.3.a)(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation for more details.

The agencies use glider weight to apply non-powertrain mass reduction technology, and use Autonomie simulations to determine the size of the powertrain and corresponding powertrain weight for the respective glider weight. The combination of glider weight (after mass reduction) and re-sized powertrain weight equal the vehicle curb weight. See Section VI.C.4.e)(1) glider mass and mass reduction subsection below for more detail on glider mass and glider mass reduction.

a) Material Trends

Advanced high strength steel (AHSS) and aluminum (AL) have played a major role in recent years as materials used to reduce vehicle mass. The penetration rate of AHSS or AL depends on a number of factors such as vehicle redesign cycle timing, material availability, accompanying changes in manufacturing equipment, and changes in joining methods, among other things. A study conducted for the American Iron and Steel Institute shows the application of AHSS in vehicles has increased from 81 lbs. on average in 2006 to 254 lbs. in 2015.[1455]

[1453] When the mass of the vehicle is reduced by an appropriate amount, the engine may be downsized to maintain performance. *See* Section VI.B.3.a)(5) Maintaining Vehicle Attributes] and Section VI.B.3.a)(6) Performance Neutrality for more details.

[1454] Since powertrains are sized based on the glider weight for the analysis, glider weight reduction beyond a threshold amount during a redesign will lead to re-sizing of the powertrain. For the analysis, the glider was used as a base for the application of any type of powertrain. A conventional powertrain consists of an engine, transmission, exhaust system, fuel tank, radiator and associated components. A hybrid powertrain also includes a battery pack, electric motor(s), generator, high voltage wiring harness, high voltage connectors, inverter, battery management system(s), battery pack thermal system, and electric motor thermal system.

[1455] Abey Abraham, Metallic Material Trends in the North American Light Vehicle (May 2015), available online at - http://www.steelsustainability.org/~/media/Files/Autosteel/Great%20Designs%20in%20Steel/GDIS%202015/Track%202%20-%20Abraham.pdf

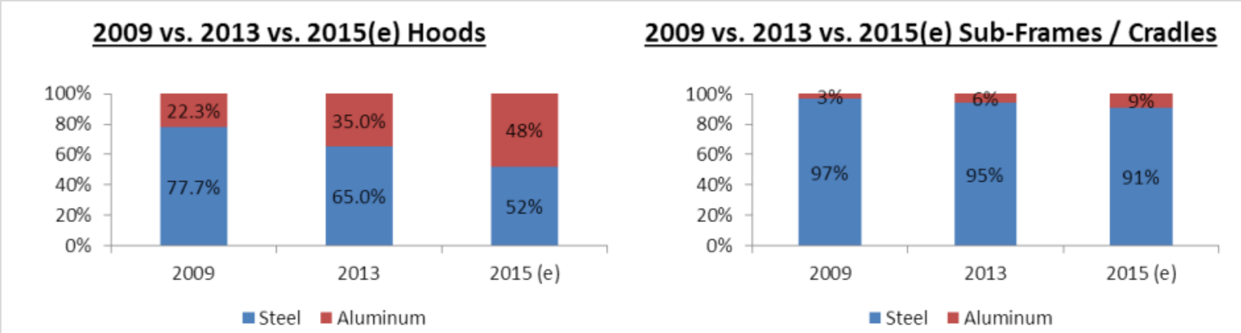

Figure VI-98 – Penetration of AL in Hoods and Engine Cradles from 2009 to 2015

According to a study conducted for the Aluminum Association, aluminum content in vehicles has increased from nearly 300 lbs. in 2005, to 394 pounds in 2015, up from roughly 80 pounds in 1975, and a little more than 150 pounds in 1990. [1456] Since the 1980s, many castings have migrated from steel to aluminum.[1457] Figure VI-98 shows AL replacing steel in greater percentages in vehicle hoods, and AL beginning to penetrate engine sub frames/cradles in small percentages.[1458]

Some manufacturers have also begun to experiment with advanced composites, such as carbon fiber, to achieve mass reduction. Currently, the cost of carbon fiber and production complexity limits wide-scale adoption in many high production automotive components. However, there are growing examples where carbon fiber is being strategically used, such as in roof bows, supporting pillars, door frames and in chassis in luxury vehicles. While many of these applications do decrease curb weight, many carbon fiber applications provide additional (or primary) benefits of lower center of gravity and improved weight distribution.

A 2017 report published by American Chemistry Council (ACC) shows that while the overall share of plastics and polymer composites in vehicles have decreased by 0.1% in the last 10 years,[1459] the share of AL has increased by 2.3%.[1460] The report also published data on material content in vehicles as shown in Table VI-137 and Table VI-138.

[1456] Available online at - http://www.autonews.com/assets/PDF/CA95065611.PDF

[1457] For instance, engine blocks and transmission cases are nearly universally aluminum in the MY 2016 fleet, but aluminum was rarely used in these applications prior to the 1990's.

[1458] *Id.*

[1459] After rapidly increasing in the 1960's through the 1990's.

[1461] Despite long lead times for material qualification of new metal alloys, medium and high strength steels have been and continue to be widely adopted in the automotive industry at a rapid pace. Advanced steel materials typically replace regular steel, and often compete with aluminum and composites in body systems.

[1462] "Other Metals" are typically used sparingly in specialty applications in the auto industry, and these metals make up a small portion of total vehicle weight.

b) Mass Reduction in the CAFE Model

Several studies have explored the amount of vehicle mass reduction that is feasible in the rulemaking timeframe and the cost for that mass reduction.[1463,1464,1465,1466] Those studies were sponsored by the agencies, CARB, ICCT, the automotive industry, and material manufacturers, and are discussed in Section VI.C.4.f)(1), below. All of the studies showed that the maximum feasible amount of mass reduction that can be applied in the rulemaking timeframe is around 20 percent of a baseline vehicle's curb weight. The National Academies of Sciences similarly concluded, based on some of these same studies along with other information, that it is feasible to reduce up to 20 percent of the mass of the vehicle.[1467]

As discussed in Section VI.C.4.f), the mass reduction studies show that the cost for mass reduction increases progressively as the amount of mass reduction increases. In other words, lower levels of mass reduction are more cost effective than higher levels of mass reduction. As in past rulemakings, the agencies have considered multiple levels of mass reduction to provide options similar to what manufacturers could consider at vehicle redesigns.

For the NPRM, the agencies included five levels of mass reduction with a maximum of 20 percent glider mass reduction, corresponding to 10 percent curb mass reduction, using the assumption that the glider was 50 percent of curb weight. Table VI-139 shows the glider and curb weight mass reduction levels for each level of mass reduction considered in the NPRM analysis.

Table VI-139 – NPRM Mass Reduction Technology Level and Associated Glider and Curb Mass Reduction (Passenger Cars and Light Trucks)

MR Level	MR % (50% Glider Share)	Approximate Percentage Mass Reduction at Curb Weight Level
MR0	0%	0.0%
MR1	5%	2.5%
MR2	7.5%	3.8%
MR3	10%	5.0%
MR4	15%	7.5%
MR5	20%	10.0%

The agencies received a number of comments suggesting that the amount of mass reduction allowed should be 20 percent of curb weight, as well as suggestions that the agencies

[1467] Cost, Effectiveness and Deployment of Fuel Economy Technologies for Light-Duty Vehicles, National Academy of Sciences, 2015, at 212 .

should assume the glider represents 75 percent of the vehicle's curb weight. These comments are addressed in more detail in Section VI.C.4.e) below, but some understanding of how the glider share assumption affects the maximum amount of mass reduction allowed in the CAFE model is required here.

Several commenters stated that the agencies should allow further levels of mass reduction technology improvements in the CAFE model. For example, ICCT commented that the agencies must revise their treatment of mass reduction because studies have demonstrated that at least 20% mass reduction of curb weight is available for adoption across vehicle classes by 2025.[1468] ICCT stated that based on these studies, the agencies must increase the maximum available mass reduction potential levels to include up to 20% and 25% mass reduction of curb weight, as the industry "will cost-effectively deploy at least 15% vehicle curb mass reduction in the 2025 timeframe at net zero cost." ICCT caveated that amount of mass reduction seems less likely in smaller cars, which typically employ lower levels of mass reduction, so a constraint of 7.5 percent mass reduction as was applied in the Draft TAR would be appropriate for those vehicles.

ICCT also commented that there were numerous material improvements in development that were not considered in the rule, including but not limited to higher strength aluminum, improved joining techniques for mixed materials, third-generation steels with higher strength and enhanced ductility, a new generation of ultra-high strength steel cast components, and metal/plastic hybrid components, among other technologies mentioned in ICCT's working paper on light-weighting.

In assessing these comments, the agencies reconsidered the mass reduction studies and available reports and agreed that additional levels of mass reduction should be available for the final rule analysis. In response to comments, the agencies made two adjustments to allow higher levels of mass reduction in the analysis. First, as explained in Section VI.C.4.e)(1), below, the agencies increased the glider percentage of vehicle curb weight used for the analysis from 50 percent to 71 percent. As explained in that section, increasing the glider percentage also increases the amount of curb weight reduction for all levels of mass reduction. Second, the agencies created another level of mass reduction (MR6) in the CAFE model, which represents a significant application of carbon fiber in the vehicle to achieve nearly 30 percent reduction in glider weight (which approximately translates to 20 percent reduction in vehicle curb weight). For example, incorporating a carbon fiber tub,[1469] or a carbon fiber monocoque with aluminum sub frame in the front and back,[1470] or a carbon fiber splitter and carbon fiber wheels,[1471] allows for greater levels of mass reduction, albeit at a very high cost. These technologies are not ready for high volume production vehicles.

[1468] NHTSA-2018-0067-11741. ICCT also alleged that the agencies intentionally disregarded the studies that presented this result; those comments are discussed in Section VI.C.4.f) Mass Reduction Costs, below

[1469] The BMW i3 and BMW i8, which are about 20 percent lighter than an average MY 2017 vehicle, use a carbon fiber tub.

[1470] The Alfa Romeo 4c/4c Spider, which is about 20 percent lighter than an average MY 2017 vehicle, uses this design.

[1471] The Ford Shelby GT350R which is about 20 percent lighter than an average MY 2017 vehicle, uses this design.

Table VI-140 shows the levels of mass reduction technology available for application in the final rule analysis, with the associated glider weight percentage reduction and the percentage curb weight reductions for passenger cars and light trucks. As discussed in Section VI.C.4.d) below, the agencies declined to place a constraint on the amount of mass reduction technology that smaller cars could adopt.

Table VI-140 – Final Rule Mass Reduction Technology Level and Associated Glider and Curb Mass Reduction

MR Level	Percent Glider Weight	Percent Vehicle Curb Weight (Passenger Cars)	Percent Vehicle Curb Weight (Light Trucks)
MR0	0%	0.00%	0.00%
MR1	5%	3.55%	3.55%
MR2	7.5%	5.33%	5.33%
MR3	10%	7.10%	7.10%
MR4	15%	10.65%	10.65%
MR5	20%	14.20%	14.20%
MR6	28%	20.00%	20.00%

The agencies continue to believe the maximum feasible mass reduction levels identified in comprehensive design studies, such as those discussed in Section VI.C.4 Mass Reduction Costs are the most reliable for projecting the maximum amount of mass reduction in the rulemaking timeframe, and therefore have determined MR6 is the highest level that should be used for the final rule analysis. While the information provided by ICCT on newer materials and manufacturing and assembly methodology is interesting and relevant, this information, by itself, is insufficient to assess the amount of mass reduction that is feasible and the cost for the mass reduction. ICCT did not provide a comprehensive analysis showing a design concept that maintains vehicle attributes and performance, such as noise, vibration and harshness, stiffness, handling, compliance with NHTSA safety standards, good performance under NHTSA NCAP and IIHS rating systems, and other criteria. The various studies in Section VI.C.4.f) Mass Reduction considered those factors to varying degrees. Without that rigorous analysis, the actual amount of mass reduction that could be enabled through the use of those materials and methods described by ICCT, and the cost of achieving that mass reduction, would be highly speculative. As explained in Section VI.C.4.f) Mass Reduction below, the agencies determined the NHTSA-sponsored design studies remain a reasonable basis for estimating a feasible amount of mass reduction and the cost for mass reduction in the rulemaking timeframe, because those studies considered a wide range of materials (including advanced materials) and design solutions.

c) Analysis Fleet Mass Reduction Assignments

The agencies included an estimated level of mass reduction technology for each vehicle model in the MY 2016 analysis fleet for the NPRM, and have updated the estimates for the MY 2017 analysis fleet for the final rule analysis. The methodology used to provide each vehicle model an appropriate initial mass reduction technology level for further improvements was described in detail in the Draft TAR (when NHTSA first employed this methodology), in the PRIA accompanying the NPRM, and is reproduced here, in part, to provide additional context to the agencies' responses to comments on analysis fleet mass reduction assignments. The methodology used in this final rule was unchanged from the NPRM.

For the Draft TAR, NHTSA/Volpe Center staff developed regression models to estimate curb weights based on other observable attributes. With regression outputs in hand, Volpe evaluated the distribution of vehicles in the analysis fleet. In addition, vehicle platforms were evaluated based on the sales-weighted residual of actual vehicle curb weights versus predicted vehicle curb weights. Based on the actual curb weights relative to predicted curb weights, platforms (and the subsequent vehicles) were assigned a baseline mass reduction level (MR0 through MR6). For the NPRM and final rule analysis, the agencies followed a similar procedure for the MY 2016 and MY 2017 analysis fleets.

To develop the curb weight regressions, the agencies grouped vehicles into three separate body design categories for analysis: 3-Box, 2-Box, and Pick-up.

Table VI-141 – Mass Reduction Body Styles Sets

3-Box	**2-Box**	**Pick-up**
Coupe Sedan Convertible	Hatchback Wagon Sport Utility Minivan Van	Pick-up

For the NPRM and final rule analysis, the agencies retained the MY 2015 regressions for 3-Box and 2-Box vehicles, however the pickup category regression was updated in response to comments on the Draft TAR. The agencies trained a new regression with EPA MY 2014 data and added pick-up bed length as an independent variable. As a result of stepping back to MY 2014 data for the pick-up regression, the training data did not include the all-aluminum body Ford F-150 in the calculation of the baseline. The advanced F-150 in the MY 2015 pick-up regression meaningfully affected Draft TAR regression statistics because the F-150 accounted for a large portion of observations in the analysis fleet, and the F-150 included advanced weight savings technology.

The agencies leveraged many documented variables in the analysis fleet as independent variables in the regressions. Continuous independent variables included footprint (wheelbase x track width) and powertrain peak power. Binary independent variables included strong HEV (yes or no), PHEV (yes or no), BEV or FCV (yes or no), all-wheel drive (yes or no), rear-wheel drive (yes or no), and convertible (yes or no). In addition, for PHEV and BEV/FCV vehicles, the capacity of the battery pack was included in the regression as a continuous independent variable. In some body design categories, the analysis fleet did not cover the full spectrum of independent variables. For instance, in the pickup body style regression, there were no front-wheel drive vehicles in the analysis fleet, so the regression defaulted to all-wheel drive and left an independent variable for rear-wheel drive.

Furthermore, the agencies evaluated alternative regression variables in response to comments from vehicle manufacturers on the NHTSA/Volpe analysis in the Draft TAR.[1472] The agencies evaluated regressions including overall dimensions of vehicles, such as height, width, and length, instead of and in addition to just wheelbase and track width. The experimental regression variables only marginally changed predicted curb weight residuals as a percentage of predicted curb weight, at an industry level and for most manufacturers. The results were not significantly different, and therefore the agencies opted not to add these variables to regressions or replace independent variables presented in Draft TAR with new variables.

Each of the three regressions produced outputs effective for identifying vehicles with a significant amount of mass reduction technology in the analysis fleet. Many coefficients for independent variables provided clear insight into the average weight penalty for the utility feature. In some cases, like battery size, the relatively small sub-sample size and high collinearity with other variables confounded coefficients.

By design, no independent variable directly accounted for the degree of weight savings technology applied to the vehicle. Residuals of the regression captured weight reduction efforts and noise from other sources.

The agencies received many comments on the Draft TAR encouraging the use of observed technologies in each vehicle, and in each vehicle subsystem to assign levels of mass reduction technology. As a practical matter, the agencies cannot conduct a tear down study and detailed cost assessment for every vehicle in every model year. However, upon review of many vehicles and their subsystems, the agencies recognized a few vehicles with MR0 or MR1 assignments in NHTSA's analysis of the Draft TAR that contained some advanced weight savings technologies, yet these vehicles and their platforms still produced ordinary residuals. Engineers from industry confirmed important factors other than glider weight savings and the independent variables considered in the regressions may factor into the use of lightweight technologies. Such factors included the desire to lower the center of gravity of a vehicle, improve the vehicle weight distribution for handling, optimize noise-vibration-and-harshness, increase torsional rigidity of the platform, offset increased vehicle content, and many other factors. In addition, engineers highlighted the importance of sizing shared components for the most demanding applications on the vehicle platform; optimum weight savings for one platform application may not be suitable for all platform applications. For future analysis, the agencies will look for practical ways to improve the assessment of mass reduction content and the forecast of incremental mass reduction costs for each vehicle.

Figure VI-99 below shows results from the pickup truck regression on predicted curb weight versus actual curb weight. Points above the solid regression line represent vehicles heavier than predicted (with lower mass reduction technology levels); points below the solid regression line represent vehicles lighter than predicted (with higher mass reduction technology levels). The dashed lines in the Figure VI-99 show the thresholds (5, 7.5, 10, 15, 20 and 28 percent of glider weight). Final rule glider weight assumption is 71 percent of vehicle curb weight.

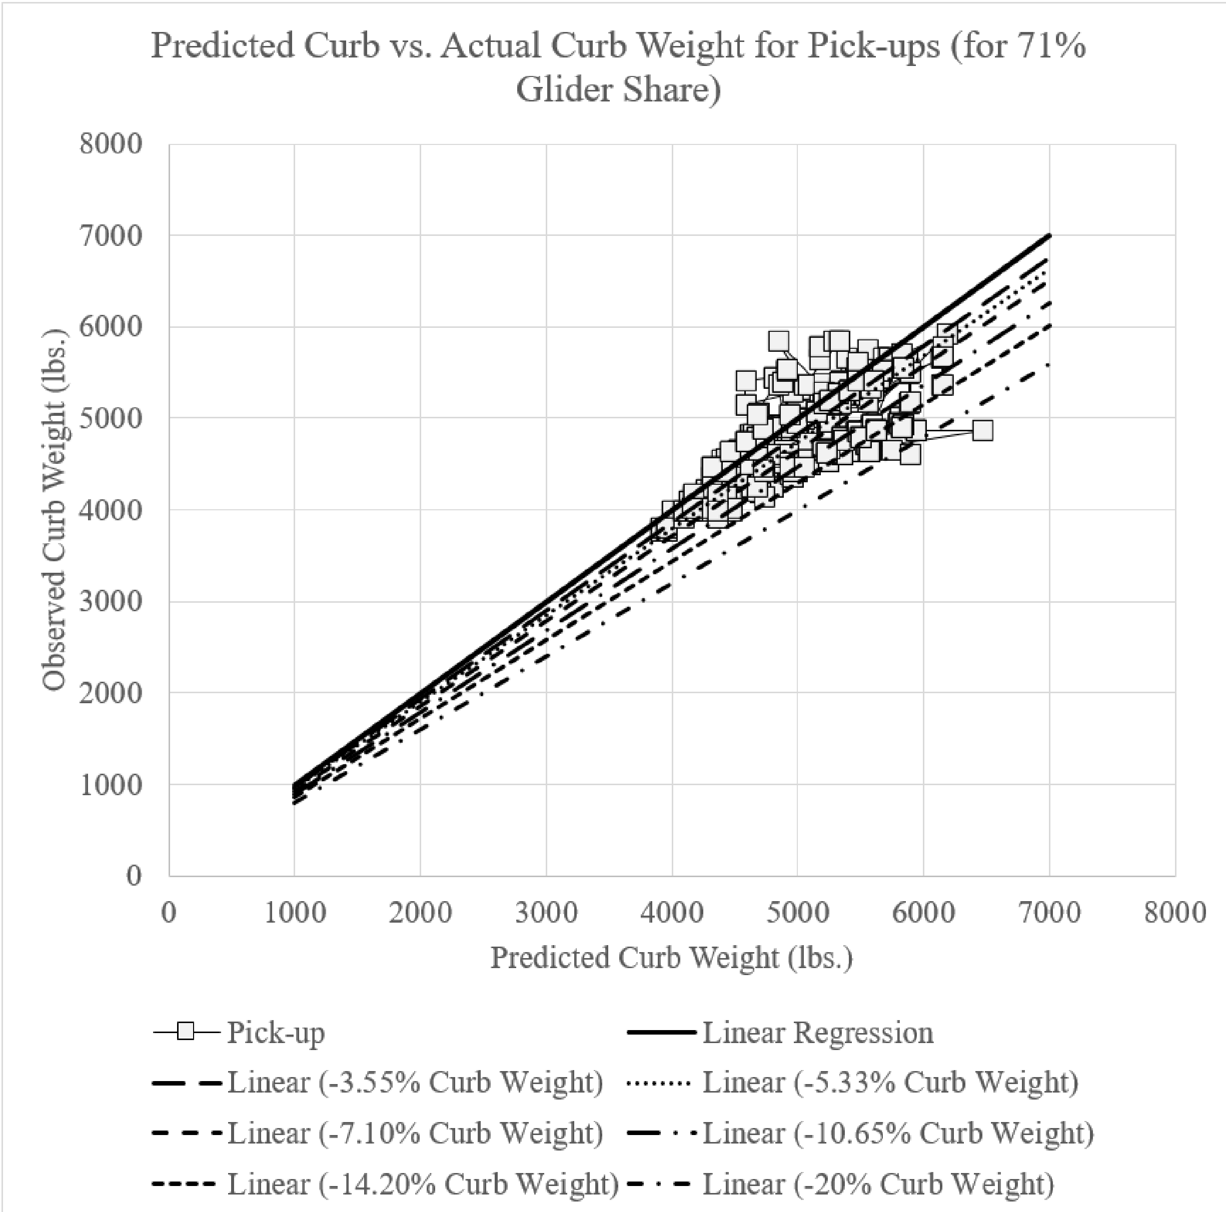

Figure VI-99 – Observed Curb Weight vs. Actual Curb Weight for the MY 2017 Analysis Fleet for 71 Percent Glider Share

For points with actual curb weight below the predicted curb weight, the agencies used the residual as a percent of predicted weight to get a sense for the level of current mass reduction technology used in the vehicle. Notably, vehicles approaching -20% curb weight widely use advanced composites throughout major vehicle systems, and few examples exist in the MY 2016 fleet.[1473]

Generally, residuals of regressions as a percent of predicted weight appropriately stratified vehicles by mass reduction level. Most vehicles showed near zero residuals or had actual curb weights close to the predicted curb weight. Few vehicles in the analysis fleet were identified with the highest levels of mass reduction. Most vehicles with the largest negative residuals have demonstrably adopted advanced weight savings technologies at the most expensive end of the cost curve.

To validate the residuals, the agencies estimated the mass reduction technology level for several vehicle models in the analysis fleet and compared those estimates to the numerical results from the regression analysis. To estimate the mass reduction technology level for the selected vehicles, the agencies conducted an in-depth review of available information on the materials, design, and last redesign year for those vehicle models, and compared that information with the designs and materials used in the mass reduction feasibility and cost studies summarized in Section VI.C.4.f), below. That comparison showed good agreement with the technology levels from the regression analysis.

The agencies believe the regression methodology is a technically sound methodology for estimating mass reduction levels in the analysis fleet.

As part of their comments stating the NPRM modeling reflected reality better than the Draft TAR and Proposed Determination analyses, Toyota commented broadly that the MY 2016 baseline fleet used in the NPRM encompassed powertrain and tractive energy (including mass reduction) improvements more representative of vehicles on the road today.[1474] Toyota noted that the 2016 baseline fleet generally contained higher levels of technology compared to the MY 2014 and MY 2015 baseline fleets, and included a comparison of its initial fleet mass reduction assignments in the Draft TAR and the NPRM. Toyota showed how moving further up the technology tree (e.g., starting with a baseline that includes higher levels of technology) for certain pathways such as mass reduction increased costs exponentially. Toyota stated that the NPRM underestimated mass reduction cost values.

While a more specific discussion of costs is located in Section VI.C.4.f), the agencies agree with Toyota's assessment that the costs for mass reduction technology increase exponentially as progressively higher levels of mass reduction are incorporated. Having an accurate assessment of baseline technology levels ensures that the subsequent application of technology and its associated costs is correctly accounted for.

[1473] This evidence suggests that achieving a 20% curb weight reduction for a production vehicle with a baseline defined with this methodology is extremely challenging, and requires very advanced materials and disciplined design.

[1474] NHTSA-2018-0067-12098.

C.A.R produced a report in response to the Draft TAR that generally agreed with the regression methodology of using observed vehicle attributes for estimating mass reduction levels, as opposed to comparing vehicle curb weight from a newer model year to a previous generation of the same vehicle, pointing to several of the limitations discussed above.[1475]

Both ICCT and H-D Systems commented on the methodology for identifying mass reduction technology levels in the analysis fleet, with ICCT broadly stating that by placing additional mass reduction technology in the baseline, the agencies artificially removed "the most cost-effective lightweighting from future use, which incorrectly increases the costs of all subsequent mass-reduction in the compliance modeling."[1476]

ICCT claimed that the agencies unjustifiably increased the amount of vehicle mass reduction technology present in the 2016 baseline fleet from the 2015 baseline used in the Draft TAR, stating that the 2015 Draft TAR fleet had 26 percent of vehicles sold with some level of mass reduction applied (MR1 or a higher level), whereas the 2016 NPRM fleet had 47 percent of vehicles sold with some level of mass reduction applied. In addition to faulting the agencies for not acknowledging the change and not attempting to justify it, ICCT stated that the 2016 analysis fleet mass reduction assignments were overstated, as "it appears that the agencies have applied mass reduction technology to vehicles in the model that did not have mass reduction applied in the real world." ICCT stated that the effect of this change was to "render unavailable mass reduction technologies for these vehicles in the model," causing the model to select less cost-effective technologies instead and driving the modeled compliance costs higher.

ICCT argued that to substantiate the changes made to the baseline fleet mass reduction assignments, the agencies must show data on how these improvements are evident in the fleet and to quantify and include their realized benefits in the analysis, including a detailed and justified explanation of all mass reduction technologies deemed already to have been applied to the MY 2016 analysis fleet. More specifically, ICCT stated that the agencies "must clearly and precisely share their estimated percent (and absolute pounds) mass reduction amount for each vehicle make and model in the baseline fleet (rather than simply showing binned categories), and their technical justification for each value," and "[t]o not do so obscures the agencies' new methods and data sources from public view, rendering their lightweighting calculations a black box."

In addition, ICCT recommended that the agencies conduct two sensitivity analyses, one assuming that every baseline make and model has not yet applied any lightweighting (setting the baseline to 0% mass reduction), and one assuming that each vehicle model has applied Draft TAR baseline mass reduction assignments, to demonstrate how much the agencies' decision to load up more baseline technology affects the compliance scenarios.

[1475] EPA Mass Reduction Analysis – Observations and Recommendations, Center for Automotive Research, October 2017 (page 15), available at https://www.cargroup.org/wp-content/uploads/2017/10/EPA-MR-Analysis-Critique_Oct-5_final.pdf.
[1476] NHTSA-2018-0067-11741 full comments.

ICCT concluded that because the changes in baseline mass reduction assignments from prior analyses to the NPRM "are opaquely buried in the agencies' datafiles and unexplained, we believe the agencies have to reissue a new regulatory analysis and allow an additional comment period for review of their methods and analysis."

To address ICCT's comment, it is important to understand the mass reduction baseline technology assignment methodology previously used by EPA in the Draft TAR and Proposed Determination.[1477] As stated in the Draft TAR, the curb weight of each vehicle model in the MY 2008 analysis fleet (used for the 2012 rulemaking to establish MYs 2017-2025 standards) was assumed to be at a baseline MR0 level. The mass reduction technology level in the MY 2014 analysis fleet was determined by comparing the curb weight of the MY 2014 vehicle to the most similar vehicle in the MY 2008 analysis fleet.[1478] The curb weight of the newer model year vehicle was adjusted to account for changes in the vehicle footprint and changes in mass due to added safety technology. If a vehicle did not have a previous generation vehicle, then the sales weighted average percent mass reduction over the manufacturer's name plate product line was used to represent the expectation of mass reduction technology available within the vehicle.

EPA listed some limitations to this methodology in the Draft TAR,[1479] and others are also addressed here. First, assuming that every vehicle started with MR0 technology did not account for the actual varying levels of mass reduction technology that existed in the MY 2008 fleet. Second, for each vehicle model, there was no accounting for the mass associated with different powertrain configurations. This was particularly problematic because the method did not account for light weight technology already available in the vehicle structure to counter the increased mass associated with more advanced powertrains, such as HEV, PHEV, and EV technologies.[1480] Third, there was no sales-weight accounting for the various configurations in estimating the vehicle model mass reduction technology level, meaning that if a high-sales-volume vehicle employed significant mass reduction technology, that vehicle was not credited as such in the analysis fleet. Fourth, there was no accounting for mass increases due to the addition of future regulatory requirements like potential safety regulations. Fifth, there was no accounting for mass associated with changes in vehicle attributes and utility, such as the addition of infotainment systems and crash avoidance technologies. These limitations all individually had the effect of overestimating mass reduction technology effectiveness and undercounting mass reduction technology costs across the fleet, and accordingly their combined effect was significant. The lack of controls for these items introduced errors into the mass reduction technology level effectiveness estimates.

After considering the comments, the agencies determined the use of the regression method, based on observable attributes, is the best available methodology to provide a reasonable estimate of mass reduction technology for the analysis fleet. The agencies believe that, contrary to ICCT's assertion, the regression methodology used in the NHTSA Draft TAR, NPRM, and final rule analyses provides a more transparent method for calculating baseline mass

[1480] PRIA at 413.

reduction technology assignments. The methodology was fully explained in the Draft TAR and PRIA, and avoided the limitations identified by EPA by using data from the analysis fleet, and not requiring the use of or assumptions about the exact mass reduction levels of vehicles in a prior model year fleet. In addition, the regression accounted for differences in powertrains between trim levels, including non-ICE powertrains by accounting for these factors in the regression analysis.

Also, because manufacturers generally apply mass reduction technology at a vehicle platform level (i.e. using the same components across multiple vehicle models that share a common platform) to leverage economies of scale and to manage component and manufacturing complexity, conducting the regression analysis at the platform level leads to more accurate estimates for the real-world vehicle platform mass reduction levels. The platform approach also addresses the impact of potential weight variations that might exist for specific vehicle models, as all of the individual vehicle models are aggregated into the platform group, and are effectively averaged using sales weighting, which minimizes the impact of any outlier vehicle configurations.

The agencies also disagree that the changes in baseline mass reduction assignments were unexplained. The PRIA discussed reasons that baseline mass reduction assignments differed from prior analyses, including that, "[s]ince the Draft TAR, many platforms have not been redesigned, but in some cases the sales-weighted residuals for carryover platforms have moved. In the case of 2-Box and 3-Box vehicles, the analysis attributes such changes to differences in sales mix year-over-year and other updates to reported curb weights and platform designations. In the case of platforms with pick-up trucks, the analysis updated the pick-up regression since the Draft TAR, so that may be a contributing factor."[1481]

To the extent that the NPRM glider weight assumption impacted the NPRM MY 2016 analysis fleet baseline mass reduction assignment values, the agencies presented a table in the PRIA showing how different glider weight assumptions impacted mass reduction technology levels for the analysis fleet.[1482] The following Table VI-145 recreates that table in part, with updates based on the glider weight values used for the final rule.

For example, from the regression analysis, the Ford F-150 has a predicted curb weight (residual) of 12.4 percent of the actual curb weight. If the glider weight assumption is 50 percent of the vehicle curb weight (like in NPRM), then the agencies would assign MR5 as an initial mass reduction assignment in the analysis fleet. With this high level of mass reduction technology already applied, the opportunity for further mass reduction would be limited. However, if the glider weight is assumed to be 71 percent of the vehicle curb weight, then Ford F-150 would be assigned MR4, and would have an opportunity to apply another level of mass reduction albeit at higher cost.

Table VI-145 – Mass Reduction Technology Levels for the MY 2017 Analysis Fleet for 50% and 71% Glider Share of Curb Weight

CAFE Model Platform Code	Example Code	Mass Reduction Residual (%)	Mass Reduction Level for 71% Glider Weight (Final Rule)	Mass Reduction Level for 50% Glider Weight (NPRM)
Li8	BMW i8	-23.0%	MR6	MR5
Lamborghini-A	Aventador	-17.4%	MR6	MR5
Alfa	Alfa Romeo 4C	-23.2%	MR6	MR5
Li8	BMW i3 94 R19	-18.4%	MR5	MR5
Omega	Cadillac CT6	-14.4%	MR4	MR5
Y-CAR/Y1XX	Chevrolet Corvette	-12.5%	MR4	MR5
T3	Ford F-150	-12.4%	MR4	MR5
RamVan	Ram ProMaster	-12.0%	MR4	MR5
Lamborghini-H	Huracan	-11.7%	MR4	MR5
Global Epsilon/E2XX	Chevrolet Malibu	-11.2%	MR4	MR5
NBC(2)	Toyota Prius C	-15.5%	MR3	MR5
SKYACTIV R	Mazda MX-5	-14.4%	MR3	MR5
MODEL S	Tesla Model S	-11.3%	MR3	MR5
V	Nissan Versa	-10.8%	MR3	MR5
II	Honda Civic	-10.6%	MR3	MR5
Basic(K-Basic1)	Kia Soul	-10.0%	MR3	MR5

The agencies also disagree that the amount of vehicle mass reduction technology present in the 2016 baseline fleet was "unjustifiably increased" from the 2015 baseline used in the Draft TAR. Table VI-146 shows the percent mass reduction technology used in Draft TAR, NPRM, and in final rule. It is clear from the table below that total percentage of MY 2016 vehicle fleet used in the NPRM had nearly the same level of some mass reduction technology applied compared to the Draft TAR. Similar to ICCT's observations, 28 percent of the MY 2015 vehicle fleet used in the Draft TAR had some level of mass reduction technology (MR1 to MR5) and 26 percent of MY 2016 vehicle fleet had some mass reduction technology applied. Since the agencies assumed a reduced glider share in the NPRM, the percentage of vehicles assigned a MR4 or MR5 technology level increased compared to Draft TAR. In addition, for this final rule, the agencies observed that many of the vehicles in the MY 2017 fleet had been redesigned, which provided the opportunity to incorporate additional mass reduction technologies.

Table VI-146 – Mass Reduction Assignment

		Draft TAR	NPRM	Final Rule
	Percentage glider weight reduction	**75% Percent glider**	**50 percent glider**	**71 percent glider**
MR0	0%	72.00%	73.01%	57.18%
MR1	5%	11.93%	7.68%	15.62%
MR2	7.5%	8.35%	3.30%	7.66%
MR3	10%	6.91%	5.88%	7.79%
MR4	15%	0.56%	5.34%	11.42%
MR5	20%	0.25%	4.80%	0.10%
MR6	28%	0.00%	0.00%	0.03%

The agencies considered a sensitivity case that assumed no mass reduction, rolling resistance, or aerodynamic improvements had been made to the MY 2017 fleet (i.e., setting all vehicle road levels to zero - MRO, AERO and ROLL0), in response to ICCT's comment. While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity analysis to understand any affect it may have on technology penetration along other paths (e.g. engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong hybrids and plug-in hybrids) in the baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about $300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about $200 per vehicle. Under the CO_2 program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost change is also comparable, but slightly smaller ($200 per vehicle in the baseline) than the CAFE program results. Cost savings under the preferred alternative are further reduced by about $100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Second, as discussed above, EPA's Draft TAR baseline mass reduction assignments had identified limitations that the regression methodology has addressed. Moreover, as discussed above, the regression methodology was updated from the Draft TAR to characterize data better on pickup trucks. The agencies do not believe that conducting sensitivity analyses using these outdated or limited assumptions would be useful for this final rule.

More narrowly, HDS commented that while the regression coefficients between 2-box and 3-box vehicles for footprint seemed consistent, the regression coefficients for horsepower between the 2-box and 3-box vehicles seemed incorrect because both types of vehicles use similar engines.[1483] HDS stated that "[c]ollinearity between footprint and HP or other effects

[1483] H-D Systems, NHTSA-2018-0067-11985.

caused by having electric vehicles (with electric motor HP ratings) in the regression data is the probable cause of these inconsistent coefficients for HP, but this cannot be confirmed without access to the same database used by NHTSA." HDS concluded that "[r]evisions to the regression could have a significant effect on the baseline assignment of vehicles, as the current assignment for vehicles like the 2016 Mazda MX5 as having the highest level of weight reduction technology (MR5) and the 2016 Chevy Malibu as having MR4 technology appear incorrect as their curb weights are comparable to other similar MY 2016 vehicles in their respective class."

While many of the vehicles share same the same powertrain for passenger cars and SUVs or for cars and pickup trucks, the utility and functionality of the vehicle in SUVs and pickup trucks (2-box) is different than passenger cars (3-box). The presence of additional structure for towing or higher capacity towing, rear cross member, higher capacity suspension, and other differences, enable SUVs and pickup trucks to have towing and heavier payload capability. For example, Ford uses the nearly similar displacement and horsepower engines in Mustang Ecoboost Coupe and in F150 2WD XL, Regular Cab, Long Box. However, the curb weight for the pickup truck is higher than the Mustang. Directionally, this supports that the 2-box weight per horsepower coefficient should be greater than the 3-box coefficient, just as it is in the for the regression. The coefficient for passenger cars and SUVs has not changed since the Draft TAR (based on MY2015 vehicle fleet). Based on the comments to Draft TAR, for the NPRM, a new set of coefficients were generated for pickups using the MY 2014 vehicle fleet. This was done so that coefficients were not skewed due to presence of the aluminum intensive Ford F150 pickup truck. Hence, the agencies believe the coefficients used in the regression analysis are directionally correct and disagree with HDS's assertion. The agencies further note that HDS did not suggest any alternate methodology or specific coefficients to use in the regression analysis.

d) Mass Reduction Technology Adoption Features

The agencies described in the NPRM that given the degree of commonality among the vehicle models built on a single platform, manufacturers do not have complete freedom to apply unique technologies to each vehicle that shares the platform: while some technologies (e.g. low rolling resistance tires) are very nearly "bolt-on" technologies, others involve substantial changes to the structure and design of the vehicle, and therefore often necessarily affect all of the vehicle models that share that platform. In most cases, mass reduction technologies are applied to platform level components and therefore the same design and components are used on all of the vehicle models that share the platform.

As discussed in Section Analysis Fleet, above, each vehicle in the analysis fleet is associated with a specific platform. Similar to the application of engine and transmission technologies, the CAFE model defines a platform "leader" as the vehicle variant of a given platform that has the highest level of observed mass reduction present in the analysis fleet. If there is a tie, the CAFE model begins mass reduction technology on the vehicle with the highest sales in model year 2017. If there remains a tie, the model begins by choosing the vehicle with the highest Manufacturer Suggested Retail Price (MSRP) in MY 2017. As the model applies technologies, it effectively levels up all variants on a platform to the highest level of mass reduction technology on the platform. So, if the platform leader is already at MR3 in MY 2017, and a "follower" starts at MR0 in MY 2017, the follower will get MR3 at its next redesign (unless the leader is redesigned again before that time, and further increases the mass reduction level associated with that platform, then the follower would receive the new mass reduction level).

Important for analysis fleet mass reduction assignments (discussed above), and for understanding adoption features as well, is the agencies' handling of vehicles that traditionally operated on the same platform but had a mix of old and new platforms in production when the analysis fleet was created. As described in the PRIA, the Honda Civic and Honda CR-V traditionally share the same platform. In MY 2016, Honda redesigned the Civic and updated the platform to include many mass reduction technologies. Also in MY 2016, Honda continued to build the CR-V on the previous generation platform—a platform that did not include many of the mass reduction technologies on the all new MY 2016 Civic. In MY 2017, Honda launched the new CR-V that incorporated changes to the Civic platform, and the Civic and CR-V again shared the same platform with common mass reduction technologies. The NPRM and final rule analyses treat the old and new platforms separately to assign technology levels in the baseline, and the CAFE model brings vehicles on the old platform up to the level of mass reduction technology on the new shared platform at the first available redesign year.

Furthermore, as stated in the NPRM and PRIA, unlike the analysis presented in the Draft TAR that restricted high levels of mass reduction for cars to show a safety neutral pathway to compliance, the NPRM analysis did not artificially restrict mass reduction to achieve a safety neutral outcome.[1484] The NPRM CAFE model considered MR0 through MR5 for all vehicles at redesign, and similarly for the final rule, the CAFE model considers MR0 through MR6 for all vehicles at redesign.

Ford commented in support of the removal of "previously applied modeling rules that disallowed the mass reduction technology pathway for certain vehicle classes since this restriction was not supported by an adequate technical justification."[1485] ICCT commented that a constraint of 7.5 percent mass reduction to smaller cars, as was applied in the Draft TAR, would be appropriate for those vehicles.
