The agencies considered ICCT's comment that mass reduction on small passenger cars should be limited to 7.5 percent, and Ford's comment supporting the removal of "previously applied modeling rules that disallowed the mass reduction technology pathway for certain vehicle classes." Neither CAFE standards nor this analysis mandate mass reduction, or mandate that mass reduction occur in any specific manner. The mass reduction cost subsection below shows mass reduction is a cost-effective technology for improving fuel economy and CO_2 emissions. The steel, aluminum, plastics, composite, and other material industries are developing new materials and manufacturing equipment and facilities to produce those materials. In addition, suppliers and manufacturers are optimizing designs to maintain or improve functional performance with lower mass. Manufacturers have stated that they will continue to reduce vehicle mass to meet more stringent standards, and therefore, this expectation is incorporated into the modeling analysis supporting the standards to: (1) determine capabilities of

[1484] PRIA at 494.
[1485] NHTSA-2018-0067-11928.

manufacturers; and (2) predict costs and fuel consumption effects of CAFE standards. The CAFE and CO_2 rulemakings in 2012, and the Draft TAR and EPA Proposed Determination, imposed an artificial constraint that limited vehicle mass reduction in some small vehicles to achieve a desired safety-neutral outcome. For the current rulemaking, this artificial constraint is eliminated so the analysis reflects manufacturers' applying the most cost effective technologies to achieve compliance with the regulatory alternatives and the final standards; this approach allows mass reduction to be applied across the fleet. This approach is consistent with industry trends. To the extent that mass reduction is only cost-effective for the heaviest vehicles, the CAFE model would create the outcome predicted by commenters. In reality, however, mass reduction is a cost-effective means of improving fuel economy and does take place across vehicles of all sizes and weights. Accordingly, the model reflects that manufacturers may reduce vehicle mass—regardless of vehicle class—when doing so is cost effective.

The agencies have included one additional mass reduction level for the final rule in response to comments by ICCT and others, and to account for carbon fiber use in vehicles. For the NPRM, the maximum level of mass reduction was limited to 10 percent of a vehicle's curb weight, and that amount of mass reduction could be applied during the rulemaking timeframe. For the final rule, based on the current state of mass reduction technology and the application rate of different levels of mass reduction technologies, the agencies applied phase-in caps for MR5 and MR6 (15 percent and 20 percent reduction of a vehicle's curb weight, respectively). The agencies applied a phase-in cap for MR5 level technology so that 15 percent of the vehicle fleet starting in 2016 employed the technology, and the technology could be applied to 100 percent of the fleet by MY 2022. This cap is consistent with the NHTSA lightweighting study that found that a 15 percent curb weight reduction for the fleet is possible within the rulemaking timeframe.[1486] The agencies also applied a phase in cap for MR6 technology so that one percent of the vehicle fleet starting in MY2016 employed the technology, and the technology could be applied to 13 percent of the fleet by MY2025. The agencies believe that this phase-in cap appropriately functions as a proxy for the cost and complexity currently required (and that likely will continue to be required until manufacturing process evolve) to produce carbon fiber components. Again, MR6 technology in this analysis reflects the use of a significant share of carbon fiber content, as seen through the BMW i3 and Alfa Romeo 4c as discussed above.

e) Mass Reduction Technology Effectiveness

As discussed in Section VI.B.3, Argonne developed a database of vehicle attributes and characteristics for each vehicle technology class that included over 100 different attributes like frontal area, drag coefficient, fuel tank weight, transmission housing weight, transmission clutch weight, hybrid vehicle component weights, and weights for components that comprise engines and electric machines, tire rolling resistance, transmission gear ratios, and final drive ratio. Argonne used these attributes to "build" each vehicle that it used for the effectiveness modeling and simulation. Important for precisely estimating the effectiveness of different levels of mass

[1486] DOT HS 811 666: Mass Reduction for Light Duty Vehicles for Model Years 2017-2025: Figure 397 at page 356.

reduction is an accurate list of initial component weights that make up each vehicle subsystem, from which Autonomie considered potential mass reduction opportunities.

As stated above, glider weight, or the vehicle curb weight minus the powertrain weight, is used to determine the potential opportunities for weight reduction irrespective of the type of powertrain.[1487] This is because weight reduction can vary depending on the type of powertrain. For example, an 8-speed transmission may weigh more than a 6-speed transmission, and a basic engine without variable valve timing may weigh more than an advanced engine with variable valve timing. Autonomie simulations account for the weight of the powertrain system inherently as part of the analysis, and the powertrain mass accounting is separate from the application and accounting for mass reduction technology levels (MR0-MR6) that are applied to the glider in the simulations. Similarly, Autonomie also accounts for battery and motor mass used in hybrid and electric vehicles separately. This secondary mass reduction is discussed further, below.

Accordingly, in the Autonomie simulation, mass reduction technology is simulated as a percentage of mass removed from the specific subsystems that make up the glider, as defined for that set of simulations (including the non-powertrain secondary mass systems such as the brake system).

(1) Glider Mass and Mass Reduction

Autonomie accounts for the mass of each subsystem that comprises the glider. For the NPRM, the glider subsystems included the vehicle body and the chassis, but did not include mass from subsystems such as the interior system, brake system, electrical accessory system, and steering and wheel systems. The agencies described in the PRIA that based on advances in active and passive safety technologies that add some mass to the interior system, certain subsystems were not considered for potential light-weighting to maintain safety performance.[1488] For the NPRM, the A2Mac1 database was used to estimate the average mass of each subsystem considered as part of the glider based on the subsystem assumptions, and to compute the average glider share of vehicle curb weight.[1489] That analysis showed the glider accounted for 50 percent of the vehicle curb weight. The agencies solicited comment on whether systems or components beyond the vehicle body and chassis should be included as part of the glider, and also indicated that the glider weight assumption might increase for the final rule based on further research.

The agencies received several comments on the NPRM glider weight assumptions, with the overarching theme of the comments being that the NPRM did not include all systems and components that should be included, and if those systems and components were included, the glider share would be higher. Commenters also stated that the 50 percent glider share value used

---

[1487] Depending on the powertrain combination, the total curb weight of the vehicle includes glider, engine, transmission and/or battery pack and motor(s).

[1488] PRIA at 411-12.

[1489] The A2Mac1 database was used and this analysis was presented in ANL report docketed here: NHTSA‐2018‐0067‐1490. The mass data in the database were obtained from vehicle teardown studies.

for the NPRM reduced the amount of mass reduction that could be applied to vehicles in the analysis.

UCS stated that representing the glider as a reduced fraction of the curb weight caused the agencies significantly to underestimate the potential for mass reduction. UCS noted that because mass reduction is applied at the glider level, reducing the share of the glider inherently caps the potential reduction in the curb weight, and this single change cut the potential improvement from mass reduction by one-third. Similarly, CARB stated that the updated glider weight assumption severely limited the effectiveness of mass reduction, as the most aggressive mass reduction category of 15 to 20 percent mass reduction can only reduce the vehicle curb weight by 10 percent.

UCS cited previous agency analyses and analyses from other organizations that stated the total potential for mass reduction by 2025 is between 15.8 and 32 percent of curb weight, contrasted to the NPRM assumption of a maximum 10 percent reduction.[1490] UCS also cited industry data which showed that the glider represented a higher share of vehicle curb weight than was assumed in the Draft TAR analysis, and both UCS and CARB cited to industry data from vehicles like the Ford F-150, which UCS stated was able to achieve the NPRM maximum achievable mass reduction through the deployment of aluminum alone.[1491] UCS concluded that by capping the total potential for mass reduction at such a low level, the agencies artificially reduced the potential for the cost-effective technology, which increased the use of more expensive and more advanced technologies. CARB concluded that the agencies' 10 percent restriction means that real-world improvements that have already happened on production vehicles were not considered feasible in the NPRM analysis.

Several commenters also stated that the 50 percent glider weight assumption was unexplained and unjustified, and argued that the agencies' own studies showed that the glider weight percentage should range from 75-80 percent.[1492] UCS stated that both the NHTSA-sponsored 2011 Honda Accord study, which showed the glider making up 79 percent of the vehicle, and the NHTSA-sponsored 2014 Chevrolet Silverado study, which showed the glider making up 73.6 percent, showed values substantially higher than the 50 percent value, and were in line with the agencies' prior analyses.[1493] As part of its comments that key assumptions about mass reduction changed from the Draft TAR without any supporting rationale, CARB stated that EPA had previously relied on four studies (two contracted for by EPA and two contracted for by NHTSA), and for the NPRM analysis the agencies only cited two of those studies.[1494] Moreover, ICCT commented that the agencies' previous studies showed a glider fraction greater than 75 percent even with numerous safety features considered. Accordingly, ICCT stated that the agencies must specifically identify the "safety components" referred to in the NPRM and justify

[1490] NHTSA-2018-0067-12039 (citing Caffrey et al. 2013, Caffrey et al. 2015, Lotus 2012, NAS 2015, Singh et al. 2012, Singh et al. 2016, Singh et al. 2018).
[1491] NHTSA-2018-0067-12039. *See also* NHTSA-2018-0067-11873.
[1492] NHTSA-2018-0067-11985; NHTSA-2018-0067-12039; NHTSA-2018-0067-11873.
[1493] NHTSA-2018-0067-12039.
[1494] NHTSA-2018-0067-11873.

the limitations placed on light weighting in response. ICCT affirmatively concluded that the agencies must re-adopt the Draft TAR methodology in which glider mass is assumed to be 75 percent of vehicle mass, or provide detailed justification and evidence supporting the new value of 50 percent.[1495]

The agencies carefully considered these comments and reexamined available data and information. The NHTSA-sponsored passenger car light weighting study showed a glider mass of 79 percent, and the NHTSA-sponsored light duty truck light weighting study showed a glider mass of 73.6 percent, and the 75 percent value used for the Draft TAR was a value between the values from these two studies. The agencies determined it would be more rigorous to consider data from a broader array of vehicles with various powertrain combinations and trim levels to assess the glider share for the final rule, considering that the vehicle fleet analyzed in this rule consists of over 2900 vehicle models.

The agencies examined glider weight data available in the A2Mac1 database.[1496] The A2Mac1 database tool is widely used by industry and academia to determine the bill of materials and mass of each component in the vehicle system.[1497] The A2Mac1 database has been used by the agencies to inform past CAFE and CO_2 rulemakings. The agencies analyzed a total of 147 MY 2014 to 2016 vehicles, covering 35 vehicle brands with different powertrain options representing a wide array of vehicle classes to determine the glider weight for the final rule analysis.[1498]

The agencies also considered that the NHTSA passenger car and light truck light-weighting studies examined mass reduction in the body, chassis, interior, brakes, steering, electrical accessory, and wheels subsystems and had developed costs for light weighted components in those subsystems. As a result, the agencies determined it is appropriate to include all of those subsystems as available for mass reduction as part of the glider. Therefore, all of these systems were included for the analysis of glider weight using the A2Mac1 database. Table VI-147 shows the average mass for each subsystem and the glider share for each of the vehicle classes for all powertrain combinations.

This data was also compared with the glider weight measured in the NHTSA MY 2014 Chevrolet Silverado light weighting study,[1499] and the glider weight data range was similar to the analysis results. Based on the comments and the agencies' updated assessment, the agencies have increased the glider weight assumption to 71 percent of the vehicle curb weight for the final rule.

As stated above, for the NPRM, the interior, brake system, electrical accessory system, and steering and wheel systems were not included as part of the glider. The decision not to include the interior system was based on an assumption at that time that interior system mass reduction might adversely impact safety. In addition, the decision not to include the brake

[1499] DOT HS 812 487: Mass Reduction for Light-Duty Vehicles for Model Years 2017–2025.

system was based on an assumption at that time that there would be little or no opportunity for downsizing and reducing mass based on the reduced weight from body and chassis only. As a result, brake systems were not considered as part of the glider in the NPRM. For the final rule, the agencies included the interior system based on market observations that light-weighted seats, side door trim, frontal dash, and others interior components have been incorporated on production vehicles that meet FMVSSs and perform well on voluntary NCAP and IIHS safety tests. The agencies also considered that interior, brakes, steering, wheel and electrical subsystems were included in the NHTSA light weighting studies. By adding the interior, steering, wheel subsystems and electrical subsystems as part of glider, the agencies believe light weighting the glider increases the opportunity for brake system optimization and mass reduction. Similarly, there is increased opportunity for mass reduction for wheels using gauge optimization, resulting from including more subsystems in the glider.

By including the interior, brake, steering, electrical accessory, and wheel subsystems in addition to the body and chassis subsystems in the definition of what subsystems comprise the glider, the agencies increased the glider weight from 50 percent of the vehicle curb weight to 71 percent of the vehicle curb weight. This increase in turn means that the potential for vehicle mass reduction was increased from 10 percent of the vehicle curb weight to 20 percent of the vehicle curb weight. Table VI-148 shows the percent of light truck glider weight reduction and the corresponding vehicle curb weight reduction for each level of mass reduction for the glider shares used in the Draft TAR (75 percent), NPRM (50 percent), and final rule (71 percent) analyses.[1500]

Table VI-148 – Light Truck Glider Weight and Curb Weight Comparison for the Draft TAR, NPRM and Final Rule

	Glider Weight Percentages by MR Level	**Percent of Curb Weight for Light Trucks**		
		Draft TAR 75% glider share	NPRM 50% glider share	Final Rule 71% glider share
MR0	0.0%	0.00%	0.00%	0.00%
MR1	5.0%	3.75%	2.50%	3.55%
MR2	7.5%	5.63%	3.75%	5.33%

MR5	20.0%	15.00%	10.00%	14.20%
MR6	28.2%	21.15%		20.00%

1500 Table 6-57 in PRIA showed the vehicle curb weight changes for different glider weight assumptions.

(2) Powertrain Mass Reduction

As explained above, any mass reduction due to powertrain improvements is accounted for separately from glider mass reduction. Autonomie considers several components for powertrain mass reduction, including engine downsizing, and transmission, fuel tank, exhaust systems, and cooling system lightweighting.

The 2015 NAS report suggested an engine downsizing opportunity exists when the glider mass is lightweighted by at least 10%. The 2015 NAS report also suggested that 10% lightweighting of the glider mass alone would boost fuel economy by 3% and any engine downsizing following the 10% glider mass reduction would provide an additional 3% increase in fuel economy.[1501] The agencies' lightweighting studies applied engine downsizing (for some vehicle types but not all) when the glider weight was reduced by 10 percent. Accordingly, the NPRM analysis limited engine resizing to several specific incremental technology steps;[1502] important for this discussion, engines in the analysis were only resized when mass reduction of 10% or greater was applied to the glider mass, or when one powertrain architecture was replaced with another architecture.

Argonne performed a regression analysis of engine peak power versus weight for the NPRM based on attribute data taken from the A2Mac1 benchmarking database, to account for the difference in weight for different engine types. For example, to account for weight of different engine sizes like 4-cylinder versus 8-cylinder, Argonne developed a relationship curve between peak power and engine weight based on the A2Mac1 benchmarking data. For the NPRM analysis, this relationship was used to estimate mass for all engine types regardless of technology type (e.g., variable valve lift and direct injection). Weight associated with changes in engine technology was applied by using this linear relationship between engine power and engine weight from the A2Mac1 benchmarking database. When a vehicle in the analysis fleet with an 8-cylinder engine adopted a more fuel efficient 6-cylinder engine, the total vehicle weight would reflect the updated engine weight with two less cylinders based on the peak power versus engine weight relationship.

When Autonomie selects a powertrain combination for a lightweighted glider, the engine and transmission are selected such that there is no degradation in the performance of the vehicle relative to the baseline vehicle. The resulting curb weight is a combination of the lightweighted glider with the resized and potentially new engine and transmission. This methodology also helps in accurately accounting for the cost of the glider and cost of the engine and transmission in the CAFE model. This is one of the fundamental differences between the analysis for this rulemaking the analysis for the Proposed Determination. For the Proposed Determination, the cost for mass reduction included mass reduction and cost reduction for one specific engine downsizing, and applied it to all vehicle classes without regard for performance and utility.

[1501] National Research Council. 2015. Cost, Effectiveness, and Deployment of Fuel Economy Technologies for Light-Duty Vehicles. Washington, D.C. - The National Academies Press. https://doi.org/10.17226/21744.
[1502] 83 FR 43027.

There also was no accounting for the mass of other applied powertrains and the associated effectiveness impacts.

As explained in the introduction, secondary mass reduction is possible from some of the components in the glider after mass reduction has been incorporated in primary subsystems (body, chassis, and interior). Similarly, engine downsizing and powertrain secondary mass reduction is possible after certain level of mass reduction is incorporated in the glider. For the analysis, the agencies include both primary mass reduction, and when there is sufficient primary mass reduction, additional secondary mass reduction. The Autonomie simulations account for the aggregate of both primary and secondary glider mass reduction, and separately for powertrain mass.

The agencies received several comments about secondary mass reduction and powertrain mass reduction. Broadly, CARB commented that the agencies did not include powertrain downsizing and associated secondary mass reduction, which was a departure from the analysis done by EPA for the Draft TAR.[1503] CARB stated that the agencies "inexplicably" did not consider secondary mass reduction opportunities "including but not limited to drive axles, suspension, and braking components (as a result of the overall vehicle being lighter); fuel tank (and corresponding weight of fuel during certification testing); powertrain (lighter engine and transmission needed to power the lighter vehicle); and thermal systems." CARB cited both EPA and NHTSA light weighting studies for the proposition that there are significant opportunities for secondary mass reduction that lead to additional cost savings. As a result, CARB stated that the agencies inflated the cost of mass reduction as well as the amount of mass reduction that is feasible and cost-effective, leading to an over estimate in the technology costs to meet the existing standards.

As CARB correctly noted, the NHTSA-sponsored studies have taken into consideration secondary mass reduction benefits such as radiator engine support, and optimized engine cradles, wheels, and suspension systems. As discussed above, in response to comments, the agencies have included additional subsystems such as brakes, wheels, steering, electrical, and interior systems to the glider for the final rule analysis, thereby accounting for mass reduction opportunities for these systems.

Also, as discussed further in Section VI.C.4.f), below, secondary mass reduction is integrated into the mass reduction cost curves. Specifically, the NHTSA studies, upon which the cost curves were built, first generated costs for lightweighting the vehicle body, chassis, interior, and other primary components, and then calculated costs for lightweighting secondary components. Accordingly, the cost curves reflect that, for example, secondary mass reduction for the brake system is only applied after there has been sufficient primary mass reduction to allow the smaller brake system to provide safe braking performance and to maintain mechanical functionality.

[1503] NHTSA-2018-0067-11873.

CARB appears to have misunderstood how the analysis accounts for powertrain mass reduction. The agencies described in the PRIA that the Autonomie simulations recognize that many powertrain packages have different weights for each vehicle class; for example, an eight-speed transmission may weigh more than a six-speed transmission, and a basic engine with variable valve timing may weigh more than a basic engine without variable valve timing.[1504] Autonomie varies the weight of these powertrain systems as part of the analysis, and these changes are done separately from the glider mass reduction technology levels (MR0 to MR6) in the simulations. Accordingly, accounting for powertrain mass reduction as part of the mass reduction technology analysis would double count impacts. The use of separate accounting assures that the analysis accounts for mass associated with secondary mass reduction from glider, and engine downsizing, as well as mass associated with each individual engine, transmission, and electrification technology. These mass changes were not accounted for in the Draft TAR and Proposed Determination analyses. Moreover, these are accounted for separately in the cost accounting, which is discussed further in the Section VI.C.4.f), below.

HDS commented that some assumptions in the Autonomie modeling related to engine weight appeared incorrect, such as the assumption that a turbocharged 4-cylinder engine weighed the same as a DOHV V6 engine with 1.5 times the 4-cylinder's displacement, when in fact that engine is often 75 to 100 lbs. lighter.[1505]

HDS also noted that "mass reduction assumes no reduction of powertrain weight for mass reduction levels of 2.5% and 5%. Mass reduction effectiveness therefore are somewhat more appropriate for reductions over 5% which apparently include some powertrain weight reduction. More transparency in the PRIA regarding powertrain weight changes will allow more detailed comment on engine weight assumptions used."

We agree with the comment that certain advanced engines could be lighter than a basic engine. For the final rule, the estimated mass levels for engines were updated, as discussed in Section VI.B.3 Tech Effectiveness, based on the A2Mac1 database and other sources that provided more precise mass data for powertrain technologies. Also, the agencies improved upon the precision of estimated engine weights by creating two curves to represent separately naturally aspirated engine designs and turbocharged engine designs.[1506] This update resulted in two benefits. First, small naturally aspirated 4-cylinder engines that adopted turbocharging technology reflected the increased weight of associated components like ducting, clamps, the turbocharger itself, a charged air cooler, wiring, fasteners, and a modified exhaust manifold. Second, larger cylinder count engines like naturally aspirated 8-cylinder and 6-cylinder engines that adopted turbocharging and downsized technologies would have lower weight due to having fewer engine cylinders. For the final rule analysis, a naturally aspirated 8-cylinder engine that adopts turbocharging technology and is downsized to a 6-cylinder turbocharged engine

[1506] ANL Final Model Documentation for final rule analysis Chapter 5.2.9 Engine Weight Determination.

appropriately reflects the added weight of the turbocharging components, and the lower weight of fewer cylinders. These refinements address the issues identified in HDS's comments.

Regarding HDS's second comment, as discussed in the NPRM, to address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.[1507] As discussed further in Section VI.B.3.a)(6) Performance Neutrality, the NPRM also referred to the 2015 NAS report conclusion that "[f]or small (under 5 percent [of curb weight]) changes in mass, resizing the engine may not be justified, but as the reduction in mass increases (greater than 10 percent [of curb weight]), it becomes more important for certain vehicles to resize the engine and seek secondary mass reduction opportunities."[1508] In consideration of both the NAS report and comments received from manufacturers, the agencies determined it would be reasonable to allow allows engine resizing upon adoption of 7.1%, 10.7%, 14.2%, and 20% curb weight reduction, but not at 3.6% and 5.3%.[1509] Resizing is also allowed upon changes in powertrain type or the inheritance of a powertrain from another vehicle in the same platform. The increments of these higher levels of mass reduction, or complete powertrain changes, more appropriately match the typical engine displacement increments that are available in a manufacturer's engine portfolio.

(3) Summary of Final Rule Mass Reduction Technology Effectiveness

Figure VI-100 below shows the range of incremental effectiveness used for the NPRM analysis. The chart lumps all of the vehicle classes for each of the technology types.

[1507] *See* 83 FR 43027 (Aug. 24, 2018).

[1508] National Research Council. 2011. Assessment of Fuel Economy Technologies for Light-Duty Vehicles. Washington, D.C. – The National Academies Press. http://nap.edu/12924.

[1509] These curb weight reductions equate to the following levels of mass reduction as defined in the analysis: MR3, MR4, MR5 and MR6, but not MR1 and MR2; additional discussion of engine resizing for mass reduction can be found in Section VI.B.3 Technology Effectiveness.

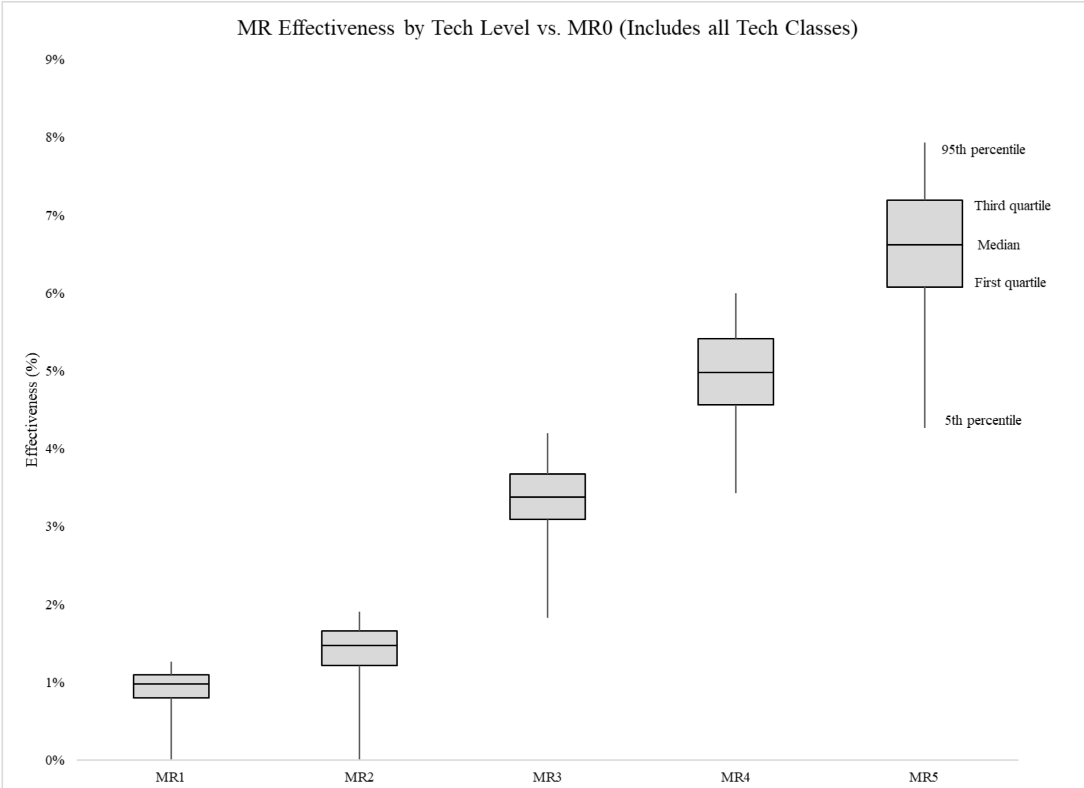

Figure VI-100 – NPRM Mass Reduction Technology Effectiveness

Figure VI-101 below shows the range of incremental effectiveness improvement from full vehicle modeling when mass reduction technologies were applied to vehicles for the final rule analysis.

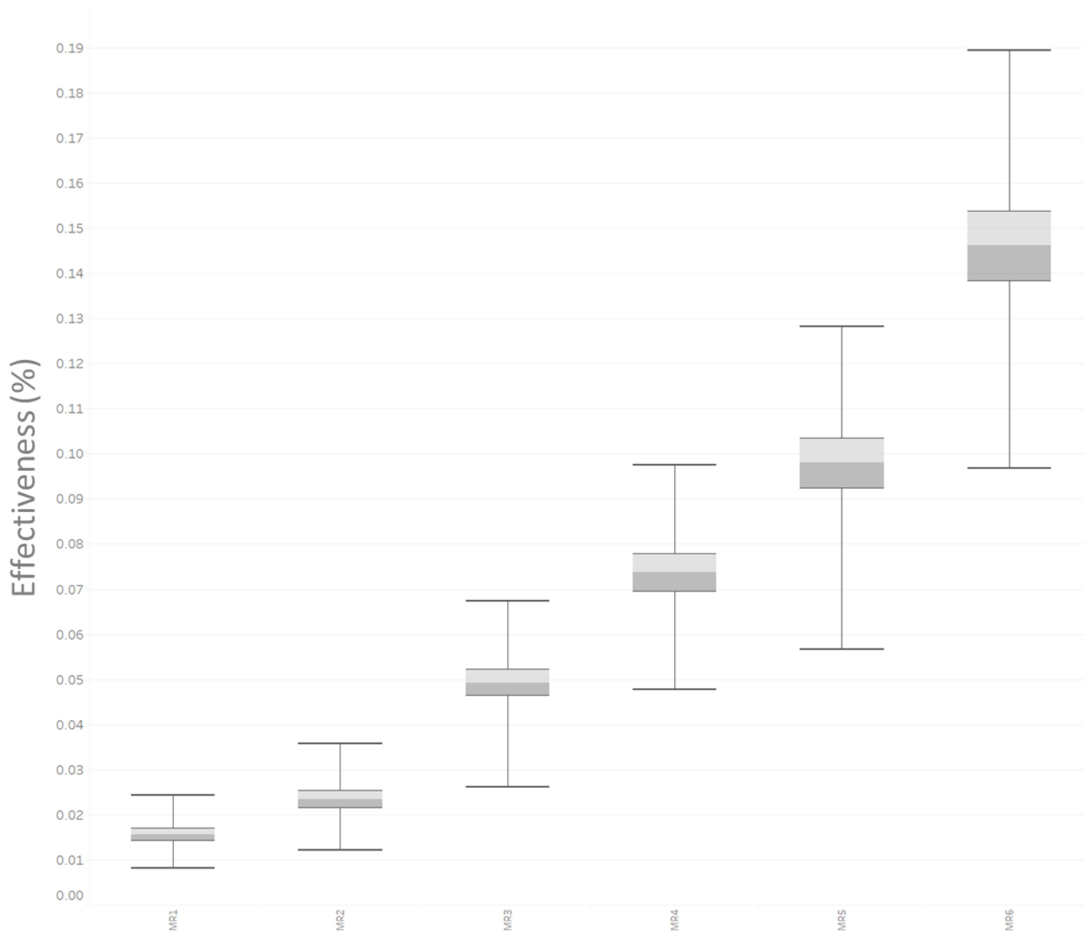

Figure VI-101 – Final Rule Incremental Improvements From Mass Reduction Technologies

f) Mass Reduction Costs

The PRIA described the decision to use NHTSA's passenger car light weighting study based on a MY 2011 Honda Accord and NHTSA's full-size pickup truck light weighting study based on a MY 2014 Chevrolet Silverado to derive the estimated cost for each of the mass reduction technology levels.[1510] The agencies relied on the results of those studies because they considered an extensive range of material types, material gauge, and component redesign while taking into account real world constraints such as manufacturing and assembly methods and complexity, platform-sharing, and maintaining vehicle utility, functionality and attributes, including safety, performance, payload capacity, towing capacity, handling, NVH, and other characteristics. In addition, the agencies described that the baseline vehicles assessed in the NHTSA-sponsored studies were reasonably representative of baseline vehicles in the MY 2016 analysis fleet.[1511] The agencies also noted they made the decision to rely on these studies after

[1510] PRIA at 391; Table 6-38 and Table 6-41 in PRIA.
[1511] PRIA at 403.

reviewing other agency, CARB, ICCT and industry studies.[1512] The other studies often did not consider important factors, made unrealistic assumptions about key vehicle systems, and/or applied secondary mass reduction inappropriately, resulting in unrealistically low costs. The PRIA also described how the cost estimates derived from the NHTSA lightweighting studies were adjusted to reflect the NPRM glider share assumption.[1513]

Furthermore, the agencies changed the cost of mass reduction accounting from a curb weight basis in the Draft TAR to glider weight basis in the NPRM.[1514] Because the mass reduction studies provide mass reduction costs for the glider, this change enabled more direct use of cost curve data from the studies in the CAFE model. This change also allowed independent accounting for powertrain mass, which enabled the CAFE model to account more accurately for the unique mass of each of the powertrains that are available in each vehicle model. The cost of the engine, transmission, and electrification are accounted for separately from the glider in the CAFE model.

The agencies received several comments on the mass reduction costs used in the NPRM. FCA commented that the costs and benefits used the CAFE model were overly optimistic, stating that although its Ram 1500 pickup truck achieved several hundred pounds of weight reduction, the cost of achieving that weight reduction was greater than that used in the CAFE model.[1515] Similarly, as mentioned above, Toyota commented that mass reduction cost values were underestimated.[1516] Conversely, CARB, UCS, and the City of Oakland in California commented that the costs used for mass reduction in the NPRM overstated the cost of mass reduction. The agencies also received several comments relating to the studies used to develop the mass reduction cost curves, how the values from those curves were applied in the CAFE model, and costs for secondary mass reduction; those comments are discussed in turn.

(1) Studies Used to Develop Mass Reduction Cost Curves

The agencies described in the PRIA that since the 2012 final rule, both agencies conducted lightweighting studies to assess the technical feasibility and cost of mass reduction.[1517] The agencies also stayed apprised of studies performed by other agencies, manufacturers, and industry trade associations, and reviewed them in development of

---

[1512] As described in the PRIA at 390-91, studies by EPA, CARB, Transport Canada, the American Iron and Steel Institute (AISI), the Aluminum Association, and the American Chemistry Council were all reviewed for potential incorporation into the analysis.
[1513] *See* PRIA at 396, Tables 6-38 and 6-39; PRIA at 401, Tables 6-41 and 6-42. *See also* PRIA at 391 ("While the definitions of glider may vary from study to study (or even simulation to simulation), the agencies referenced the same dollar per pound of curb weight to develop costs for different glider definitions. In translating these values, the agencies took care to track units ($/kg vs. $/lb.) and the reference for percentage improvements (glider vs. curb weight).").
[1514] In the Draft TAR, the agencies presented the cost estimates from mass reduction studies sponsored by both NHTSA and EPA. EPA presented the cost of mass reduction as function of vehicle curb weight. To harmonize the cost estimates with EPA, NHTSA also presented the cost of mass reduction as a function of vehicle curb weight.
[1515] NHTSA-2018-0067-11943.
[1516] NHTSA-2018-0067-12098.
[1517] PRIA at 390.

lightweighting assumptions used in the NPRM and final rule analysis.[1518] Among the several lightweighting studies, the agencies used NHTSA's passenger car lightweighting study, based on a MY 2011 Honda Accord, and NHTSA's full-size pickup truck lightweighting study, based on a MY 2014 Chevrolet Silverado, to derive the cost estimates to achieve different levels of mass reduction for the NPRM and final rule.

The agencies described that the decision to rely on those studies included that those studies considered materials, manufacturing, platform-sharing, functional attribute, performance, and noise-vibration- and harshness (NVH), among other constraints pertaining to cost, effectiveness, and safety considerations, in addition to that these vehicles were a reasonable representation of the baseline vehicles in the MY 2016 compliance simulation.[1519] Specifically in regards to safety, the agencies described a preference to use studies that considered small overlap impact tests conducted by the Insurance Institute for Highway Safety (IIHS) and not all studies took that test into account. In regards to maintaining vehicle functionality, the agencies described that the NHTSA pickup truck study accounted for vehicle functional performance for attributes including towing, noise and vibration, and gradeability, in addition to considering platform sharing constraints.

In contrast, the agencies explained that the other studies often did not consider many important factors, or those studies made unrealistic assumptions about key vehicle systems through secondary downsizing, resulting in unrealistically low costs. Specifically, the agencies referenced EPA's past analysis of a MY 2010 Toyota Venza as an example of a study that employed overly aggressive secondary mass reduction, which translated into cost savings for the initial 10% mass reduction.[1520]

The agencies received several comments on the studies used to generate the mass reduction cost curves. Ford commented in support of the agencies' decision to exclude mass reduction studies that were misaligned with tear-down studies.[1521] Ford cited the MY 2010 Toyota Venza Phase II study used to establish the mass reduction cost values used for the Draft TAR and Proposed Determination that suggested the first 7-10% of mass reduction could be accomplished with zero or reduced cost,[1522] which Ford characterized as "a gross underestimation of industry investment and material costs associated with any weight reduction."

ICCT commented that The National Academies of Science "specifically endorsed tear-down studies as the most appropriate way to get at vehicle technology costs, [as those] studies are typically more accurate and far more transparent than the older method of surveying manufacturers, and such whole-vehicle studies are key to capturing holistic vehicle level mass-reduction technology costs." ICCT noted that there are many peer-reviewed tear-down studies that demonstrate that at least 20 percent mass reduction is available for adoption across vehicle classes by 2025, including studies by EDAG, FEV, Ford, and Lotus Engineering; however, ICCT

[1518] PRIA at 403.
[1519] PRIA at 403.
[1520] PRIA at 391.
[1521] NHTSA-2018-0067-11928.
[1522] EPA-420-R-16-021: Proposed Determination Technical Support Document at 2-158, November 2016.

alleged that the agencies "have either incorrectly interpreted or invalidly nullified the most relevant detailed engineering teardown studies on mass-reduction technology." ICCT noted that the agencies were "well aware" of these studies, as they were performed by CARB in conjunction with the agencies, however, ICCT alleged that the agencies "reinterpreted the results of the main study relied upon in the TAR in order to inflate costs," and that the "technical assessment by the agencies has a clear technical bias towards reducing CAFE and GHG standards." ICCT concluded that "[e]xcluding these studies amounted to intentionally disregarding the most pertinent and rigorous engineering studies that are applicable to the rulemaking timeframe."

ICCT recommended the agencies adjust their technology cost inputs to reflect the "best-available technology studies." ICCT stated that the correct cost assumption from these studies is that "a 5-10% mass reduction by 2025 reduces vehicle cost, and the auto industry will cost-effectively deploy at least 15% vehicle curb mass reduction in the 2025 timeframe at near zero net cost (and consistently less than $500)."

CARB asserted that the agencies inflated the costs of mass reduction in the NPRM analysis by only considering NHTSA-sponsored studies and improperly excluding the effects of secondary mass reduction as documented in those studies.[1523] CARB provided a table of studies that largely mirrored the tables of studies the agencies considered in the Draft TAR and PRIA,[1524] and also included the associated mass reduction costs in $/kg included in each study, noting that for all excluded studies cited in the table, all mass reduction costs were substantially lower than the values used in the agencies' analysis.[1525] Similarly, UCS commented that while the PRIA did state that additional studies "often did not consider many important factors or…made unrealistic assumptions about key vehicle systems," the agencies did not specifically identify the factors and assumptions that merited disregarding those studies, which were included previously in agency analysis as part of the record when deriving previous estimates for the costs of mass reduction.[1526]

The agencies agree with ICCT that peer-reviewed tear-down studies present an appropriate method to capture holistic vehicle-level mass reduction technology costs. The agencies also agree with ICCT that the agencies were well aware of studies conducted by EDAG, FEV, Ford, and Lotus Engineering; in fact, the agencies presented a table listing several of those studies in the PRIA with the qualification that those studies were reviewed in developing lightweight assumptions for the analysis, but those studies did not consider important factors, or those studies made unrealistic assumptions about key vehicle systems through secondary downsizing, resulting in unrealistically low costs.

The agencies also agree with UCS' comment that the language could have been more specific about identifying the factors and assumptions that merited disregarding studies that were previously included as part of the record when deriving previous estimates for the costs of mass

[1523] NHTSA-2018-0067-11873.

[1526] NHTSA-2018-0067-12039.

reduction. The following discussion briefly summarizes the record since the Draft TAR and differences between NHTSA's and other lightweighting studies' approach to factors listed in the PRIA. Important for this discussion is an understanding of primary versus secondary mass reduction; as described above, when there is sufficient primary mass reduction, other components that are designed based on the mass of primary components may be redesigned and have lower mass. Recall the braking system example used throughout this section; mass reduction in the braking system is secondary mass reduction because it requires primary mass reduction before it can be incorporated. If the mass of primary components is reduced sufficiently, the resulting lighter weight vehicle could maintain braking performance, attributes, and safety with a lighter weight brake system.

Several studies were referenced in the Draft TAR that either used tear-down analyses and computer-aided engineering (CAE) to produce a future engineered lightweight vehicle, or considered future technologies and processes for lightweighting vehicle components.[1527]

EPA developed cost curves for cars and CUVs based on the MY 2010 Toyota Venza study, and pickup truck cost curves based on the MY 2011 Chevrolet Silverado study.[1528] The other studies were considered by EPA, but not used to develop the Draft TAR, Proposed Determination and Final Determination cost curves. In brief, EPA described that the Toyota Venza Phase I was a mass reduction opportunity study only, and the Phase II study was a holistic vehicle study that examined nearly every component in the vehicle for mass reduction potential and calculated a related cost and mass saved for each. For the cost curve, EPA applied the individual components in sequence from largest cost per kilogram savings to largest cost per kilogram increase. For example, the cost curve for the Draft TAR and Proposed Determination applied engine downsizing and transmission system mass reduction first, and before lightweighting the body, chassis, doors and other components.[1529] EPA stated this methodology was chosen based on the understanding that OEMs will choose the cost saving technologies first and that some cost mass reduction technologies will be paid for by the cost save mass reduction technologies, citing a 2016 publication by CAR and a GM presentation that stated over $2,000,000,000 was saved in material costs through various lightweighting approaches.[1530]

The NHTSA cost curves were developed by rearranging the lightweighted components from the MY 2011 Honda Accord and MY 2014 Chevrolet Silverado studies based on cost effectiveness, assuming the vehicle body, chassis, interior, and other primary components were lightweighted first, followed then by lightweighting powertrain components and other secondary

[1530] Draft TAR at 5-172 (citing "Identifying Real world Barriers to Implementing Lightweighting Technologies and Challenges in Estimating the Increase in Costs," Center for Automotive Research, Jay Baron, PhD, January 2016 http://www.cargroup.org/?module=Publications&event=View&pubID=128; General Motors, "General Motors 2015 Global Business Conference," Presentation, October 1, 2015, Slides 43-45 in document, https://www.gm.com/content/dam/gm/events/docs/5194074-596155-ChartSet-10-1-2015.).

systems.[1531] The cost curves based on the NHTSA studies reflect that, returning to this example, secondary mass reduction for the brake system is only applied after there has been sufficient primary mass reduction to allow the smaller brake system to provide safe braking performance and to maintain mechanical functionality.[1532]

The EPA and NHTSA studies took fundamentally different approaches to accounting for the costs of mass reduction technology, and accordingly, EPA needed to translate the cost curves from the NHTSA studies to use a similar methodology as the cost curves from the EPA studies.[1533] To "normalize" the NHTSA studies with the EPA's studies, EPA listed components identified for lightweighting in the NHTSA studies and reorganized those components from the lowest cost to highest cost along with associated mass reduction per the "whole vehicle" approach mentioned above, distributed mass savings from secondary mass reduction to all points along the cost curve, and included the mass saved from engine downsizing without taking into consideration the cost of added engine technology. This resulted in lower-cost secondary mass reduction opportunities being considered before primary mass reduction opportunities, which in turn resulted in artificially low $/kg costs for mass reduction.

For the NPRM and final rule, the agencies simply used the original ordered list of components from the MY 2011 Honda Accord study and MY 2014 Chevrolet Silverado study, arranged sequentially for cost effectiveness based on primary then secondary mass reduction opportunities, to generate the cost curves for passenger cars and light trucks. Accordingly, the agencies did not "reinterpret" the results of studies used in the Draft TAR in the NPRM, as ICCT alleged, but rather appropriately represented how primary and secondary mass reduction opportunities are implemented in the real world (to the extent that ICCT is referring to the translation of the study costs to the NPRM glider weight assumptions, that is discussed in Section VI.C.4.f)(1), below). To maintain utility and performance in the real world, primary components must be lightweighted first before the engine and transmission can be resized. Moreover, as described in the Draft TAR, NHTSA's mass reduction studies did not "improperly exclude" the effects of secondary mass reduction, rather those effects were appropriately accounted for after primary components achieved certain levels of mass reduction. As discussed in Section VI.B.3.a)(6) Performance Neutrality, this approach aligned with the NAS approach to consider powertrain downsizing only after the vehicle structural components achieved 10 percent mass reduction.

OEMs have also disagreed with the conclusion that mass reduction could come at a cost savings. For instance, Ford characterized the Toyota Venza studies, which concluded the first 7-10% of mass reduction could come at a negative cost as "a gross underestimation of industry investment and material costs associated with any weight reduction." The agencies believe that

---

[1531] Draft TAR at 5-421 ("The powertrain components which include engine, transmission, and fuel systems such as fuel filler pipe, fuel tank, fuel pump, etc., exhaust systems and cooling systems were not considered for application of primary mass reduction but benefits of secondary mass reduction were accounted for. These powertrain components are assumed to be downsized only after the primary vehicle structural components (Body-In-White) achieve certain level of mass reduction.").
[1532] Draft TAR at 5-422.
[1533] Draft TAR at 5-369.

the approach to secondary mass reduction followed in the NHTSA passenger car and pickup truck lightweighting studies appropriately incorporated both the costs and real-world constraints associated with employing primary and secondary mass reduction technologies.

Aside from the differences in how studies treated secondary mass reduction, the agencies opted not to use, or could not use, other studies either previously considered in the rulemaking record or mentioned by commenters for several reasons:

Studies were not comprehensive, and therefore could not be used to develop a comprehensive cost curve: Some studies narrowly assessed lightweighting of a portion of vehicle, such as the body in white subsystem, or as stated in the PRIA,[1534] were limited to material substitution of the vehicle components, such as replacing steel with aluminum or replacing mild steel with AHSS or replacing mild steel with CFRP in selective components. Factors important to vehicle functionality, like material joining techniques and the feasibility of manufacturing processes or necessary retooling requirements were not considered, and therefore could not be used to develop a comprehensive cost curve representative of the costs required to reduce mass in a vehicle.[1535]

Cost curves were not developed or no cost analysis was performed: For the CARB Holistic Vehicle Mass Reduction/Cost Study, a cost curve was not developed, and the resulting cost per kilogram data points were point estimates. The calculated cost per kilogram was used as one data point of several to indicate the direction for mass reduction beyond EPA's original passenger car/CUV curve.[1536] Or, as in the case of the DOE/Ford/Magna Multi Material Lightweight Vehicle (MMLV) project, no cost analysis was performed for the initial project, and later project(s) concluded that "a 37% to 45% mass reduction in a standard mid-sized vehicle is within reach if carbon fiber composite materials and manufacturing processes are available and if customers are willing to accept a reduction in vehicle features and content, as demonstrated with the Multi-Materials and Carbon Fiber Composite-Intensive vehicle scenarios."[1537]

Engineered vehicles did not meet functional design or manufacturing requirements: As noted in the update to EPA's Light-Duty Vehicle Mass Reduction and Cost Analysis for the Toyota Venza, the Phase I engineered Venza did not meet the design target of no expected NVH degradation.[1538] The Phase II (High Development) study assumed significant cost savings from reduced parts manufacturing, but did not appropriately explain the methodology used to conclude that the part count reduction was feasible.[1539]

[1539] Peer Review of Demonstrating the Safety and Crashworthiness of a 2020 Model-Year, Mass-Reduced Crossover Vehicle (Lotus Phase 2 Report), EPA-420-R-12-028 (September 2012).

In addition, the agencies qualified in the PRIA a preference to use studies that considered the small overlap impact test conducted by IIHS, and not all studies took that test into account.[1540] NHTSA's "Update to Future Midsize Lightweight Vehicle Findings in Response to Manufacturer Review and IIHS Small-Overlap Testing" based on the MY 2011 Honda Accord presented results incorporating suggestions from Honda regarding NVH and durability, and updating the engineered vehicle to achieve a "good" rating in seven crash safety tests.[1541] EPA studies also accounted for the IIHS small overlap test through an ad hoc estimate of mass and cost, unlike the NHTSA update, which explicitly modeled to account for NVH performance and to comply with the IIHS small overlap test.

The agencies continue to believe that the MY 2011 Honda Accord and MY 2014 Chevrolet Silverado lightweighting studies are the best studies upon which to estimate the costs of mass reduction in the rulemaking timeframe.

(1) Development of mass reduction costs for the NPRM

Among the several light-weighting studies, the agencies agreed to use NHTSA's passenger car light-weighting study and NHTSA's full size pickup truck light-weighting study to derive the cost estimates to achieve different levels of mass reduction for the NPRM. The light-weighting studies initiated by other agencies and by industry often were limited to material substitution of the vehicle components, such as replacing steel with aluminum or replacing mild steel with AHSS or replacing mild steel with CFRP in selective components. The cost estimates for light weighting from other agencies varied due to incorrect or impractical assumptions such as aggressive secondary mass reduction which translated to cost savings for the initial 10% mass reduction.[1542]

For the NPRM analysis, the agencies chose to use studies that evaluated materials, as well as material gauge and component geometry. Additionally, the agencies preferred to use studies that considered small overlap impact tests conducted by IIHS, and not all studies took that test into account. For pickup trucks, the NHTSA study accounted for vehicle functional performance for attributes including towing, noise and vibration and gradeability, in addition to considering platform sharing constraints.

Previously, in the Draft TAR, the agencies provided an incremental cost per pound for each stage of mass reduction. For the NPRM analysis, the agencies presented an average cost per pound over the baseline (MR0) for the vehicle's glider weight. While the definitions of glider may vary from study to study (or even simulation to simulation), the agencies referenced the same dollar per pound of curb weight to develop costs for different glider definitions. In

[1540] PRIA at 391.
[1541] Singh, H., Kan, C-D., Marzougui, D., & Quong, S. (2016, February). Update to future midsize lightweight vehicle findings in response to manufacturer review and IIHS small-overlap testing (Report No. DOT HS 812 237). Washington, DC: National Highway Traffic Safety Administration.
[1542] EPA-420-R-12-019, EPA-420-R-12-026, SAE Paper 2013-01-0656.

translating these values, the agencies took care to track units ($/kg vs. $/lb.) and the reference for percentage improvements (glider vs. curb weight).

(a) Passenger Cost Curve Used in NPRM

NHTSA relied on a MY 2011 Honda Accord light-weighting study to develop the passenger cost curve used in the NPRM. The NHTSA-funded study, performed by Electricore, Inc., George Washington University, and EDAG, Inc, was completed in 2012 and the final report peer reviewed by industry experts and Honda Motor Company. EDAG and Electricore conducted further work to consider and make changes to the light-weighted model based on the feedback from Honda, and continued to make additional changes to the design concept to address the IIHS small overlap impact test. This study was completed in February 2016.[1543] Table VI-149shows the list of components identified in the MY 2011 Honda Accord light-weighting study and the corresponding direct manufacturing cost (DMC) estimated to light weight those components. Cost estimates include consideration of advanced materials, redesign, tooling changes, and manufacturing setup changes. Figure VI-102 shows the cost curve derived from the list of components in Table VI-149. Figure VI-103 shows the DMC at different levels of mass reduction for the passenger car. The DMC shown in Figure VI-103 is the average DMC and not the marginal cost for each additional mass reduction level. As the average cost per pound over baseline increases, the marginal cost per pound may increase dramatically. (Figure VI-102 units are in kg and $/kg).

[1543] https://www.nhtsa.gov/corporate-average-fuel-economy/light-duty-cafe-midterm-evaluation.

The curb weight of MY 2011 Honda Accord used in the light-weighting study is approximately 1480kg. The glider weight[1544, 1545] of the MY 2011 Honda Accord is approximately 1165kg. In this case, the glider represents 79% of curb weight. As shown in Figure VI-102, approximately 4.67% of the glider mass is light weighted by substituting mild steel with AHSS in body-in-white (BIW) structure, and 3.39% of the glider mass is light weighted by substituting mild steel with AL in closures (closures include hood, front door, rear door and deck lid). Between BIW and closures, approximately 8.06% of glider mass is light weighted by substituting mild steel with AL. The additional light-weighting was achieved by using advanced plastics for door trims, switching copper wiring harness to aluminum wiring harness, using AHSS for seat frames, using AHSS and optimizing design for parking brakes, among other substitutions. As shown in Figure VI-103, a total of 13.65% of glider mass was light weighted. This translates to 10.74% mass reduction at the curb weight level. The light-weighting report noted that follow-on mass reduction can be achieved by downsizing the engine and optimizing the powertrain components, while maintaining the same level of performance. The report shows powertrain downsizing translates to some cost savings as well (the cost savings comes from manufacturers selecting downsized engines from the inventory of engines used in other product lines through economies of scale and common parts).

The 2015 NAS report suggested an engine downsizing opportunity exits when the glider mass is light weighted by at least 10%.[1546] The 2015 NAS report also suggested that 10% light weighting of glider mass alone would boost the fuel economy by 3% and any engine downsizing following the 10% glider mass reduction would provide an additional 3% increase in fuel economy. This analysis uses the 2015 NAS recommendation and does downsize the engine at a 10% glider weight reduction, and the analysis rely on full vehicle simulations to estimate the effects of this action.

[1544] Glider weight is typically all components of the vehicle except the powertrain components such as engines, transmissions, radiator, fuel tank and exhaust systems.

[1545] Not all subsystems considered in the light-weighting study were considered in the ANL simulations and CAFE model.

(b) Light Truck Cost Curve Used in NPRM

NHTSA's cost curve for light trucks used in the NPRM was developed through an agency-funded light-weighting study on a MY 2014 Chevrolet Silverado 1500 full-size pickup truck. EDAG Inc. performed this light-weighting study along with other sub-contractors. This study considered lessons learned during the MY 2011 Honda Accord light weighting study, and included requirements that the vehicle meet the IIHS small overlap performance test. This project was completed in 2016 and the final report is available on NHTSA's website. [1547]

Table VI-152 shows the list of components light-weighted in the MY 2014 Chevrolet Silverado 1500 full-size pickup truck. Figure VI-104 shows the cost curve generated from the

[1547] https://www.nhtsa.gov/corporate-average-fuel-economy/light-duty-cafe-midterm-evaluation.

list of the light weighted components, and Figure VI-105 shows the DMC at different levels of mass reduction.

Table VI-152 – List of Components Light Weighted in the MY 2014 Chevrolet Silverado 1500

#	Vehicle Component/System	Baseline Mass	Substitution Material	Light-weighted Mass	Mass Saving	Δ Cost	Δ Cost	Cumulative Mass Saving	Cumulative MR	Cumulative Cost	Cumulative Cost

Table VI-154 – Cost numbers used in the CAFE model for Light Truck Mass Reduction

MR% (glider, 50% of curb weight)	**MR Technology Level**	**$/kg, including RPE markup**	**$/lbs, including RPE markup, MY 2016 SUV's and Trucks**	**New Curb Weight after Glider Mass Reduction (lbs)**	**Approximate Percentage Mass Reduction at Curb Weight Level**
0%	MR0	$-	$ -	Depends on the vehicle as specified in the CAFE model	0.0%
5.0%	MR1	$0.62	$0.28		2.5%
7.5%	MR2	$0.82	$0.37		3.8%
10.0%	MR3	$1.41	$0.64		5.0%
15.0%	MR4	$3.68	$1.67		7.5%
20.0%	MR5	$5.38	$2.44		10.0%

Table VI-153 shows the percentage of Glider mass identified in the passenger car light-weighting study (which is 79% of curb weight). The mass reductions were applied to the Glider mass and the cost estimates derived from the light weighting study was applied.

However, the percentage of Glider mass for the NPRM analysis was limited to 50% of the curb weight to align with the Autonomie simulations. The cost estimates derived from the light-weighting study was adjusted to reflect 50% of the curb weight.

(c) Cost of Carbon Fiber

Achieving the highest levels of mass reduction often necessitates extensive use of advanced materials like higher grades of aluminum, magnesium, or carbon fiber reinforced plastics (CFRP). CFRP is attractive in terms of strength to weight ratio, and CFRP is typically 30 to 50% lighter than conventional materials. Challenges to using CFRP include high cost of materials, failure mode predictability in crashes, longer lead time and cycle time to manufacture, and special tools required to assemble, and join components with other metallic components. Once limited to performance cars, CFRP is now strategically used in some automotive components in luxury vehicles. Manufacturers have used these expensive components strategically, not only to reduce mass, but also to change the vehicle's center of gravity and improve the vehicle's weight distribution. In the case of BMW i3, most of the cab structure is made of CFRP, including the bodysides. A teardown study by Munro & Associates showed the BMW i3 cab structure plus the CFRP cradle is 68 kg lighter than a comparable steel structure.[1548] This study also estimated the upfront investment and resulting part cost to manufacture CFRP components.

The IACMI Composites Institute also conducted a study to establish baseline metrics to determine the cost metric in terms of $/kg for automotive components, among other composite parts. [1549] As part of the study, Oak Ridge National Laboratory (ORNL) provided cost estimates for carbon fiber in automotive applications. The ORNL cost estimates were higher than the NHTSA passenger car light-weighting study but in line with the cost estimates done for the NHTSA full size pickup truck light-weighting study. One reason for this difference could be that the NHTSA mass reduction study considered CFRP only for small components, whereas the ORNL study considered carbon fiber polymers for use in large automotive parts such as floor pan, door inner, tail gate closures etc.

During the Center for Automotive Research (CAR) annual management briefing seminar at Traverse City, Michigan, Ducker Worldwide presented on the cost and weight reduction estimates required to be implemented in the coming years to meet NHTSA's augural fuel economy standards.[1550] Ducker's cost estimates to achieve higher levels of mass reduction using CFRP match closely with the estimates from NHTSA's light-weighted truck study.

In the MY 2011 Honda Accord light-weighting study, the estimated cost of CFRP was $5.37/kg and the cost of CFRP used in the MY 2014 Chevy Silverado light-weighting study was $15.50/kg. The $15.50 estimate closely matches the cost estimates from BMW i3 teardown analysis, the cost figures provided by Oak Ridge National Laboratory, and from the Ducker Worldwide presentation at the CAR management briefing seminar.

The cost estimates for CFRP used in the MY 2011 Honda Accord light-weighting study were updated to reflect more realistic costs for higher levels of mass reduction (up to 20% mass reduction on the glider).

(d) Development of Cost Curves for Different Class of Vehicles

Several mass reduction studies from the agencies or from the industry have used either a mid-size passenger car or a full-size pickup truck as an exemplar vehicle to demonstrate the technical and cost feasibility of mass reduction. While the finding of these studies may not apply directly to different vehicle classes, the cost estimates derived for the mass reduction technologies identified in these studies can be useful for formulating general guidance on costs. For this NPRM, this analysis compared weights of components from teardown studies with similar components from other vehicles in the other vehicle segments using the A2Mac1 database. The agencies applied the same mass reduction technologies identified in the NHTSA studies to estimate the level of mass reduction that may be achievable in other vehicles.

This analysis applied the cost estimates per pound derived from passenger cars to all passenger car segments, and the cost estimates per pound derived from full-size pickup trucks to all light-duty truck and SUV segments. The agencies are seeking comment on whether separate cost curves for each vehicle segment is necessary, or if the existing cost curves for PCs and LTs is sufficient to be applied for all vehicle segments.

(2) How the Cost Curves Are Applied in the Model

Commenters also submitted comments on how the cost curves were applied in the model, including that the studies the agencies relied upon to generate cost curves, discussed above, did not support the 50 percent glider share assumption used in the NPRM, and the agencies did not correctly scale the costs to match the glider share assumption.

UCS commented that the agencies based the costs for mass reduction on glider weight reduction, however, the need for more expensive materials and more advanced engineering and design strategies only results from the need for greater levels of absolute mass reduction on the vehicle.[1551] UCS stated that the cost curves had effectively been derived from the assumption of reductions as great as 16.8 percent reduction in curb weight in the case of the Silverado (Singh et al. 2018) and as great as 18 percent reduction in curb weight in the case of the Honda Accord (Singh et al. 2016), but applied to curb weight reductions approximately two-thirds that magnitude. UCS stated that approach was "completely invalid and significantly overstates the costs for mass reduction." UCS also commented that the agencies incorrectly scaled the cost curves based on the agencies' mass reduction studies, which refer to direct manufacturing costs as a function of vehicle curb weight, not just glider weight. UCS stated this incorrectly yielded the same costs for two-thirds the amount of mass reduction.

CARB similarly commented that the mass reduction costs assigned to both passenger cars and light trucks in the CAFE model were inappropriately inflated based on incorrect scaling from the glider share assumptions used in the Honda Accord and Chevy Silverado studies to the NPRM glider share value.[1552] CARB analyzed two tables in the PRIA that showed the agencies'

[1551] NHTSA-2018-0067-12039.
[1552] NHTSA-2018-0067-11873.

translation of cost numbers derived from the two studies to the cost numbers used in the CAFE model, and asserted that the agencies improperly used costs from the upper end of the mass reduction range rather than the midpoint of the range, leading to cost overestimation.

Similarly, HDS commented that the PRIA passenger car cost curves used data that were not in agreement with the study that they were based upon, noting that the Honda Accord study showed the glider accounting for 78% of curb weight, and this limited absolute weight reduction.[1553] HDS noted that the truck weight reduction cost data were closer to those cited in the Chevy Silverado teardown study, although the glider share for that study was also 73.6% of vehicle curb weight.

HDS also commented that although the agencies relied on the same Honda Accord study that was used in the Draft TAR, "the costs have been changed significantly [from the Draft TAR] for unexplained reasons."[1554] HDS stated that the PRIA showed average costs for mass reduction, whereas earlier studies showed the cost increment for each 5% mass reduction, noting that with increasing incremental cost with increased mass reduction, average cost will always be lower than incremental cost. HDS claimed that it was "unusual" for the Draft TAR incremental costs to decrease between 11% and 19% mass reduction but increase elsewhere, but also noted the unexplained increase in cost, specifically a $536 cost for 175kg weight reduction, shown in the PRIA.

HDS also compared manufacturing costs from the Draft TAR to the PRIA analysis, noting that the direct manufacturing cost was found to be negative (i.e., a cost saving) in the Draft TAR analysis for mass reduction up to 15 percent, but EPA assumed the indirect costs were positive so that the total cost was a sum of positive and negative costs—meaning the total cost could be positive or negative. In contrast, HDS noted there were no negative costs in the cost curves used for the PRIA analysis, resulting in a very large differential between the costs of mass reduction, with the 2018 average cost being higher than even the 2016 marginal costs.

Three notable changes from the NHTSA Draft TAR to NPRM and final rule analysis impacted how the cost curves for mass reduction are applied in the CAFE Model.

First, the Draft TAR considered mass reduction in the glider and powertrain together, and calculated the percentage mass reduction on a vehicle curb weight basis. In the Draft TAR, only one engine and transmission combination were considered to account for the mass change associated with downsizing the engine, and the cost estimates for mass reduction for this *one* powertrain combination was applied to *all* powertrain combinations. This approach did not account for the mass changes associated with the application of powertrain technologies (engine, transmission and electrification) technologies, and did not account for the corresponding change in glider mass needed to offset the powertrain mass change and to achieve the specified curb weight mass reduction level. This approach did not reflect the real world, where there are many

---

[1553] NHTSA-2018-0067-11985.
[1554] NHTSA-2018-0067-11985.

vehicles with different body styles and powertrain combinations, and therefore did not account for differences in mass for different engines, transmissions, or electrification.

Accordingly, for the NPRM and final rule, the cost of mass reduction was calculated on a glider weight basis so that the weight of each powertrain configuration could be directly and separately accounted for. This approach provides the true cost of mass reduction without conflating the mass change and costs associated with downsizing a powertrain or adding additional advanced powertrain technologies. Hence, the mass reduction costs in the NPRM reflect the cost of mass reduction in the glider and do not include the mass reduction associated with engine downsizing, and therefore appear to be higher than the cost estimates in the Draft TAR.

Second, the glider share of curb weight changes from the Draft TAR to NPRM and from the NPRM to the final rule analysis also affected the absolute amount of curb weight reduction that was applied, and therefore for cost per pound for the mass reduction changes with the change in the glider share. The cost for removing 20 percent of the glider weight when the glider represents 75% of a vehicle's curb weight is not the same as the cost for removing 20 percent of the glider weight when the glider represents 50% of the vehicle's curb weight. For example, the glider share of 79 percent of a 3,000-pound curb weight vehicle is 2,370 pounds, while the glider share of 50 percent of a 3,000-pound curb weight vehicle is 1,500 pounds, and the glider share of 71 percent of a 3,000-pound curb weight vehicle is 2,130 pounds. The mass change associated with 20 percent mass reduction is 474 pounds for 79 percent glider share (=[3,000 pounds x 79% x 20%]), 300 pounds for 50 percent glider share (=[3,000 pounds x 50% x 20%]), and 426 pounds for 71 percent glider share (=[3,000 pounds x 71% x 20%]). The mass reduction cost studies show that the cost for mass reduction varies with the amount of mass reduction. Therefore, for a fixed glider mass reduction percentage, different glider share assumptions will have different costs.

To further illustrate, Table VI-155 and Table VI-156 below shows the associated curb weight percentage mass reduction and the associated average cost per pound for different glider weight assumptions for each glider mass reduction technology level used in the final rule analysis. For reference, the costs from the passenger car light weighting study are presented.[1555] These costs were the basis for deriving the costs for each mass reduction technology level in the Draft TAR, NPRM, and final rule analyses, using the unique glider share values for each of those analyses. In the light weighting study, NHTSA applied the mass reduction technologies identified for the exemplar vehicle on other vehicle(s) and vehicle types to understand the level of mass reduction that could be achieved. In the case of passenger cars, the maximum level of mass reduction was around 15% of the vehicle curb weight if all the mass reduction technologies are applied. In other words, achieving mass reduction greater than 10% of the curb weight for passenger cars will require extensive use of advanced materials such as high strength aluminum and carbon fiber composite material.

[1555] Table 6-39 in PRIA.

Table VI-155 – Mass Reduction RPE Costs per Pound for MY 2017 as a Function of Percentage Curb Weight Reduction for 79%, 50%, and 71% Glider Shares for Passenger Car (2018$)

	Final Rule 71% Glider Weight		**NPRM 50% Glider Weight**		**Draft TAR 75% Glider Weight**		**NHTSA Light Weighting Study 79% Glider Weight**

MR6	20%	$17.79						

Finally, as explained earlier, to determine the mass reduction technology levels for the NPRM 2016 analysis fleet, a distribution of the residuals from the regression using 50 percent glider weight generally showed a greater percentage of vehicles achieving higher levels of mass reduction. With this high level of mass reduction already achieved, the opportunities for further mass reduction would be limited and have higher costs. For the final rule, since the agencies updated the glider share to 71 percent of the vehicle curb weight, the distribution of residuals from the regression shifted some vehicles to lower baseline mass reduction technology levels, providing more opportunity for further mass reduction, on average. Even as some of the vehicles start further up on the mass reduction cost curve due to higher levels of mass reduction technology (MR3, MR4) already present in the vehicles, there are additional opportunities for further mass reduction to achieve MR5 and above.

Table VI-155 and Table VI-156 show that for the final rule, cost estimates with the 71 percent glider share come closer to the cost estimates used in Draft TAR, which assumed a 79 percent glider share.

(3) Secondary Mass Reduction Costs

As discussed above, the agencies changed the cost of mass reduction calculation from a curb weight basis in the Draft TAR to a glider weight basis in the NPRM.[1556] This change allowed us to estimate the cost of mass reduction independently of the cost associated with downsized advanced engines and advanced transmissions, as the cost of downsized advanced engines and transmissions are accounted for separately in the CAFE model.

The MY 2011 Honda Accord and MY 2014 Chevy Silverado studies used to develop the NPRM and final rule cost curves for mass reduction technologies include some non-powertrain secondary mass reduction technologies such as brakes and wheels. The agencies presented the list of mass reduction technologies in NPRM.[1557] Following the publication of NHTSA's light weighting studies, peer reviewers and manufacturers commented that many components such as drive axles, engine cradles, and radiator engine support that are considered to be non-powertrain secondary mass reduction opportunities cannot be downsized, as the same components are used across many vehicles with different powertrain options. Even though some of these components may provide opportunities for additional mass reduction, NHTSA agreed with peer reviewers and manufacturers that retaining a common design for all powertrain options provides for cost reductions due to economies of scale.

Commenters faulted the agencies for a perceived lack of accounting for the cost decreases from secondary mass reduction. ICCT commented although the agencies relied on the Honda Accord study, which considered cost savings from downsizing the powertrain, in the NPRM only glider weight reduction was ever considered without the cost-offsetting engine downsizing.[1558] ICCT stated that this omission had two effects, first that accounting for associated powertrain weight reductions would have allowed for more mass reduction, thus allowing for greater efficiency benefits at a lower cost, and second, that vehicle performance was erroneously improved, contrary to the agencies' assertion that the analysis assumed a level of performance neutrality. ICCT concluded that it was unclear if and how costs were reduced for powertrain downsizing, as well as the precise changes to fuel efficiency.

CARB faulted the agencies for not including secondary mass reduction in the NPRM analysis, and stated that by failing to account for secondary mass reduction as was done in the

[1556] In the Draft TAR, the agencies presented the cost estimates from mass reduction studies sponsored by both NHTSA and EPA. EPA presented the cost of mass reduction as function of vehicle curb weight. To harmonize the cost estimates with EPA, NHTSA also presented the cost of mass reduction as a function of vehicle curb weight.
[1557] Table 6-37 and Table 6-40 in PRIA.
[1558] NHTSA-2018-0067-11741.

Draft TAR, the agencies inflated the costs for mass reduction as well as the amount of mass reduction that is feasible and cost-effective leading to an overestimate in the technology costs needed to meet the existing standards.

The agencies note that the cost curves used for the NPRM and this final rule do in fact include secondary mass reduction. The cost curves reflect secondary mass reduction applied when there is sufficient primary mass reduction to implement secondary mass reduction without degrading function and safety. Specifically, the NHTSA studies, upon which the cost curves were built, first generated costs for lightweighting the vehicle body, chassis, interior, and other primary components, and then calculated costs for lightweighting secondary components. Accordingly, the cost curves reflect that, for example, secondary mass reduction for the brake system is only applied after there has been sufficient primary mass reduction to allow the smaller brake system to provide safe braking performance and to maintain mechanical functionality.

In addition, CARB stated that the 2011 Honda Accord and the 2014 Chevrolet Silverado studies had "markedly" lower costs than the proposal when secondary mass reduction is included. Again, the agencies believe these comments resulted from a lack of understanding about how the analysis considers primary and secondary mass reduction, even though the NPRM and PRIA explicitly stated how costs are accounted for separately.[1559] Also, as discussed above, engine mass reduction enabled by mass reduction in the glider is accounted for separately and therefore not included as part of glider mass reduction technology, as doing so would result in double counting the impacts.

(4) Summary of Final Rule Mass Reduction Costs

For the final rule, the agencies continue to use multiple mass reduction technology levels and costs based on the lightweighting studies that were presented in PRIA.[1560] Since the agencies have changed the glider share of curb weight assumption from 50 percent in NPRM to 71 percent in the final rule, the mass reduction costs reflect the updated glider share. Table VI-157 and Table VI-158 show mass reduction costs used in the CAFE model for passenger car and light trucks.

5. Aerodynamics

The energy required to overcome aerodynamic drag accounts for a significant portion of the energy consumed by a vehicle, and can become the dominant factor for a vehicle's energy consumption at high speeds. Reducing aerodynamic drag can, therefore, be an effective way to reduce fuel consumption and emissions.

Aerodynamic drag is proportional to the frontal area (A) of the vehicle and coefficient of drag (C_d), such that aerodynamic performance is often expressed as the product of the two values, C_dA, which is also known as the drag area of a vehicle. The coefficient of drag (C_d) is a dimensionless value that essentially represents the aerodynamic efficiency of the vehicle shape. The frontal area (A) is the cross-sectional area of the vehicle as viewed from the front. It acts with the coefficient of drag as a sort of scaling factor, representing the relative size of the vehicle shape that the coefficient of drag describes. The force imposed by aerodynamic drag increases with the square of vehicle velocity, accounting for the largest contribution to road loads' higher speeds.

Aerodynamic drag reduction can be achieved via two approaches, either by reducing the drag coefficient or reducing vehicle frontal area, with two different categories of technologies, passive and active aerodynamic technologies. Passive aerodynamics refers to aerodynamic attributes that are inherent to the shape and size of the vehicle, including any components of a fixed nature. Active aerodynamics refers to technologies that variably deploy in response to driving conditions. These include technologies such as active grille shutters, active air dams, and active ride height adjustment. It is important to note that manufacturers may employ both passive and active aerodynamic technologies to achieve aerodynamic drag values.

The greatest opportunity for improving aerodynamic performance is during a vehicle redesign cycle when significant changes to the shape and size of the vehicle can be made. Incremental improvements may also be achieved during mid-cycle vehicle refresh using restyled exterior components and add-on devices. Some examples of potential technologies applied during mid-cycle refresh are restyled front and rear fascia, modified front air dams and rear valances, addition of rear deck lips and underbody panels, and low-drag exterior mirrors. While manufacturers may nudge the frontal area of the vehicle during redesigns, large changes in frontal area are typically not possible without impacting the utility and interior space of the vehicle. Similarly, manufacturers may improve C_d by changing the frontal shape of the vehicle or lowering the height of the vehicle, among other approaches, but the form drag of certain body styles and airflow needs for engine cooling often limit how much C_d may be improved.

During the vehicle development process, manufacturers use various tools such as Computational Fluid Dynamics (CFD), scaled clay models, and full size physical prototypes for wind tunnel testing and measurements to determine aerodynamic drag values and to evaluate alternate vehicle designs to improve those values.

The agencies presented a table in the PRIA showing aerodynamic drag improvements from individual technologies based on wind-tunnel testing for a study commissioned by Transport Canada, which is reproduced in Table VI-159 below.[1561] The individual technologies are present in many of the 2016 and 2017 vehicles in the fleet. Table VI-159 shows the list of aerodynamic technologies and corresponding aero drag improvements.

[1561] Table 6-63 in PRIA.

Table VI-159 – Aerodynamic Technologies and Aero Drag Improvements

Aero Feature (A-B Testing)		Aero Drag Reduction (%)	Comments
Fixed Air Dam-Bumper		1 - 6%	OEM stock components
Active Air Dam – Bumper (Conceptual)		4 - 9% (fixed air dam + 3%)	Fixed, prototype parts w/ lowest deployment height used
Fixed Air Dam-Wheels		1% (front)/4.5% (front & rear)	
Underbody Panels		1-7% (stock OEM)	Addtn'l 0.5%-4% w/ full body panels. Dodge Ram prototype: 8%
Increased Tire Size		-2.0 - 3.2%	17"/18" stock OEM rims vs. 22" optional OEM rims
Wheel Covers		1.5 - 3%	Solid wheel covers only; brake cooling affects not considered
Front License Plates		+/- 0.3%	Negligible impact
Decorative Grille Optimization		1.6%	Smoothing of grille features; function vs. styling trade-offs
Pick-up Tailgates	Open	-5.2%	
	Removed	-7.5%	Open tailgate + 2.3%
Pick-up Tonneau Cover		3.7%	

As discussed in the PRIA and further below, the agencies made several notable changes for modeling aerodynamic improvement technologies from the Draft TAR to the NPRM. First, the agencies revised the aerodynamic improvements from two levels in the Draft TAR (10% and 20% improvement over the baseline) to four levels (5%, 10%, 15% and 20% aerodynamic drag improvement values over the baseline). This change provided the improved granularity to bin the vehicles with different aerodynamic improvements more appropriately. Next, the agencies assigned levels of aerodynamic technology to the MY 2016 fleet on a relative basis based on confidential business information submitted by the manufacturers, taking steps to verify information submitted by manufactures with other sources, and making changes particularly for vehicles that showed large improvements over baseline values. Third, the agencies limited the maximum level of aerodynamic improvements that certain body styles (pickup trucks, minivans) could achieve and limited the maximum level of improvements that cars and SUVs with more than 405 horsepower could achieve, based on the agencies' assessment of industry comments. Finally, the agencies updated the cost for aerodynamic improvements based on the assessment of comments that the National Academy of Sciences (NAS) cost estimates used in the Draft TAR underestimated the cost for aerodynamic improvements.

Broadly, Ford commented in support of the approach to aerodynamic improvement modeling in the NPRM, stating that the rule recognized potential constraints like consumer needs and preferences regarding vehicle styling, vehicle utility, and interior space, by among other things, recognizing that the potential for aerodynamic drag differs among different vehicle body styles and vehicle classes.[1562] Ford stated that these are major factors considered by customers when comparing competing vehicles, and the failure of a manufacturer to deliver in these areas can lead to the production of non-competitive, poor-selling vehicles.

On the other hand, ICCT claimed that the agencies greatly limited the availability of many load reduction technologies (i.e., mass reduction improvements, aerodynamic improvements, and rolling resistance improvements) by pushing very large amounts of these technologies into the 2016 model year baseline fleet, thereby making the technologies unavailable for use in future years.[1563] ICCT commented that these improvements in the analysis fleet would ostensibly amount to massive efficiency improvements, however, these assumed changes were not substantiated as resulting in any test-cycle efficiency improvements in the model year 2016 fleet versus the 2015 fleet. ICCT concluded that the adjusted baseline had been developed and presented opaquely, apparently based primarily upon estimations from automaker-supplied data, without critical analysis, vetting, or sharing of the necessary data to substantiate the changes and real-world benefits by the agencies.

As discussed further in Section VI.C.5.b) AERO drag analysis fleet assignments below, the agencies believe the updated analysis fleet aerodynamic technology level assignments in the NPRM analysis represent an improvement over the MY 2015 assignments in the Draft TAR, as the updated assignments are based on precise values, not estimated from road load coefficients, and have been corroborated by observed improvements on actual production vehicles. Accordingly, the agencies carried over the NPRM approach for determining the aerodynamic technology levels for the analysis fleet to the final rule.

a) Aerodynamics Drag Reduction Modeling in the CAFE Model

The agencies summarized in the PRIA that the Draft TAR aerodynamic improvement levels were binned into two groups, AERO1 and AERO2. However, market observations showed that many vehicles had aero improvements from 0% to 10%, and some vehicles showed improvements from 10% to 20%.[1564] Based on industry feedback and market observations, the agencies revised the aerodynamic improvements from two levels in the Draft TAR (10% and 20% improvement over the baseline) to four levels (5%, 10%, 15% and 20% aerodynamic drag improvement values over the baseline). This revision provided the necessary granularity to bin the vehicles with different aerodynamic improvements appropriately.

ICCT commented that to model appropriately the baseline standards, the agencies would need to include increasing use of aerodynamic off-cycle technology credits across all companies through 2025. ICCT stated that it appeared that the agencies did not use EPA's engineering expertise or compliance data, where EPA would be able to advise better based on their certification data from the off-cycle program.

[1562] NHTSA-2018-0067-11928.
[1563] NHTSA-2018-0067-11741 full comments.
[1564] PRIA at 437.

As discussed further in Sections VI.A and VI.C.8, the NPRM analysis carried forward manufacturers' off-cycle fuel consumption improvement values (FCIVs) at MY 2016 levels unless an explicitly simulated off-cycle technology, like start-stop systems, was added to a vehicle in the simulation modeling. Specific to aerodynamic improvements, active grille shutters were assumed to be applied at the 20 percent aerodynamic improvement (AERO20) level. For the final rule analysis, based on the assessment of comments that the application of off-cycle technologies in the analysis was too conservative, the agencies agreed and increased each manufacturers' application of off-cycle technologies so that 10 g/mi of technology was applied by 2023, using an extrapolated increase in levels in MYs 2017-2023 based on EPA compliance data.[1565] This approach did not assume any specific mix of off-cycle technologies that would be used by manufacturers to achieve the 10 g/mi off-cycle improvement, because manufactures currently use a variety of technologies, and different manufacturers likely would implement unique combinations of technologies. It is expected that aerodynamic off-cycle technologies would be included in the mix of off-cycle technologies.

Table VI-160 and Table VI-161 show aerodynamic technologies that could be used to achieve 5%, 10%, 15% and 20% aero improvements in passenger cars, SUVs, and pickup trucks.[1566] The agencies developed these potential combinations of technologies using aerodynamic data from a National Research Council (NRC) of Canada sponsored wind tunnel testing program that included an extensive review of production vehicles utilizing these technologies, and industry comments.[1567,1568] These technology combinations are intended to show a *potential* way for a manufacturer to achieve each aerodynamic improvement level; however, in the real world, manufacturers may implement different combinations of aerodynamic technologies to achieve a percentage improvement over their baseline vehicles.

b) Aerodynamic Drag Reduction Analysis Fleet Assignments

The agencies described in the PRIA that for the 2015 analysis fleet used in the Draft TAR, the agencies received C_d values for the MY 2015 vehicles' baseline assignments from manufacturers, or used estimated C_d values. In response, the industry commented that C_d values often varied by measurement approach and, therefore, it was important to account for differences in the methodologies used to estimate those values. For instance, aerodynamic drag coefficients for the same vehicle often vary significantly from wind-tunnel to wind-tunnel, complicating cross-comparison and cross-referencing.[1569] The industry commented that, on average, the manufacturer-reported C_d values are nine percent lower than the values reported by USCAR.[1570] For reference, USCAR follows the SAE J2881 test procedure. However, because C_d values are not required to be reported for compliance, manufacturers can and do choose different methods to estimate the C_d values. Therefore, the industry commented that assigning baseline aerodynamic improvement levels should not simply be comparing the lowest reported C_d value in a vehicle segment to other reported C_d values. The industry commented that such a comparison would not reflect the plausible amount of aerodynamic drag improvement that could be achieved. Accordingly, the industry suggested that the analysis should normalize manufacturer-reported C_d values using SAE J2881.

The commenters stated manufacturers have the option to use other methods (apart from coast down testing) to estimate the C_d values such as wind tunnel testing, cross referencing the C_d value from other vehicles with similar frontal design and aero technologies deployed. Since manufacturers do not have to specify the methodology used to estimate the C_d value, the agencies have limited capability to make accurate comparisons of the C_d value estimates from different testing methods. As a result, the agencies determined using average(s) of the fleet provide a better estimate of C_d levels than using the lowest C_d value in the fleet to assign aerodynamic improvement levels. The agencies determined it is appropriate to continue to use the NPRM approach for the final rule.

The NPRM and final rule analysis used a relative performance approach to assign the current aerodynamic technology level to a vehicle. Different body styles offer different utility and have varying levels of baseline form drag. In addition, frontal area is a major factor in aerodynamic forces, and the frontal area varies by vehicle. This analysis considered both frontal area and body style as utility factors affecting aerodynamic forces; therefore, the analysis assumed all reduction in aerodynamic drag forces come from improvement in the C_d. Per the

[1569] PRIA at 435.
[1570] Footnote in PRIA at 435: FCA Draft TAR comments. Docket ID: NHTSA-2016-0068-0082.

process outlined in NHTSA's section of the Draft TAR,[1571] the agencies computed an average C_d for each body style segment in the MY 2015 analysis fleet from drag coefficients published by manufacturers. By comparing the C_d among vehicles sharing body styles, this allowed the agencies to estimate the level of aerodynamic improvement present on specific vehicles.

While some small differences existed between the aggregate MY 2015 and MY 2016 data, the agencies retained the NHTSA-calculated MY 2015 average C_d as the baseline drag coefficient for nearly all body styles. For pickup trucks, the agencies assigned a baseline drag coefficient of 0.42, considering that a large portion of the pickups sold in MY 2015 already included aerodynamic features assumed for advanced levels of aero. The agencies harmonized the Autonomie simulation baselines with the analysis fleet assignment baselines to the fullest extent possible.[1572]

The agencies assigned levels of aerodynamic technology to the MY 2016 fleet based on confidential business information submitted by manufacturers on aerodynamic drag coefficients, and from other information sources such as in product release information. The analysis referenced manufacturer-submitted data (if that data was supplied), and the agencies took industry comments to Draft TAR into account and closely reviewed the manufacturer-submitted C_d data. In the few cases that manufacturers did not submit C_d values as confidential business information, the agencies estimated the C_d based vehicle attributes, design, and aero technologies applied to that vehicle. The agencies noted that the C_d values reported by some manufacturers showed high levels of improvement relative to the previous model year or previous generation. In some cases, the agencies contacted the manufacturers to further discuss differences in C_d estimation methodologies. Where appropriate, the agencies adjusted MY 2016 fleet C_d values after consultation with the manufacturers and used these values to assign baseline technology levels for each vehicle in the NPRM CAFE model simulation.

The Alliance commented that the NPRM analysis fleet had more appropriately assigned aerodynamic technology levels, and the assignments were more accurate than the Draft TAR, where vehicles were generally considered to have little aerodynamic improvement technology, and the CAFE model would add aerodynamic improvement despite the fact that manufacturers had already made significant improvements and there was little opportunity remaining for more.[1573] The Alliance concluded that the Draft TAR approach ultimately led the CAFE model to under-predict how much powertrain technology was required for compliance. The Alliance also commented that it is possible to estimate aerodynamic features of a vehicle using road load coefficients, but the process requires various assumptions and is not very accurate. The Alliance concluded that the agencies' use of CBI to assign initial aerodynamic improvement values is an accurate and practical solution to support correct baseline assignments.

[1571] Draft TAR at 4-80.
[1572] Often, vehicles assigned to technology classes do not perfectly match up with simulated vehicles, but in most cases this analysis assumed the aerodynamic effects and other specifications were comparable and appropriate for use as proxies.
[1573] NHTSA-2018-0067-12039 at 136.

Ford commented that the use of actual data, like manufacturer confidential information or other sources, to characterize better the aerodynamic improvements already incorporated into the baseline fleet is a substantial improvement over previous analyses that either assumed no aero improvement due to insufficient data, or attempted to infer C_d from the road load coefficients.[1574] Ford stated that attempting to infer C_d from road load coefficients is not sufficiently accurate for a vehicle-level determination since the aerodynamic component of the road load coefficients is inextricably confounded with tire, transmission, and other parasitic losses. As part of its comments that the proposed rule analysis recognized constraints like consumer needs and preferences regarding vehicle styling and utility, Ford stated that the baseline C_d for pickup trucks properly recognized that these vehicles already include many advanced-level aerodynamic technologies. Ford concluded that an accurate assessment of the current technological state of the baseline fleet is critical to ensuring that the benefits of technological improvements are not "double-counted" in the modeling.

On the other hand, ICCT commented that the agencies artificially limited the availability of aerodynamic technologies in the CAFE model in future years by assigning approximately three times as many aerodynamic technology packages in the 2016 analysis fleet as they did in the 2015 baseline fleet used in the Draft TAR.[1575] ICCT noted that the 2015 Draft TAR fleet had about 8 percent vehicles with one of the aerodynamic packages, whereas the NPRM's 2016 fleet had about 53 percent, and argued that the agencies did not justify the increase with data to show that automakers actually deployed the technology. ICCT pointed to the agencies' introduction of intermediate aerodynamic improvement steps as the justification for the change, which ICCT argued "redistributes the baseline fleet into more advanced aerodynamic levels without observing or verifying real-world aerodynamic improvements."

ICCT argued that if an improvement of this magnitude were true, it would be evident in fleet level miles-per-gallon and CO_2 levels (e.g., in EPA's *Trends* and *Manufacturer Performance* reports), but none of the quantifiable mpg or CO_2 benefits that would be associated with these additional aerodynamic improvements were reflected in any real-world evidence in the model year 2016 fleet. ICCT stated that to show the automakers deployed this level of aerodynamic improvements, the agencies needed to show data on how these improvements are evident in the fleet and delivering benefits. Specifically, ICCT stated that the agencies must share the basis for any aerodynamic calculation and exact estimated percent improvement (rather than binned percentage categories) for each vehicle make and model in the baseline and future modeled fleet, and their technical justification for each value, arguing that not doing so would obscure the agencies' methods. In addition, ICCT stated that the agencies must conduct two sensitivity analysis cases that assume that every baseline make and model is set to 0 percent aerodynamic improvement and set to the previous baseline aerodynamic levels (i.e., from TAR) to demonstrate how much the agencies' decision to load up more baseline technology affects the compliance scenarios. ICCT concluded that because changes in aerodynamic improvement assumptions "are opaquely buried in the agencies' datafiles and unexplained," the agencies must

[1574] NHTSA-2018-0067-11928.
[1575] NHTSA-2018-0067-11741 full comments.

issue a new regulatory analysis and allow an additional comment period for review of the methods and analysis.

ACEEE asserted, as part of its comments that the MY 2016 analysis fleet assignments appeared to contain errors, that the assignment of AERO10 for the MY 2016 Toyota Tundra pickup truck was in error.[1576] ACEEE stated that Tundra pickup trucks have had similar specs from MY 2011 to today, and the C_d for all Tundra models has been 0.37 or 0.38 for 2WD and 4WD, respectively, since MY 2011. ACEEE noted that this is higher than the AERO10 C_d cut off value of 0.355 for pickups, as shown in the 2016 Draft TAR and referenced in the PRIA.

As described above, the agencies assigned levels of aerodynamic technology to the NPRM MY 2016 analysis fleet on a relative basis based on confidential business information submitted by the manufacturers on aerodynamic drag coefficients and other information sources such as in product release information. In addition, based on the Draft TAR comments, the agencies verified wherever possible the information submitted by manufactures with other sources (product release information and cross referencing with vehicles with similar design features and aero technologies), and made changes particularly for vehicles which showed large improvements over baseline values. Figure 6-175 in PRIA presented the distribution of different levels of aerodynamic drag improvements in MY 2016 vehicle fleet in NPRM relative to MY 2015 vehicle fleet used in Draft TAR. The distribution shows that 46 percent of the MY 2016 vehicle fleet was assigned AERO0 (0 percent improvement), 31 percent of the fleet was assigned AERO5 (5% improvement), and 15 percent of the vehicle fleet was assigned AERO10 (10 percent improvement). This distribution clearly shows that there is substantial opportunity for additional aerodynamic drag improvements in the vehicle fleet.

Regarding comments by ACEEE on Toyota Tundra pickup trucks, as just stated, the agencies used manufacturer submitted information and other available information to assign aerodynamic technology levels and the agencies applied the same process for all of the manufacturers for the NPRM and for the final rule. The agencies did assign AERO10 for some Toyota Tundra pickups, but not for all as asserted by ACEEE. Some of the Toyota Tundra pickups with 2WD and short bed and crew cab or double cab were assigned AERO5 and other configurations were assigned AER10.[1577] For reference, the baseline C_d value used in the NPRM for pickups is 0.395; a 5 percent improvement in Cd value is 0.375 and 10 percent improvement in Cd value is 0.355. The agencies considered the ACEEE comment and available information and determined the aerodynamic assignments for the Toyota Tundra were reasonable for the final rule analysis.

Table VI-162 below shows the percentage aerodynamic drag improvement assigned to the MY 2015 (Draft TAR), MY 2016 (NPRM) and MY 2017 (final rule) analysis fleets. It is clear from this table that there is natural progression of aero technologies being adopted and the vast majority of the MY 2017 vehicle fleet is at or below AERO10 (81percent).

[1576] NHTSA-2018-0067-12122, at 6.
[1577] The variations could be from coast down testing with different powertrains and with different pickup bed length and crew cab configurations.

Table VI-162 – Aerodynamic Technology Assignments in MY 2017, MY 2016 and MY 2015 Vehicle Fleet

AERO Levels	Final Rule (MY 2017)	NPRM (MY 2016)	Draft TAR (MY 2015)
AERO0	41%	46%	92%
AERO5	40%	31%	
AERO10	13%	15%	6%
AERO15	5%	7%	
AERO20	1%	1%	2%

Moreover, notable aerodynamic improvements have actually been observed on production vehicles. As described in PRIA, EPA observed 76 vehicles at the 2015 North American International Auto Show in Detroit (2015 NAIAS).[1578] EPA's observations showed that manufacturers have widely deployed both active and passive aerodynamic drag reduction technologies with significant opportunity remaining to apply aero technologies further in more optimized fashion as vehicles enter redesign cycles in the future.[1579] Although EPA did not identify the aerodynamic drag coefficient values for these vehicles, Figure 6-167 in PRIA showed the distribution of some aero technologies identified by EPA during this informal survey.

The survey showed that wheel dams and underbody panels are the most widely used aero technologies, followed by front bumper air dams and active grill shutters. Since this survey, many pickup trucks and passenger cars have active grill shutters installed to improve aerodynamic drag, and to get off-cycle credit. Table 6-67 in PRIA shows the "active grill shutter" by itself will improve aerodynamic drag reduction improvement by 3 percent. Combined with other aero technologies, this can improve the aerodynamic drag reduction values significantly in pickup trucks and SUVs. As a result, there has been overall fleet wide aerodynamic drag reduction improvement; however, the above Table VI-162 shows that only 19 percent (13 percent from AERO10, 5 percent from AERO15 and 1 percent from AERO20) of the MY 2017 vehicle fleet has aerodynamic drag reduction improvement greater than 10 percent. This shows that there is significant opportunity for the vehicle fleet to improve aero technologies by MY 2025.

The agencies also described examples of how production vehicles in different technology classes improved aerodynamic drag reduction values relative to their previous generation model since the 2012 final rule.[1580] The PRIA described how aerodynamic technologies were being deployed on production vehicles, using the MY 2015 Nissan Murano and MY 2015 Ford F150 as examples. For example, MY 2015 Ford F150 has the passive and active aerodynamic technologies as shown in Table VI-163.

[1578] PRIA at 432. *See also* Docket No. EPA-HQ-OAR-2015-0827.
[1579] Draft TAR at 5-363.
[1580] PRIA at 433.

The air curtain technology in the MY 2015 F150 guides the air flow across the front wheels to reduce wind turbulence.[1581] For reference, the wind tunnel testing by NRC of the MY 2015 Ford F150 showed a drag coefficient value of 0.37 while the coast down testing by EPA pegged the drag coefficient value between 0.35 to 0.40 depending on the type of powertrain, cab and cargo box combination. The prior generation F150 was released in 2008 as a MY 2009 and this vehicle had very few aerodynamic technologies applied. The agencies do not have the MY 2009 C_d value to estimate the percentage improvement. Since the F150 also included significant light weighting and powertrain improvements including a downsized turbocharged engine, the effectiveness improvement attributable to aerodynamic technologies is uncertain.

Table VI-163 – Aerodynamic Technologies on the MY 2015 Ford F150

Aero Technologies	Active grill shutters
	Underbody Cover
	Front corners and head lamps canted back for smooth air flow
	Rear spoiler integrated with the Tail gate (Air from the roof lands on the spoiler before trailing off thereby reducing turbulence behind the truck
	Cargo box narrower than the cab and trim piece between the cab and pickup box
	Rear tail lamps shaped for smooth air flow tailing off and reducing turbulence
	Duct under head lamp channels air to the wheel house thereby reducing wake generated by the w heel, Cross sectional area slightly larger than previous gen which resulted in some loss of benefits. More information is provided by Ford at the following link

The Nissan Murano is an example of a mid-size SUV with greater than fifteen percent improvement in aerodynamic drag values compared to the previous generation. The SAE paper published in 2015 outlines the specifics of aerodynamics in the Nissan Murano,[1582] and they include those listed in Table VI-164 below.

The exterior of this vehicle was completely redesigned from the MY 2013-2014 generation with the goal of minimizing aerodynamic drag by combining passive aerodynamic devices with an optimized vehicle shape. The primary passive devices employed include optimization of the rear end shape to reduce rear end drag, and addition of a large front spoiler to

[1582] Arai, M., Tone, K., Taniguchi, K., Murakami, M. et al., "Development of the Aerodynamics of the New Nissan Murano," SAE Technical Paper 2015-01-1542, 2015, https://doi.org/10.4271/2015-01-1542.

reduce underbody air flow and redirect it toward the roof of the vehicle, thus augmenting the rear end drag improvements. Other passive improvements include plastic fillet moldings at the wheel arches, raising the rear edge of the hood, shaping the windshield molding and front pillars, engine under-cover and floor cover, and air deflectors at the rear wheel wells. An active lower grille shutter also redirects air over the body when closed. Together, these measures for the MY 2015 model achieved a drag coefficient of 0.31, representing a 16 to 17 percent improvement over the 0.37 C_d of the previous model.

Table VI-164 – Aerodynamic Technologies on MY 2015 Nissan Murano

Design	Detail
Ideal Flow Features	
Minimum airflow into engine compartment	Reduces resistance (just enough to cool)
Airflow under front bumper toward underbody minimized	Reduce as much flow as possible underbody to reduce resistance caused by the uneven floor
Flow around ends of front bumper toward body sides	Reduce drag, covers front of front tires
Airflow at front wheel arches is routed alongside surfaces of front tires	Reduce resistance that occurs at the front surfaces of the tires
Separation angle at rear of hood is large	Minimize resistance by reducing pressure at low end of windshield, 'hide' windshield wipers and reduce rain droplets in area of air flow
Smooth area at front pillars toward body sides	Vertical vortices are minimized to reduce drag
Optimize of the rear end shape	Assure clean separation of airflow from rear to minimize drag, and equate velocity of airflow from over roof and along body sides as much as possible to minimize vortices.
Floor -lower bottom edge of front bumper	Reduces airflow toward underbody, route airflow toward vehicle rear in straight path to minimize flow resistance caused by the uneven floor. Airflow at front of wheelhouses is minimized and wheelhouse design is optimized to direct the air trapped inside rearward - all to reduce resistance at the back of the wheel arches.
Computational Fluid Dynamics (CFD) Simulations (80 simulations)	
Active Lower grille shutter at lower opening	Redirects air over the body when closed Higher opening allows sufficient air when grill shutter closed Duct type structure is used to provide direction to the airflow to the heat exchanger and minimize entry into engine compartment elsewhere
Large front spoiler beneath front bumper	Reduces underbody airflow and redirect toward roof of the vehicle Bottom edge is provided with a lip to increase the flow separation angle to reduce airflow further under the body (similar impact as a further lowering the bottom edge of the front spoiler)

Design	Detail
Ideal Flow Features	
Plastic fillet moldings at the wheel arches	To assure air flows along the side surfaces of the front tires (avoid adjusting design of front bumper ends)
Optimize shape of rear edge of hood	To promote separation by increasing flow separation angle, distance windshield wipers from airflow, reduce collection of water droplets
Optimize windshield molding shape	To smooth for wind, flow
Outside mirrors optimized for placement	Avoid airflow coming over rear edge of hood and lower edge of front pillar
Optimize shape of vehicle rear end	Shape of rear spoiler, rear combination lamps and rear bumper optimization. Secure larger roof approach resulted in increased pressure recovery and reduced drag by wake flow.
Overall vehicle shape and equal airflow	Balance roof flow and body side flow to reduce vortices
Design optimization to increase airflow to roof	Reduces rear drag caused by wake flow
Rear Spoiler part of roof approach	Tapered toward vehicle rear
Engine under-cover and floor cover	Covers beneath front bumper and over suspension links and muffler piping, raise fuel tank, resulting in smooth underbody flow of air (not full cover)
Reduce airflow into wheelhouses	Large front spoiler extends as far as the front of the wheelhouses and deflectors (optimally shaped) in front of the rear tires, bottom of front spoiler lowered on both sides as capable (governed by ground clearance)
Smoother fenders	Reduce gaps between closure panels
Small vortex-creators	Put vortices in desired places to minimize drag

A combination of a slightly lighter MY 2015 Nissan Murano (on average lighter by 94 lbs. considering all trim levels), relative to the previous generation, and engine improvements (comparing 3.5L V6 in MY 2014 to 3.5L V6 in MY 2015), and transmission improvements resulted in an overall improvement in fuel economy.[1583] Accordingly, the real-world fuel economy improvement directly attributable to the package of aerodynamic technologies included on either vehicle is uncertain, as each vehicle included other fuel economy improving technologies along with the improvements in aerodynamic technologies.

The agencies considered a sensitivity case that assumed no mass reduction, rolling resistance, or aerodynamic improvements had been made to the MY 2017 fleet (i.e., setting all vehicle road levels to zero - MRO, AERO and ROLL0), in response to ICCT's comment. While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity

[1583] https://www.fueleconomy.gov/feg/Find.do?action=sbs&id=34457&id=37198 (last visited 12.12.2019) shows 20 mpg (combined) in MY2014 Nissan Murano (3.5L VQ35DE V6 with Variable gear ratio transmission) and 24 mpg (combined in MY2015 Nissan Murano (3.5L VQ35DE V6 with Automatic AV S7 transmission)).

analysis to understand any affect it may have on technology penetration along other paths (e.g. engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong hybrids and plug-in hybrids) in the baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about $300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about $200 per vehicle. Under the CO_2 program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost change is also comparable, but slightly smaller ($200 per vehicle in the baseline) than the CAFE program results. Cost savings under the preferred alternative are further reduced by about $100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Second, as discussed above, EPA's baseline aerodynamic levels in the Draft TAR were based on road load coefficients, leading to baseline assignments that were not accurate. In the NPRM, the agencies discussed in the tradeoffs between building the analysis fleet using confidential information from manufacturers and publicly available data on the vehicles.[1584] In the case of drag coefficient values, which cannot be gleaned from publicly available information, except in cases where a manufacturer chooses to publicly release that data, or by simply observing a vehicle, the agencies decided that the improved accuracy associated with using manufacturer-provided C_d values outweighed the benefits of using publicly releasable C_d estimates based on road load coefficients, especially as manufacturer-provided C_d values are only used to assign initial aerodynamic improvement levels relative to C_d values for each body style segment in the analysis fleet.

In addition, manufacturers had submitted comments that the Draft TAR approach to baseline fleet assignments had underestimated technology already present on vehicles, leading the analysis to apply more aerodynamic drag reduction technology than could be applied in the real world. In response to those comments, as described in the Proposed Determination TSD, EPA stated that they "agree with the commenters that it is appropriate to account for aerodynamic drag reductions already present in the baseline fleet in order to avoid overestimating the amount of additional improvement that can be achieved at a given cost."[1585] Accordingly, EPA "applied some level of aerodynamic drag reduction to a significant portion of the MY2015 baseline fleet."[1586] Consequently, the agencies believe that ICCT's statement that if aerodynamic improvements between the MY 2015 analysis fleet used in the Draft TAR and the MY 2016 analysis fleet were true it would be evident in the fleet is incorrect. It is inappropriate to compare the Draft TAR MY 2015 analysis fleet, which notably included too few aerodynamic technology assignments, with the fleet's achieved fuel economy in the real world. The agencies

[1584] 83 FR 43004.
[1585] Proposed Determination TSD at 2-406.
[1586] Proposed Determination TSD at 2-408.

disagree with ICCT that the availability of aerodynamic technologies was artificially limited by appropriately assigning baseline aerodynamic technology levels in the analysis fleet.

This also relates to ICCT's comment that the agencies must share the basis for any aerodynamic calculation and exact estimated percent improvement (rather than binned percentage categories) for each vehicle make and model in the baseline and future modeled fleet, and their technical justification for each value. As discussed above, the agencies shared the relative performance approach methodology for assigning baseline aerodynamic levels to vehicles in the analysis fleet in detail in the PRIA,[1587] and this approach was the basis for the aerodynamic calculation performed for every vehicle make and model in the analysis fleet. The agencies provided the summary of aerodynamic drag coefficients (including averages for MY 2016 vehicles) by vehicle body style,[1588] and the baseline aerodynamic improvement assignments for each vehicle model were included in the 2018_NPRM_market_inputs_ref.xlsx. In addition, because aerodynamic drag information from manufacturers is provided as confidential business information, the agencies are unable to disclose that specific information. However, as discussed above, the agencies are closely examining the data provided and comparing it to other available information to assess the best estimate for aerodynamic technology for each vehicle in the analysis fleet.

For these reasons, the agencies continued to use the NPRM methodology to assign aerodynamic drag reduction improvements for the MY 2017 vehicle fleet for this final rule.

c) Aerodynamic Drag Technology Adoption Features

As discussed above, the agencies used a relative performance approach to assign current aerodynamic technology level to a vehicle. For some body styles with different utility, such as pickup trucks, SUVs and minivans, frontal area can vary, and this can affect the overall aerodynamic drag forces. In order to maintain vehicle utility and functionality related to passenger space and cargo space, the agencies assumed all technologies that improve aerodynamic drag forces would do so through reducing the C_d while maintaining frontal area.

In the NPRM, the agencies noted that the Proposed Determination analysis assumed that some vehicles from all body styles could (and would) reduce aerodynamic forces by 20 percent, which in some cases led to future pickup trucks having aerodynamic drag coefficients better than some of today's typical cars, if frontal area were held constant in order to preserve interior space and cargo space. The agencies further noted that for some vehicle types, there was limited practical capability to significantly improve aerodynamic drag coefficients over baseline levels. In those cases, the agencies deemed the most advanced levels of aerodynamic drag simulated as not technically practicable given the need to maintain vehicle functionality and utility, such as interior volume, cargo area, and ground clearance.

[1587] PRIA at 441.
[1588] PRIA at 443.

The industry had also commented in response to EPA's Proposed Determination on the difficulty to achieve AERO20 improvements for certain body styles. In the NPRM, the agencies considered the industry comments along with the observations made in the MY 2016 fleet, and tentatively determined the maximum feasible improvement in C_d that could be achieved for pickup trucks is AERO15.[1589] Similarly, the agencies determined the maximum feasible improvement in C_d that could be achieved for minivans is AERO10. Next, the NPRM analysis did not apply 15 percent or 20 percent aerodynamic drag coefficient reduction to cars and SUVs with more than 405 horsepower. The agencies noted that many high-performance vehicles already include advanced aerodynamic features despite middling aerodynamic drag coefficients. In these high-performance vehicle cases, the agencies recognized that manufacturers tune aerodynamic features to provide desirable downforce at high speeds and to provide sufficient cooling for the powertrain, and, therefore, manufacturers may have limited ability to improve aerodynamic drag coefficients for high performance vehicles with internal combustion engines without reducing horsepower. Accordingly, the agencies did not allow application of AERO15 and AERO20 technology for all vehicles with more than 405 HP. Approximately 400,000 units of volume in the MY 2016 market data file included limited application of aerodynamic technologies because of vehicle performance. The agencies sought comment on limiting the C_d improvement in these circumstances.

Ford commented in support of the agencies' decision to limit the application of AERO20 on pickup trucks, noting that limiting AERO20 on pickups is appropriate given the high inherent form drag associated with pickups' aerodynamic profile.[1590]

CARB commented that the agencies excluded AERO20 inconsistently across the fleet, noting that while some of the restrictions may be valid, the broad rule the agencies used resulted in technology being inappropriately excluded from too many vehicles.[1591] Specifically, CARB took issue with the majority of luxury sedans and SUVs being excluded from AERO20 because they had high horsepower engines, while the agencies did assign AERO20 to vehicles like the Tesla Model S and Model X SUVs, which have horsepower in excess of 405. CARB stated that while electrification provides a higher motivation to minimize road load through technologies such as aerodynamic reductions, implementing AERO20 reductions on high horsepower sedans and SUVs is clearly feasible and should not be artificially restricted in the CAFE model.

In addressing these comments, the agencies considered the relative cooling requirements for all electric powertrains and for high performance internal combustion engine powertrains since airflow diverted for cooling adversely impacts a vehicle's C_d. The peak heat rejection and engine cooling needs for high performance internal combustion engines is significantly higher than for all electric powertrains. Internal combustion engines convert a lower percentage of

[1589] The agencies noted in the NPRM that although ANL created full-vehicle simulations for trucks with 20 percent drag reduction, those simulations were not used in the CAFE modeling. The agencies concluded that level of drag reduction was likely not technologically feasible with today's technology, and the analysis accordingly restricted the application of advanced levels of aerodynamics in some instances, such as in that case, due to bodystyle form drag limitations.

[1590] NHTSA-2018-0067-11928.

[1591] NHTSA-2018-0067-11873.

energy contained in gasoline into mechanical work (and other useful work, such as lighting and sound), and the energy not converted into mechanical work (or other useful work) is converted into heat. A significant amount of the waste heat must be handled by the cooling systems. Battery electric vehicles convert most of the electrical energy stored in the battery into mechanical work and other useful work, and therefore convert less energy into heat that must be handled by the cooling system. Also, electric powertrains can provide a degree of electric braking, whereas internal combustion engines exclusively use friction braking, which generates heat and requires greater cooling, particularly on vehicles with substantial braking performance capabilities. In the case of high-performance BEVs, since the cooling needs are not as demanding as with high-performance vehicles that use internal combustion engines, manufacturers can (and do, as can be observed in the fleet) apply higher levels of aerodynamic technologies. The agencies believe it is appropriate to account for these differences in considering the amount of aerodynamic improvement that can be implemented, and determined there are valid technical reasons for allowing BEVs with greater than 405 horsepower to adopt AERO20 technology.

d) Aerodynamic Drag Technology Effectiveness

The NPRM analysis included four levels of aerodynamic improvements, AERO5, AERO10, AERO15, and AERO20, representing 5, 10, 15, and 20 percent C_d improvements, respectively. Notably, the NPRM analysis assumed that aerodynamic drag reduction could only come from reduction in the aerodynamic drag coefficient and not from reduction of frontal area, to maintain vehicle functionality and utility, such as passenger space, ingress/egress ergonomics, and cargo space.[1592]

Ford commented in support of the agencies' decision to consider the frontal area and body style as "utility factors" and requiring that aerodynamic improvements come from reductions in Coefficient of Drag (C_d) and not from reductions in frontal area.[1593]

CBD commented that EPA staff had critiqued NHTSA's characterization of research on aerodynamic drag coefficients and the NPRM did not appear to incorporate or respond to this input.[1594,1595] Specifically, CBD stated that EPA staff had commented in response to the characterization that "[f]or some bodystyles, the agencies have no evidence that manufacturers may be able to achieve 15 percent or 20 percent aerodynamic drag coefficient reduction relative to baseline (for instance, with pickup trucks" and noted that "[i]n the past, EPA has assigned aero tech in the baseline relative to a "Null" and then applied drag reduction level against that Null in order to ensure that the maximum aero level (i.e., 15 or 20 percent) would always be achievable for all body styles." This comment reflects deliberative, in-process input from EPA staff. In fact, the NPRM text was developed by the agencies with the benefit of this and other input from

EPA staff, and the NPRM clarified that reducing frontal area would likely degrade other utility features like interior volume or ingress/egress.

CARB commented, as part of its broader comments, that the agencies' effectiveness values were reduced relative to what EPA's LPM calculated, that the benefits of aerodynamic improvements were underestimated.[1596] Specifically, CARB cited the H-D Systems comparison of LPM benefits for AERO10 and AERO20 of 2.1 percent and 4.3 percent, respectively, compared with Autonomie benefits of 1.51 percent and 3.03 percent, respectively, and stated that the agencies' analysis provided no description or cited any new data or evidence as to why they reduced the projected assumptions compared to what EPA's Lumped Parameter Model calculated.

HDS also commented that the Autonomie modeling assumed no engine change when aerodynamic drag and rolling resistance reductions were implemented, as well as no changes to the transmission gear ratios and axle ratios, which vary by transmission type but not by the tractive load.[1597] HDS stated that the EPA ALPHA model adjusted for this effect, which accounted for the difference in technology effectiveness estimates that HDS characterized between the Draft TAR and NPRM. HDS provided a "correct estimate" for AERO20 effectiveness improvements of 4.3 percent, with the justification that there was no gear/axle ratio adjustment in the Autonomie analysis.

In response to HDS's comment, the Alliance submitted supplemental comments questioning the extent to which aerodynamics (and changes in top gear ratio) affect performance metrics held constant in the analysis, like low- and high-speed acceleration performance and gradeability.[1598] The Alliance cited a study for the proposition that vehicle acceleration is most influenced by engine power and weight, and also that bodystyle differences have a lesser impact on acceleration performance. The Alliance further commented that "[r]egarding changes in top gear ratios in response to aerodynamic changes, the Alliance is not aware of any examples in which a top gear ratio was changed solely due to aerodynamic improvements. There may be examples where a vehicle's top gear ratio was changed at the same time aerodynamic changes were made, but such changes would be made in response to the cumulative changes across the entire vehicle, not just aerodynamic improvements." The Alliance concluded that "[t]here are also practical manufacturing and investment constraints which limit the potential for applying engine changes in response to improved vehicle aerodynamics," citing the agencies decision to only resize engines with significant design changes, to account for product complexity and economies of scale.

In response to the Alliance's supplemental comment, HDS submitted supplemental comments stating that "[d]rag reduction is usually accomplished when a vehicle body is redesigned, so gear and axle ratios are typically re-optimized for the entire set of changes, but these changes include the drag reduction."[1599] HDS commented that the Alliance's comments

---

acknowledged that calibration changes are made in response to tractive load changes, while the Autonomie analysis recalibrates the powertrain in response only to large mass reduction improvements, and not any other vehicle changes that reduce tractive load, like aerodynamic improvements, even when those changes would result in a greater tractive load reduction than a 10 percent mass reduction. HDS reiterated its statement that "[i]n the real world (and as captured in EPA's prior ALPHA model), automakers typically alter many vehicle attributes affecting tractive load simultaneously, including aerodynamics," and the Autonomie outputs underrepresent the benefit of tractive load reduction strategies by not optimizing engine efficiency after most changes in tractive load because the model employees fixed shift points, gear ratios, and axle ratios when drag or tire rolling resistance is reduced.

Regarding the first set of comments that the aerodynamic effectiveness values were reduced from EPA's values presented in the Draft TAR, that results from differences in the two modeling approaches. As discussed above, for this analysis the agencies decided that aerodynamic drag reduction could only come from reduction in the aerodynamic drag coefficient, and not from a reduction in vehicle frontal area, at least without reducing other attributes of the vehicle. EPA's process for assigning road load technologies to baseline vehicles used road load coefficients from coast downs, which aggregated individual aero, mass and tire reduction technologies. In contrast, the CAFE Model and Autonomie used individually assigned road load technologies for each vehicle to appropriately assign initial road load and to appropriately capture benefits of subsequent individual road load technologies. The differences in using road load coefficients from coast downs and individually isolating the improvements from existing and future road load technologies in the Autonomie modeling resulted in the differences noted by commenters. And so, the resulting effectiveness from the incremental adoption of individual technologies to a newer analysis fleet will have different result than what was estimated by the previous analyses. For further discussion of the analysis fleet see Section VI.B.1.

In Section VI.B.3 Tech Effectiveness and Modeling and Section VI.C.2 Transmissions, the agencies provide a full discussion of the issues associated with assuming the engine and transmission can be optimized for every combination of technologies. It would be unreasonable and unaffordable to resize powertrains, including engines and transmission and axle ratios, for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. Product complexity and economies of scale are real, and in the NPRM, engine resizing was limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.[1600] As noted by HDS, the EPA Draft TAR and Proposed Determination analyses adjusted the effectiveness of every technology combination, including for aerodynamics technologies, assuming performance could be held constant for every combination. However, those analyses did not recognize or account for the extreme complexity nor the associated costs for that impractical assumption. The NPRM and final rule analyses account for these real-world practicalities and constraints, and doing so explains some of the effectiveness and cost differences between the Draft TAR/Proposed

---

[1600] *See* 83 FR 43027 (Aug. 24, 2018).

Determination and the NPRM/final rule. The agencies believe the NPRM and the final rule approach appropriately resizes powertrain components for specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.

For the NPRM, and carried into the final rule analysis, Autonomie simulates all road load conditions (e.g., MR, AERO, and ROLL technology levels) for each engine and transmission combination. In addition, engines are resized for appropriate specific technology changes that would be associated with a major vehicle or engine redesign. Also, as discussed further in Section VI.C.2 Transmissions, many commenters seemed to conflate the practice in the analysis of using a common (same) gear set across vehicle configurations (to address manufacturing complexity) with using the same shift maps. As commenters stated, they assumed the same shift maps were applied across vehicle models. However, the shift initializer routine was run for every unique Autonomie full vehicle model configuration and generated customized shifting maps. The algorithms' optimization was designed to balance minimization of energy consumption and vehicle performance. This balance was necessary to achieve the best fuel efficiency while maintaining customer acceptability by meeting performance neutrality requirements. The agencies believe the level of optimization of engine size, transmissions, gear ratios and shift schedules reasonably approximate what is achievable and what manufacturers actually do.

Figure VI-106 below shows the range effectiveness used for AERO technologies for the NPRM analysis.

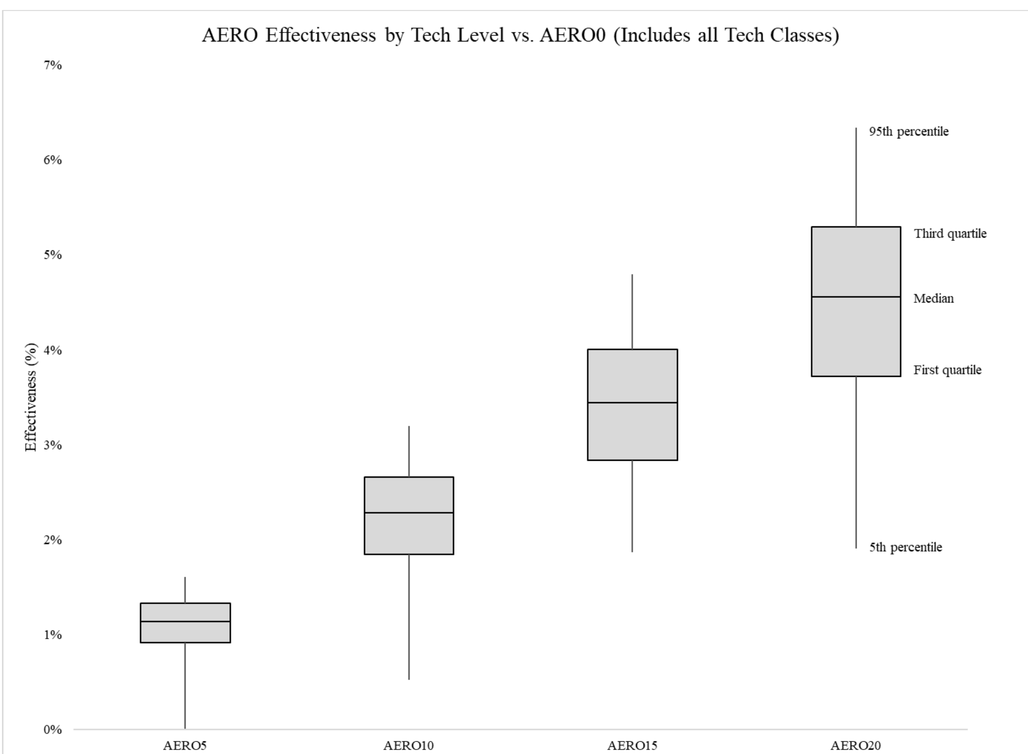

Figure VI-106 – NPRM Analysis AERO Technology Effectiveness

Figure VI-107 below shows the range of aero effectiveness used for the final rule analysis.

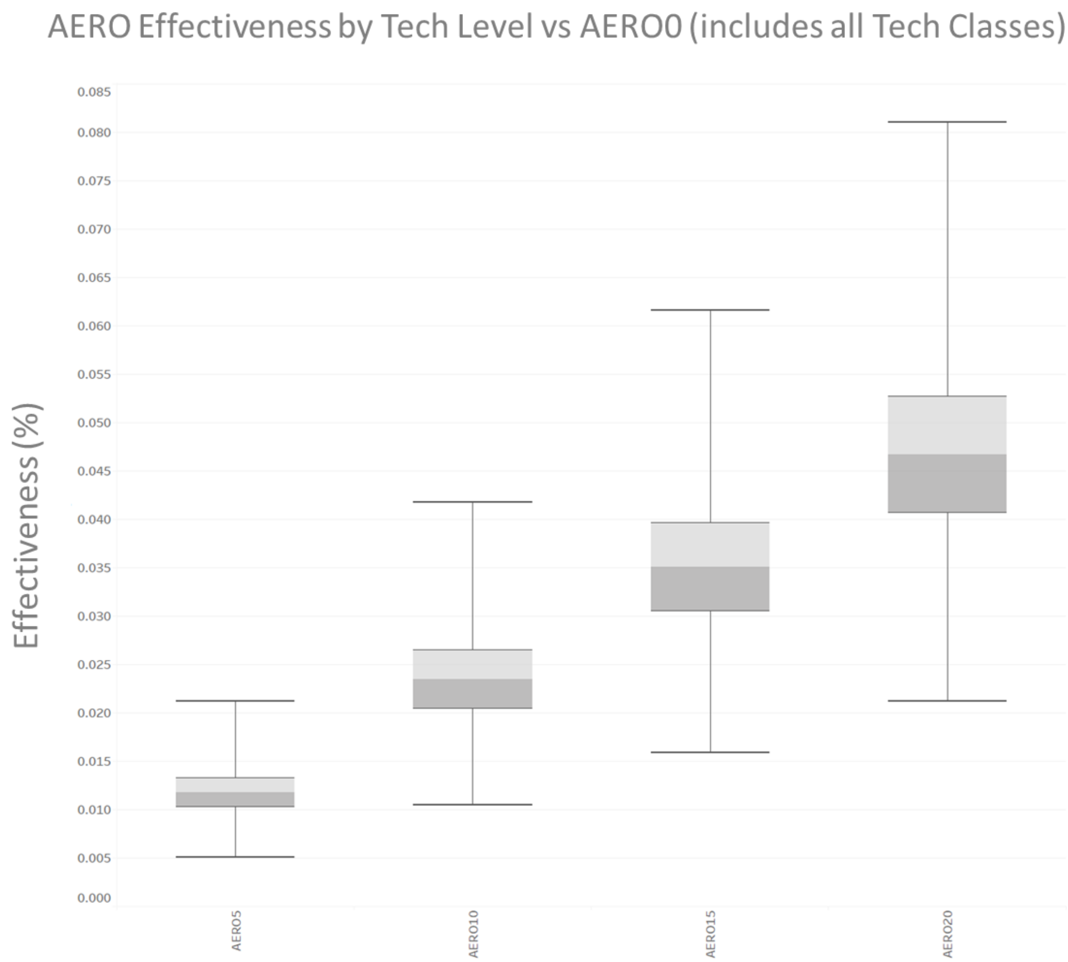

Figure VI-107 – Final Rule AERO Technology Effectiveness

e) Aerodynamic Drag Technology Cost

For the Draft TAR, the agencies relied on the 2015 NAS report to estimate the cost of AERO1 and AERO2 levels of aerodynamic drag coefficient improvements. The agencies received several comments related to the cost assumptions used in the Draft TAR, mainly that they were too low to meet AERO1 and AERO2 levels. The industry submitted confidential business information on the costs of passive aerodynamic technologies needed to achieve AERO1 (10 percent improvement in drag improvement), which showed significantly higher estimated costs than assumed for the Draft TAR. Similarly, the industry submitted confidential business information on the costs of active aerodynamic technologies, including some high cost technologies. The industry also commented that some active aerodynamic technologies could only be implemented during vehicle redesigns and not during a mid-cycle vehicle refresh.

The agencies considered these comments and performed additional research to assess the costs for passive and active aerodynamic technologies. The agencies revised the cost estimates for the NPRM, based in part on confidential information from the automotive industry, and from the agencies' own assessment of manufacturing costs for specific aerodynamic technologies from available sources. In general, the NPRM cost estimates were higher than Draft TAR cost estimates. The agencies included a high-level discussion in the PRIA that the cost to achieve AERO5 is relatively low, as most of the improvements can be made through body styling changes. The cost to achieve AERO10 is higher than AERO5, due to the addition of several passive aero technologies, and the cost to achieve AERO15 and AERO20 is higher than AERO10 due to use of both passive and active aero technologies.

The agencies did not receive any comments on the costs of aerodynamic improvements, and accordingly, for the final rule, as shown in Table VI-165 and Table VI-166 below, the agencies used the same aerodynamic improvement costs presented in NPRM.

Table VI-165 – Aerodynamic Improvement Technology Costs for Passenger Cars and SUVs for MY 2017 (in 2018$)

Aero Improvements for Passenger Cars and SUV	**$ DMC (2018$)**	**Total Cost (includes RPE and Learning)**
0%	$0.00	
5%	$39.38	$59.07
10%	$80.51	$120.76
15%	$113.76	$170.64
20%	$201.27	$301.91

Table VI-166 – Aerodynamic Improvement Technology Costs for Pickup Trucks for MY 2017 (in 2018$)

Aero Improvements of Pickups	**$ DMC (2018$)**	**Total Cost (includes RPE and Learning)**
0%	$0.00	
5%	$39.38	$59.07
10%	$80.51	$120.76
15%	$201.27	$301.91
20%	$525.06	$787.59

6. Tire Rolling Resistance

Tire rolling resistance is a road load force that arises primarily from the energy dissipated by elastic deformation of the tires as they roll. Tire design characteristics (for example, materials, construction, and tread design) have a strong influence on the amount and type of deformation and the energy it dissipates. Designers can select these characteristics to minimize rolling resistance. However, these characteristics may also influence other performance attributes, such as durability, wet and dry traction, handling, and ride comfort.

Low rolling resistance tires are increasingly specified by OEMs in new vehicles and are also increasingly available from aftermarket tire vendors. They commonly include attributes such as higher inflation pressure, material changes, tire construction optimized for lower hysteresis, geometry changes (e.g., reduced aspect ratios), and reduced sidewall and tread deflection. These changes are commonly accompanied by additional changes to vehicle suspension tuning and/or suspension design to mitigate any potential impact on other performance attributes of the vehicle.

Lower-rolling-resistance tires have characteristics that reduce frictional losses associated with the energy dissipated mainly in the deformation of the tires under load, thereby improving fuel economy and reducing CO_2 emissions. The agencies considered two levels of improvement for low rolling resistance tires in the analysis: the first level of low rolling resistance tires considered reduced rolling resistance 10 percent from an industry-average baseline, while the second level reduced rolling resistance 20 percent from the baseline.

Walter Kreucher commented that the agencies should eliminate low rolling resistance tires from the list of viable technologies, in recognition of the safety impacts of low rolling resistance tires in relation to stopping distance and accident rates.[1601] Separately, Mr. Kreucher argued that the model should reflect the safety impact of low rolling resistance tires.

The agencies have been following the industry developments and trends in application of rolling resistance technologies to light duty vehicles. As stated in the NAP special report on Tires and Passenger Vehicle Fuel Economy,[1602] cited by Mr. Kreucher, national crash data does not provide data about tire structural failures specifically related to tire rolling resistance, because the rolling resistance of a tire at a crash scene cannot be determined. However, other metrics like brake performance compliance test data are helpful to show trends like that stopping distance has not changed in the last ten years,[1603] during which time many manufacturers have installed low rolling resistance tires in their fleet—meaning that manufacturers were successful in improving rolling resistance while maintaining stopping distances through tire design, tire materials, and/or braking system improvements. In addition, NHTSA has addressed other tire-related issues through rulemaking,[1604] and continues to research tire problems such as blowouts, flat tires, tire or wheel deficiency, tire or wheel failure, and tire degradation.[1605] However, there are currently no data connecting low rolling resistance tires to accident or fatality rates.

[1601] NHTSA-2018-0067-0444.

[1602] Tires and Passenger Vehicle Fuel Economy: Informing Consumers, Improving Performance - - Special Report 286 (2006), available at https://www.nap.edu/read/11620/chapter/6.

[1603] https://one.nhtsa.gov/cars/problems/comply/index.cfm.

[1604] 49 CFR 571.138, Tire pressure monitoring systems.

[1605] Tire-Related Factors in the Pre-Crash Phase, DOT HS 811 617 (April 2012), available at https://crashstats.nhtsa.dot.gov/Api/Public/ViewPublication/811617.

With better tire design, tire compound formulations and improved tread design, tire manufacturers have tools to balance stopping distance and reduced rolling resistance. As stated in one article referenced by Mr. Kreucher, tire manufacturers can use "higher performance materials in the tread compound, more silica as reinforcing fillers and advanced tread design features" to mitigate issues related to stopping distance.[1606] The agencies do not believe that there is sufficient data or other information to support removing low rolling resistance tires as a viable technology considered in the CAFE and CO_2 analysis at this time.

HDS argued, as discussed further below, that based on available data on current vehicle models and the likely possibility that there would be additional tire improvements over the next decade, the agencies should consider ROLL30 technology, or a 30 percent reduction of tire rolling resistance over the baseline.[1607]

As stated in Joint TSD for the 2017-2025 final rule, tire technologies that enable rolling resistance improvements of 10 and 20 percent have been in existence for many years.[1608] Achieving improvements of up to 20 percent involves optimizing and integrating multiple technologies, with a primary contributor being the adoption of a silica tread technology. Tire suppliers have indicated that additional innovations are necessary to achieve the next level of low rolling resistance technology on a commercial basis, such as improvements in material to retain tire pressure, tread design to manage both stopping distance and wet traction, and development of carbon black material for low rolling resistance without the use of silica to reduce cost and weight.[1609] The agencies are continuously monitoring these and other tire technology improvements. The agencies believe that the tire industry is in the process of moving automotive manufacturers towards the first level of low rolling resistance technology across the vehicle fleet (10 percent reduction in rolling resistance), and that 20 percent improvement is achievable in the rulemaking timeframe. However, the agencies believe that at this time, the emerging tire technologies that would achieve 30 percent improvement in rolling resistance, like changing tire profile, strengthening tire walls, or adopting improved tires along with active chassis control,[1610] among other technologies, will not be available for commercial adoption in the fleet during the rulemaking timeframe. As a result, the agencies decided not to incorporate 30 percent reduction in rolling resistance technology for this final rule.

a) Rolling Resistance Modeling in the CAFE Model

The two levels of rolling resistance technology considered in the analysis include ROLL10 and ROLL20, which represent a 10 percent and 20 percent rolling resistance reduction from the baseline (ROLL0), respectively.

To understand the following discussions about rolling resistance analysis fleet assignments and effectiveness values, it is important to understand how the agencies developed the baseline value (ROLL0) used in prior analyses, and how the agencies developed the baseline value used in the NPRM and final rule. In the Draft TAR, the agencies used unique baseline rolling resistance coefficients for each vehicle class. Specifically, the compact car class value was 0.0075, the midsize car value was 0.008, the small SUV value was 0.0084, the midsize SUV value was 0.0084, and the pickup truck value was 0.009. The PRIA described that since the Draft TAR, the agencies had reassessed rolling resistance values for contemporary tires through discussions with vehicle manufacturers, tire manufactures, and independent bench testing. Based on a thorough review of confidential business information submitted by industry, and a review of other literature, including the CARB/CONTROLTEC study mentioned below, the baseline rolling resistance coefficient for all vehicle classes was updated to 0.009 for the NPRM analysis. The agencies concluded that the updated baseline value brought the NPRM simulations into better alignment with tires in the MY 2016 analysis fleet. The agencies also discussed that updated value was consistent with the findings of the CONTROLTEC study on vehicle road loads, sponsored by CARB.[1611] The following figure shows the distribution of estimated tire rolling resistance coefficient values for the 1,358 MY 2014 vehicles evaluated in the CONTROLTEC/CARB study.

[1611] Technical Analysis of Vehicle Load Reduction Potential for Advanced Clean Cars, https://www.arb.ca.gov/research/apr/past/13-313.pdf, page 39.

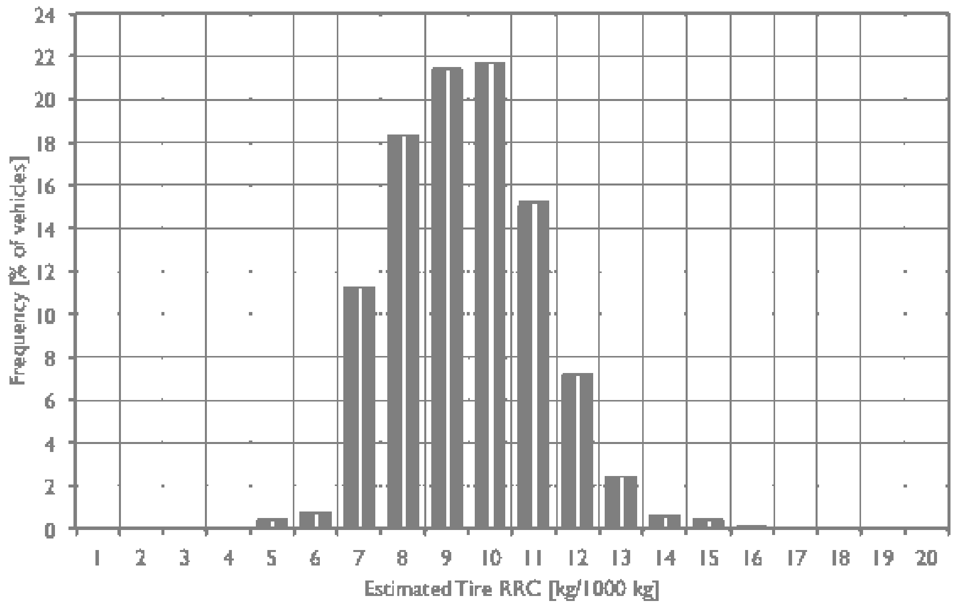

Figure VI-108 – Estimated tire rolling resistance for all vehicles from CONTROLTEC study

ICCT commented that it was "quite confusing and perhaps troubling" that the agencies adopted a higher average rolling resistance coefficient than that of the Draft TAR, "as it would imply that the fleet rolling resistance got worse, but the agencies are deciding to provide baseline credit as if there was more rolling resistance technology deployed."[1612] ICCT stated that the change appeared to be attributed to the agencies' use of CBI on tire rolling resistance received since the Draft TAR.

As described in the PRIA, the values used in the Draft TAR represented the "Best in Class" values in each of the vehicle classes and this did not necessarily reflect the average "Rolling Resistance Coefficient" (RRC) of the fleet. For the Draft TAR, the agencies did not have access to manufacturer confidential business information and relied on estimates from CONTROLTEC. As stated earlier, Figure VI-108 shows the distribution of the estimated RRC for 1,358 vehicles models. The average RRC from the CONTROLTEC study (0.009) aligned with the NPRM estimate which was based in part on manufacturer submitted confidential business information. CONTROLTEC compared the estimated RRC data with the values provided by Rubber Manufacturers Association (renamed as USTMA-U.S. Tire Manufacturers Association) for original equipment tires. The average RRC from the data provided by RMA was 0.0092,[1613] compared to average of 0.009 from CONTROLTEC. CONTROLTEC attributed the difference due to analysis assumption, tire loading during coast down vs. load during tire testing, inflation pressure during coast down vs. inflation pressure during tire testing, coast down

[1613] Technical Analysis of Vehicle Load Reduction by CONTROLTEC for California Air Resources Board (April 29, 2015) at page 40.

test reporting issues, tire types represented in the sample, tire break-in, and advancement in tire rolling resistance since the time RMA collected the data.

CONTROLTEC also stated that RRC values for some vehicles fell below the average RRC (indicating better performance) due to estimation assumptions for vehicles where manufacturer data was not available, and coast down test reporting issues.[1614] Further, CONTROLTEC performed a sensitivity study by mathematically removing aerodynamic contribution from the coast down coefficients. It was observed that the average RRC without the aerodynamic contribution is around 0.011. Accordingly, the agencies believe that it was reasonable to use 0.009 as the average RRC for the fleet for the NPRM and to continue to use that value for the final rule, based on the latest available data from manufacturers and alignment with the average RRC to the CONTROLTEC study estimate.

H-D Systems (HDS) commented that the CONTROLTEC/CARB study showed that there is a very significant fraction of the fleet with tire rolling resistance coefficients above 10kg/1000 kg, and a small percentage of vehicles with rolling resistance coefficients already at 0.05 or 0.06. HDS stated that NHTSA's baseline of 0.09 appeared "a little low but may be appropriate if the distribution was sales weighted." HDS argued that a number of vehicle models already have tires below 0.07, and the likelihood that there would be additional tire improvements over the next decade are likely, meaning that ROLL30 technology—or a 30 percent reduction of the tire rolling resistance coefficient to 0.063—is possible and appropriate for MY 2025.

Roush commented that rolling resistance is erroneously assumed to be the same across different vehicle classes, and that rolling resistance would vary depending upon the vehicle size, power, acceleration and performance package.[1615]

As explained earlier, the RRC values used in the CONTROLTEC study were a combination of manufacturer information, estimates from coast down tests for some vehicles, and application of tire RRC values across other vehicles on the same platform. CONTROLTEC stated that some RRC values were below the estimated average (showing significant improvement from the baseline) due to assumptions that were applied to some vehicles when manufacturer data was not available. Further, some of the RRC estimates were based on vehicle coast down tests which had errors.[1616] As a result, some of the RRC values used in the Draft TAR showed significant improvements (30 percent reduction in rolling resistance relative to baseline), as observed by HDS. Based on a review of manufacturer-submitted confidential business information and other sources, the agencies are unaware of any tires in production which have 30 percent reduction in rolling resistance relative to baseline values.

As stated earlier, the baseline values used for the Draft TAR analysis were "Best in Class" values from the estimates developed by CONTROLTEC and not representative of the

average of the fleet or average for the vehicle classes. For the NPRM, the agencies revisited the ROLL technology assignments based on the RRC values provided by manufacturers, and the average RRC for each of the vehicle class was near the fleet average (RRC = 0.009). As shown in Figure VI-108, a vast majority of the vehicles in the fleet are in the ROLL0 bin across the different vehicle class, vehicle size, power, acceleration and performance configurations. For these reasons, the agencies will continue to use the fleet average of RRC=0.009 as the baseline value to assess ROLL technology improvements.

b) Rolling Resistance Analysis Fleet Assignments

As discussed above, NHTSA's Draft TAR analysis showed little rolling resistance technology in the baseline fleet for three reasons: the simulations used baseline values already reflecting best-in-class tire rolling resistance, credible tire rolling resistance values for all vehicles from bench data were not available to the agencies at the time of Draft TAR, and few manufacturers submitted rolling resistance values for the Draft TAR analysis.

For the NPRM, baseline (ROLL0) rolling resistance values were updated to 0.009, and any better rolling resistance values were assigned based on whether information indicated that vehicle had technology at least 10 percent better than baseline (.0081 or better for ROLL10), or at least 20 percent better than baseline (.0072 or better for ROLL20). The agencies used confidential business information provided by manufacturers to assign initial rolling resistance values for each vehicle make and model.

The Alliance commented that the NPRM MY 2016 analysis fleet had been updated with appropriate ratings of rolling resistance improvements, compared to the Draft TAR where vehicles were generally considered to have unimproved tires (meaning the Draft TAR assumed additional improvements were more achievable than in reality).[1617] The Alliance noted that the Draft TAR approach led to the CAFE model adding additional tire rolling resistance improvements even though manufacturers had already made significant improvements with that technology. This meant that the real-world fleet had little remaining opportunity for additional tire-related improvements, ultimately leading to the Draft TAR analysis underpredicting the amount of powertrain technology required for compliance.

The Alliance noted that it is possible to estimate rolling resistance features of a vehicle using road load coefficients, but the process requires various assumptions and is not very accurate. The Alliance concluded that the agencies' use of CBI to assign baseline technology levels correctly was an accurate and practical solution. Similarly, Ford commented in support of the agencies' low rolling resistance tire assignments in the baseline fleet, stating that the accuracy of the baseline fleet assessment had been considerably improved using actual tire rolling resistance data.[1618]

[1617] NHTSA-2018-006712039 at 136.
[1618] NHTSA-2018-0067-11928.

HDS commented that the analysis fleet "accounts for the distribution of tires below 0.09 as 19% of vehicles in MY 2016 are modeled as having used ROLL10 and 25% of vehicles as having used ROLL20 in the base year, but there is no accounting for the ~25% of vehicles having RRC values 10 to 20% above the 0.09 RRC average."[1619] HDS concluded that "[a] stricter accounting of the baseline and, possibly setting specific lower limits for 2025 RRC by vehicle type (as done for aero drag in the PRIA) will show significant additional fleetwide effectiveness from RRC reduction which is a very cost-effective technology."

ICCT commented that the agencies made a "dramatic and unjustified" shift in baseline tire rolling resistance assignments from the 2015 fleet used in the Draft TAR to the 2016 fleet used in the NPRM.[1620] ICCT noted that per the agencies' updated baseline value, nearly 20 percent of all vehicles in the MY 2016 analysis fleet achieved 0.0081 (or better) rolling resistance value, and more than 26 percent achieve 0.0072 (or better). ICCT argued that rather than changing the definition of rolling resistance technology to include improvements beyond the baseline, the agencies instead redefined the technology available, reducing the number of vehicles that can use tire improvements in future compliance years within the modeling framework, which artificially forced companies to use other, more expensive technologies.

ICCT stated that to substantiate the baseline rolling resistance assignments, the agencies need to show data on how these improvements are evident in the fleet and delivering benefits. ICCT alleged that if an improvement of that magnitude were true, it would be evident in fleet level miles-per-gallon and CO_2 levels; however, "none of the quantifiable mpg or CO_2 benefits that would be associated with these additional rolling resistance improvements were reflected with any real-world evidence in the model year 2016 fleet." ICCT stated this seemed to be a case of the agencies "artificially burying efficiency technology in the baseline, rendering it unusable in the post model year 2016 compliance scenarios."

ICCT also stated that the agencies must share absolute road load coefficients for each vehicle make and model in the baseline fleet, and the technical justification for each value, in addition to conducting two sensitivity analysis cases "assum[ing] that every baseline make and model is set to 0% rolling resistance improvement and set to the previous baseline rolling resistance (from the Draft TAR) to demonstrate how much the agencies' decision to load up more baseline technology affects the compliance scenarios, as it appears that the agencies may have made a unsupportable and non-rigorous assumption about rolling resistance technology across the models." ICCT concluded that because the changes were buried in the datafiles and unexplained, the agencies must issue a new regulatory analysis and allow an additional comment period for review of the methods and analysis.

Based on the comments from HDS and ICCT, the agencies reexamined available tire rolling resistance data. The assignment of ROLL20 technology was revised for some vehicle models based on information on the use of common tires across vehicles that shared a platform. As a consequence, for the final rule, only 20 percent of the MY2017 vehicle fleet is assigned ROLL20. The agencies will continue to investigate additional methods to improve the accuracy

---

[1619] NHTSA-2018-0067-11985 at 49.
[1620] NHTSA-2018-0067-11741 full comments.

of this method, however as the Alliance and Ford noted, the accuracy of the baseline levels had been significantly improved over prior analyses by using actual tire RRC data. The agencies approach is consistent with the NAS recommendation to have two ROLL technology levels. The agencies determined that 30 percent rolling resistance improvement while maintaining other tire characteristics is unlikely to be available in the rulemaking timeframe.

The agencies considered a sensitivity case that assumed no mass reduction, rolling resistance, or aerodynamic improvements had been made to the MY 2017 fleet (i.e., setting all vehicle road levels to zero - MRO, AERO and ROLL0), in response to ICCT's comment. While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity analysis to understand any affect it may have on technology penetration along other paths (e.g. engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong hybrids and plug-in hybrids) in the baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about $300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about $200 per vehicle. Under the CO_2 program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost change is also comparable, but slightly smaller ($200 per vehicle in the baseline) than the CAFE program results. Cost savings under the preferred alternative are further reduced by about $100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Table VI-167 shows the distribution of ROLL technology for the Draft TAR, NPRM and final rule. For the NPRM, 64 percent of the MY 2016 vehicle fleet was assigned ROLL0 and for the final rule, 59 percent of the MY2017 vehicle fleet is assigned ROLL0. This shows that the majority of the fleet is still at the ROLL0 technology level and there is still significant opportunity for the vehicle fleet to improve ROLL technology.

Table VI-167 – Distribution of tire rolling resistance technology for the Draft TAR, NPRM and Final Rule

ROLL	Draft TAR (MY 2015 vehicle fleet	NPRM (MY2016 vehicle fleet)	Final Rule (MY2017 vehicle fleet)
ROLL0	99.80%	64%	59%
ROLL10	0.1%	10%	21%
ROLL20	0.1%	26%	20%

c) Rolling Resistance Adoption Features

In some cases, low rolling resistance tires can affect traction, which may adversely impact acceleration, braking and handling characteristics for some high-performance vehicles. Similar to past rulemakings, the agencies recognized in the NPRM that to maintain performance, braking and handling functionality, some high-performance vehicles would not adopt low rolling resistance tire technology. For cars and SUVs with more than 405 horsepower (hp), the agencies restricted the application of ROLL20. For cars and SUVs with more than 500 hp, the agencies restricted the application of any additional rolling resistance technology (ROLL10 or ROLL20). The agencies developed these cutoffs based on a review of confidential business information and the distribution of rolling resistance values in the fleet.

Ford commented that the NPRM analysis appropriately limited the application of ROLL technology where it would be infeasible or would be at odds with the vehicles' intended function, characterizing that the decision to restrict application of ROLL10 and ROLL20 for high performance vehicles as reasonable.[1621]

Accordingly, the agencies continued with the NPRM methodology of restricting certain ROLL technology for high performance vehicles. In the final rule, the agencies restricted the ROLL technology to ROLL0 and ROLL10 for vehicles with greater than 405 hp and below 505hp. For vehicles greater than 505hp, the agencies restricted the ROLL technology to ROLL0.

d) Rolling Resistance Effectiveness Modeling and Resulting Effectiveness Values

As discussed above, the agencies updated the baseline rolling resistance value to 0.009, based on a thorough review of confidential business information submitted by industry, and a review of other literature. To achieve ROLL10 in the NPRM and for the final rule analysis, the tire rolling resistance must be at least 10 percent better than baseline (.0081 or better). To achieve ROLL20, the tire rolling resistance must be at least 20 percent better than baseline (.0072 or better).

HDS commented that the Autonomie modeling assumed no engine change when drag and rolling resistance reductions were implemented, as well as no change to the transmission gear ratios and axle ratios, which vary by transmission type but not by the tractive load.[1622] HDS stated that "reduction in rolling resistance is accompanied by axle ratio adjustments so that the engine operates at about the same load but at lower RPM. The EPA ALPHA model adjusts for this effect, which accounts for the difference in benefit estimates" between Autonomie and the ALPHA model simulations.

As stated in Section VI.B.3 Tech Effectiveness and Modeling, Autonomie builds performance-neutral vehicle models by resizing engines, electric machines, and hybrid electric vehicle battery packs only at specific incremental technology steps. To address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.[1623] Manufacturers have repeatedly told the agencies that the high costs for redesign and the increased manufacturing complexity that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to

---

[1621] NHTSA-2018-0067-11928.
[1622] NHTSA-2018-0067-11985.
[1623] *See* 83 FR 43027 (Aug. 24, 2018).

resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. The agencies explained in the NPRM that the analysis should not include engine resizing with the application of every technology or for combinations of technologies that drive small performance changes to reflect better what is feasible for manufacturers.[1624]

Compliance modeling in the CAFE model also accounts for the industry practice of platform, engine, and transmission sharing to manage component complexity and associated costs.[1625] At a vehicle refresh cycle, a vehicle may inherit an already resized powertrain from another vehicle within the same engine-sharing platform that adopted the powertrain in an earlier model year. In the Autonomie modeling, when a new vehicle adopts fuel saving technologies (such as ROLL technology) that are inherited, the engine is not resized (the properties from the baseline reference vehicle are used directly and unchanged) and there may be a small change in vehicle performance.

Regarding customizing transmission gear ratios as rolling resistance changes are implemented, the agencies explained in Section VI.C.2 Transmissions that it is an observable practice in industry to use a common gear set across multiple platforms and applications. The most recent example is the GM 10L90, a 10-speed automatic transmission that used the same gear set in both pick-up truck and passenger car applications.[1626] In Autonomie, optimization of transmission performance is achieved through shift control logic rather than customized hardware (e.g., gear ratios) for each vehicle line. The shift initializer routine was run for every unique Autonomie full vehicle model configuration to generate customized shifting maps. The algorithms' optimization was designed to balance minimization of energy consumption against vehicle performance.[1627] This balance was necessary to achieve the best fuel efficiency while maintaining customer acceptability by meeting performance neutrality requirements. See Section VI.B.3.a)(6) Performance Neutrality for more details. If the systems were over-optimized for the agencies' modeling, such as applying a unique gear set for each individual vehicle configuration, the analysis would likely over-predict the reasonably achievable fuel economy improvement for the technology. Over-prediction would be exaggerated when applied under real-world large-scale manufacturing constraints necessary to achieve the estimated costs for the transmission technologies.

As HDS noted, the EPA Draft TAR and Proposed Determination analyses performed using the ALPHA model adjusted the effectiveness of every technology combination assuming

---

[1624] For instance, a vehicle would not get a modestly bigger engine if the vehicle comes with floor mats, nor would the vehicle get a modestly smaller engine without floor mats. This example demonstrates small levels of mass reduction. If manufacturers resized engines for small changes, manufacturers would have dramatically more part complexity, losing economies of scale.

[1625] Ford EcoBoost Engines are shared across ten different models in MY 2019. https://www.ford.com/powertrains/ecoboost/. Last accessed Nov. 05, 2019.

[1626] "GM Global Propulsion Systems - USA Information Guide Model Year 2018" (PDF). General Motors Powertrain. Retrieved September 26, 2019. https://www.gmpowertrain.com/assets/docs/2018R_F3F_Information_Guide_031918.pdf.

[1627] *See* ANL model documentation for final rule.

performance could be held constant for every combination, and did not recognize or account for the extreme complexity nor the associated costs for that impractical assumption. The NPRM and final rule analyses account for real-world practicalities and constraints related to both engine adoption and transmission adoption when other vehicle technologies are implemented, which explains some of the effectiveness and cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.

Figure VI-109 below shows the range of effectiveness used for the NPRM analysis for ROLL technologies.

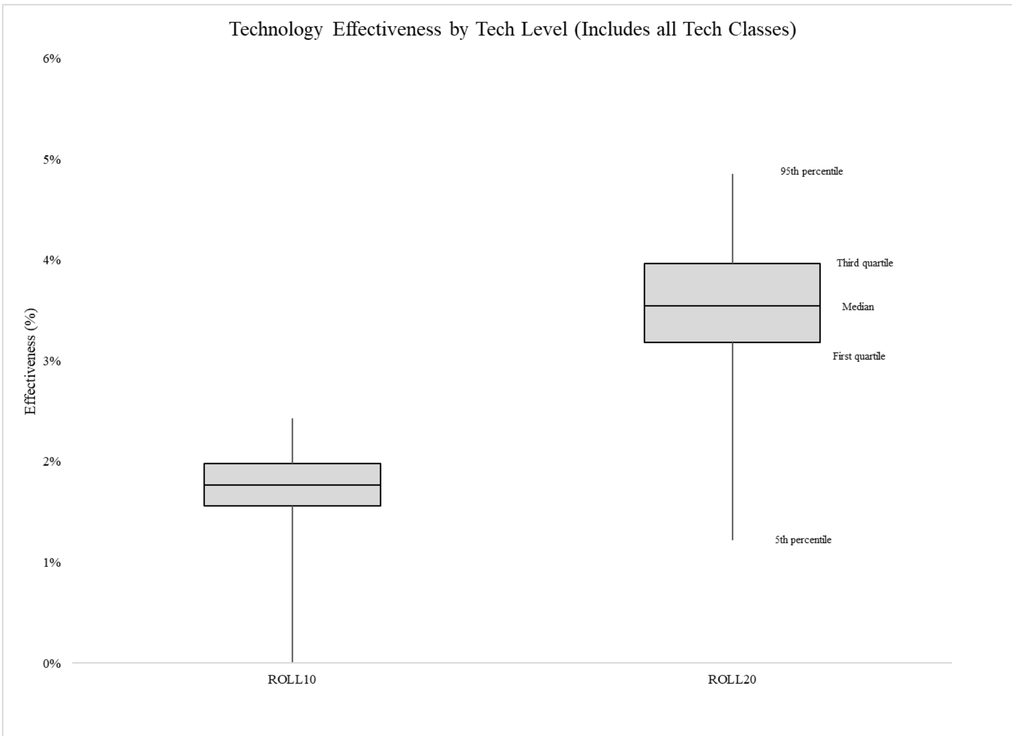

Figure VI-109 – NPRM Analysis ROLL Technology Effectiveness

Figure VI-110 below shows the range of effectiveness values used for the final rule analysis.

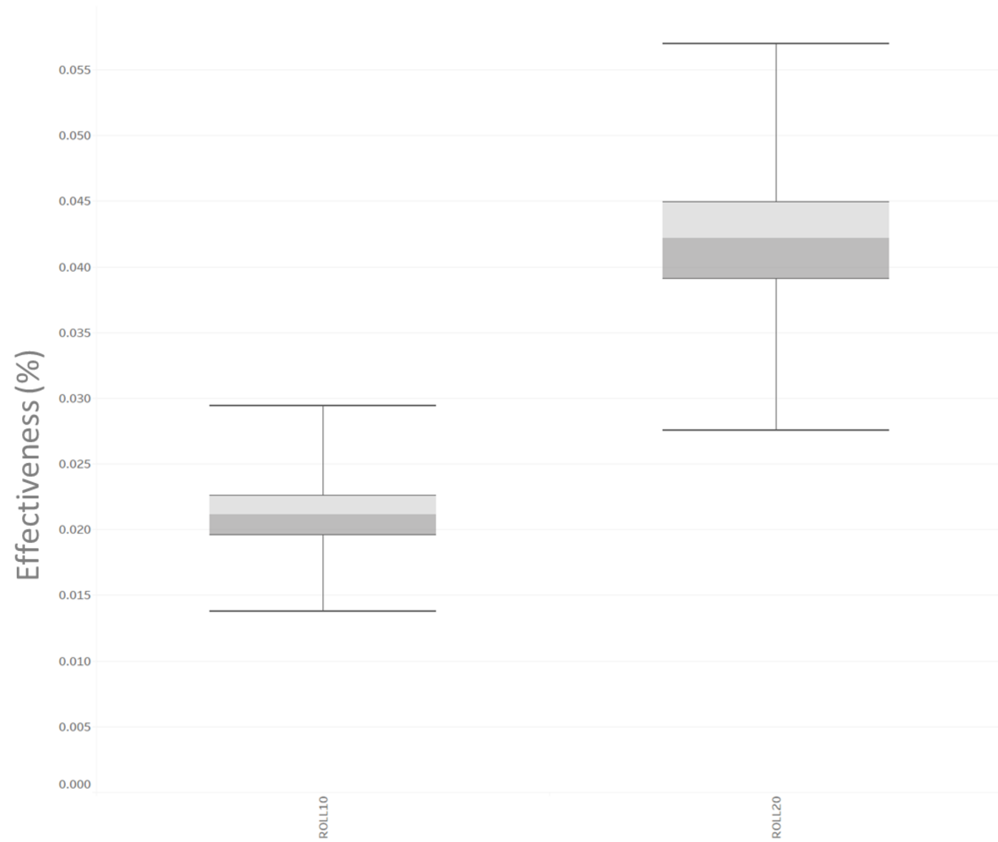

Figure VI-110 – Final Rule Analysis ROLL Technology Effectiveness

e) Rolling Resistance Cost

For the NPRM, the analysis used DMC for ROLL technology from the Draft TAR and updated the values to reflect 2016$ dollars. The agencies continued to use the same cost assumptions presented in the NPRM for the final rule, and updated the values to 2018$ dollars. Table VI-168 and Figure VI-111 show the different levels of tire rolling resistance technology cost.

Table VI-168 – Cost for tire rolling resistance technologies relative to ROLL0

	Tire Rolling Resistance Technology Costs for MY 2017 (2018$)		
Technology	**Direct Manufacturing Cost**	**Total Cost (includes RPE and Learning)**	**Incremental to**
ROLL0	$0.00	$0.00	Base V
ROLL10	$5.186	$7.78	Base V
ROLL20	$40.54	$60.81	Base V

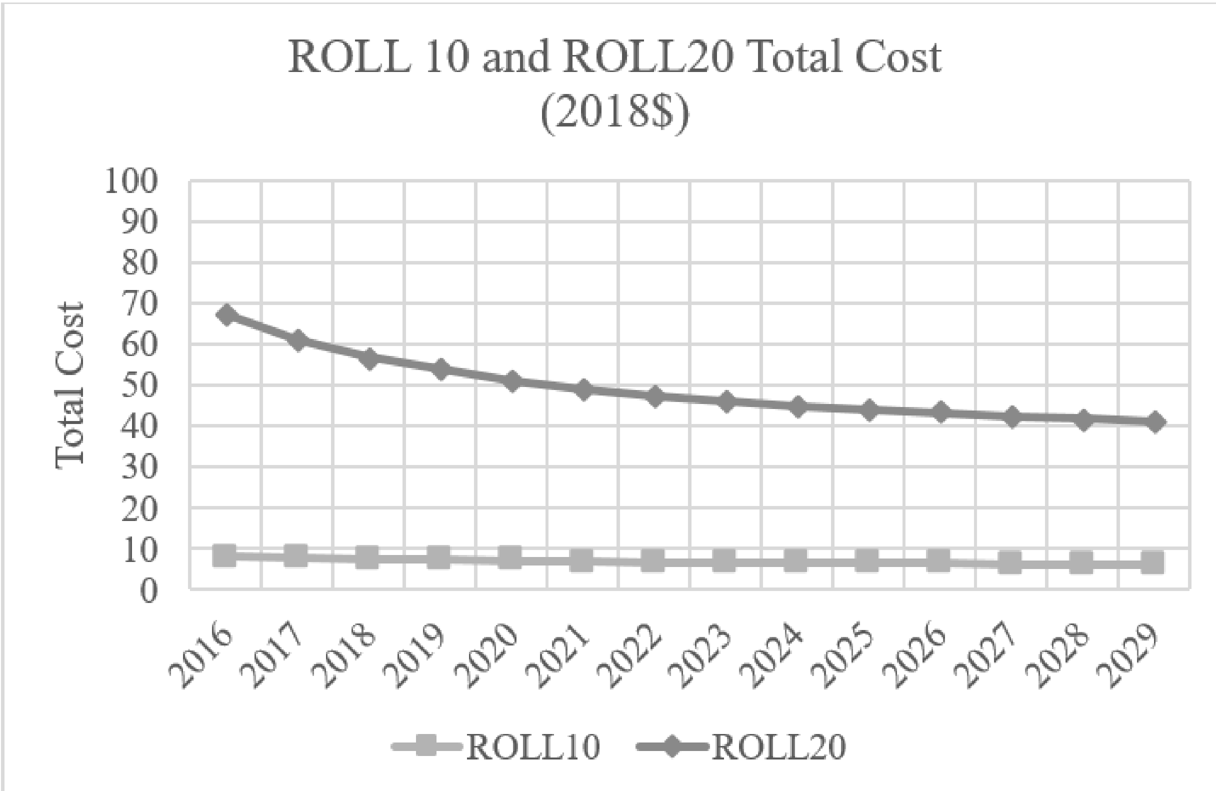

Figure VI-111 – Cost (RPE) for ROLL10 and ROLL20 Relative to ROLL0 in 2018$

7. Other Vehicle Technologies

Four other vehicle technologies were included in the analysis—electric power steering (EPS), improved accessory devices (IACC), low drag brakes (LDB), and secondary axle disconnect (SAX) (which may only be applied to vehicles with all-wheel-drive or four-wheel-drive). The effectiveness of these technologies was applied directly by the CAFE model, with unique effectiveness values for each technology and for each technology class. This methodology was used in these four cases because the effectiveness of these technologies varies little with combinations of other technologies. Also, applying these technologies directly in the CAFE model significantly reduces the number of Autonomie simulations that are needed.

a) Electric Power Steering (EPS)

Electric power steering reduces fuel consumption and CO_2 emissions by reducing load on the engine. Specifically, it reduces or eliminates the parasitic losses associated with engine-driven power steering pumps, which pump hydraulic fluid continuously through the steering actuation system even when no steering input is present. By selectively powering the electric assist only when steering input is applied, the power consumption of the system is reduced in comparison to the traditional "always-on" hydraulic steering system. Power steering may be electrified on light duty vehicles with standard 12V electrical systems and is also an enabler for vehicle electrification because it provides power steering when the engine is off (or when no combustion engine is present).

Power steering systems can be electrified in two ways. Manufacturers may choose to eliminate the hydraulic portion of the steering system and provide electric-only power steering (EPS) driven by an independent electric motor, or they may choose to move the hydraulic pump from a belt-driven configuration to a stand-alone electrically driven hydraulic pump. The latter system is commonly referred to as electro-hydraulic power steering (EHPS). As discussed in the NPRM, manufacturers have informed the agencies that full EPS systems are being developed for all types of light-duty vehicles, including large trucks.

EPS is also discussed in Section VI.C.3.a) Electrification Modeling in the CAFE model.

b) Improved Accessories (IACC)

Engine accessories typically include the alternator, coolant pump, cooling fan, and oil pump, and are traditionally mechanically-driven via belts, gears, or directly by other rotating engine components such as camshafts or the crankshaft. These can be replaced with improved accessories (IACC) which may include high efficiency alternators, electrically driven (i.e., on-demand) coolant pumps, electric cooling fans, variable geometry oil pumps, and a mild regeneration strategy.[1628] Replacing lower-efficiency and/or mechanically-driven components with these improved accessories results in a reduction in fuel consumption, as the improved accessories can conserve energy by being turned on/off "on demand" in some cases, driven at partial load as needed, or by operating more efficiently.

For example, electric coolant pumps and electric powertrain cooling fans provide better control of engine cooling. Flow from an electric coolant pump can be varied, and the cooling fan can be shut off during engine warm-up or cold ambient temperature conditions, reducing warm-up time, fuel enrichment requirements, and, ultimately reducing parasitic losses.

IACC is also discussed in Section VI.C.3.a) Electrification Modeling in the CAFE model.

c) Low Drag Brakes (LDB)

Low or zero drag brakes reduce or eliminate brake drag force by separating the brake pad from the rotor, either by mechanical or electric methods. Conventional disc brake systems are designed such that the brake pad is in contact with the brake rotor at all times. This is true even when the brakes are not being applied, and although the contact pressure is light in this case, this still produces some drag force on the vehicle.

LDBs have historically employed a caliper and rotor system that allows the piston in the caliper to retract,[1629] in turn pulling the brake pads away from the rotor. However, if pads are allowed to move too far away from the rotor, the first pedal application made by the vehicle operator can feel spongy and have excessive travel. This can lead to customer dissatisfaction regarding braking performance and pedal feel. For this reason, in conventional hydraulic-only

---

[1628] IACC in this analysis excludes other electrical accessories such as electric oil pumps and electrically driven air conditioner compressors.
[1629] The brake caliper pistons are used to push the brake pad against the brake rotor, or disc.

brake systems, manufacturers are limited by how much they can allow pads to move away from the rotor.

Recent developments in braking systems have resulted in brakes with the potential for zero drag. In these systems, the pedal feel is separated from hydraulics by a pedal simulator. This system is similar to the brake systems designed for hybrid and electric vehicles, where some of the primary braking is done through the recuperation of kinetic energy in the drive system. However, the pedal feel and the deceleration the operator experiences is tuned to provide a braking experience equivalent to that of a conventional hydraulic brake system. These "brake-by-wire" systems have highly tuned pedal simulators that feel like typical hydraulic brakes and seamlessly transition to a conventional system as required by different braking conditions. The application of a pedal simulator and brake-by-wire system is new to non-electrified vehicle applications. By using this type of system, vehicle manufacturers can allow brake pads to move farther away from the rotor and still maintain the initial pedal feel and deceleration associated with a conventional brake system.

In addition to reducing brake drag, the zero drag brake system provides ancillary benefits. It allows for a faster brake application and greater deceleration than is normally applied by the average vehicle operator. It also allows manufacturers to tune the braking for different customer preferences within the same vehicle. This means manufacturers can provide a "sport" mode, which provides greater deceleration with less pedal displacement and a "normal" mode, which might be more appropriate for day-to-day driving.

The zero drag brake system also eliminates the need for a brake booster. This saves cost and weight in the system. Elimination of the conventional vacuum brake booster could also improve the effectiveness of stop-start systems. Typical stop-start systems need to restart the engine if the brake pedal is cycled because the action drains the vacuum stored in the booster. Because the zero drag brake system provides braking assistance electrically, there is no need to supplement lost vacuum during an engine off event.

Finally, many engine technologies being considered to improve efficiency also reduce pumping losses through reduced throttling, and in turn there is less engine vacuum available to power-assist a conventional brake system. The reduction in throttling could require a supplemental vacuum pump to provide vacuum for a conventional brake system. This is the situation in many diesel-powered vehicles. Diesel engines have no throttling and require a supplemental vacuum for conventional brake systems. A zero drag brake system both eliminates brake drag and avoids the need for a supplemental vacuum pump.

d) Secondary Axle Disconnect (SAX)

All-wheel drive (AWD) and four-wheel drive (4WD) vehicles provide improved traction by delivering torque to the front and rear axles, rather than just one axle. When a second axle is rotating, it tends to consume more energy because of additional losses related to lubricant churning, seal friction, bearing friction, and gear train inefficiencies.[1630,1631] Some of these losses may be reduced by providing a secondary axle disconnect function that disconnects one of the axles when driving conditions do not call for torque to be delivered to both.

The terms AWD and 4WD are often used interchangeably, although they have also developed a colloquial distinction, and are two separate systems. The term AWD has come to be associated with light-duty passenger vehicles providing variable operation of one or both axles on ordinary roads. The term 4WD is often associated with larger truck-based vehicle platforms providing a locked driveline configuration and/or a low range gearing meant primarily for off-road use.

Many 4WD vehicles provide for a single-axle (or two-wheel) drive mode that may be manually selected by the user. In this mode, a primary axle (usually the rear axle) will be powered, while the other axle (known as the secondary axle) is not. However, even though the secondary axle and associated driveline components are not receiving engine power, they are still connected to the non-driven wheels and will rotate when the vehicle is in motion. This unnecessary rotation consumes energy,[1632] and leads to increased fuel consumption and CO_2 emissions that could be avoided if the secondary axle components were completely disconnected and not rotating.

Light-duty AWD systems are often designed to divide variably torque between the front and rear axles in normal driving to optimize traction and handling in response to driving conditions. However, even when the secondary axle is not necessary for enhanced traction or handling, in traditional AWD systems it typically remains engaged with the driveline and continues to generate losses that could be avoided if the axle was instead disconnected. The SAX technology observed in the marketplace disengages one axle (typically the rear axle) for 2WD operation, but detects changes in driving conditions and automatically engages AWD mode when it is necessary. The operation in 2WD can result in reduced fuel consumption. For example, Chrysler has estimated the secondary axle disconnect feature in the Jeep Cherokee reduces friction and drag attributable to the secondary axle by 80% when in disconnect mode.[1633]

e) Analysis Fleet Assignments for Other Vehicle Technologies

The agencies described in the PRIA that the aforementioned technologies have been applied, to some extent, in the MY 2016 fleet. However, these technologies are difficult to observe and assign to the analysis fleet, and the agencies relied heavily on industry engagement and feedback to assign the technologies properly to the NPRM analysis fleet vehicles. In the NPRM, the agencies noted that the Draft TAR analysis did not properly account for the presence

[1633] Brooke, L. "Systems Engineering a new 4x4 benchmark," *SAE Automotive Engineering*, June 2, 2014.

of these technologies in the analysis fleet, and far too few were assigned. Accordingly, the NPRM analysis reflected higher EPS and IACC application rates than the Draft TAR analysis.

The agencies received a handful of comments stating that the additional technologies were incorrectly applied to the analysis fleet. ICCT stated that the inclusion of EPS, IACC, and LDB in the analysis fleet was unsubstantiated, and removed the technologies from potential use during the subsequent simulated years.[1634] ACEEE commented that IACC should not have been applied to certain vehicles in the analysis fleet because those vehicles do not in actuality display the fuel consumption reduction that would confirm the presence of these additional technologies.[1635] In addition, ACEEE commented that the CAFE model assumes significant baseline SAX penetration that they could not corroborate from Ford F-150 product information brochures.[1636] HDS compared the available levels of IACC improvements from the Draft TAR to the NPRM analysis, noting that the NPRM only employed one level of improved accessory technologies.[1637] HDS stated that this implied the effectiveness of what was previously considered IACC1 (the first level of IACC technology improvement available in the Draft TAR) was completely used up in the 2016 analysis fleet for this rule.

As the agencies stated in the PRIA, in part because of the difficulty in observing EPS, IACC, LDB, and SAX on actual vehicles, far too few of those technologies were assigned to vehicles in the Draft TAR analysis fleets. For the final rule, each vehicle in the MY 2017 analysis fleet was studied using confidential and publicly available information to determine whether, as commenters suggested, the agencies had improperly applied any of these additional vehicle technologies. This resulted in some adjustments in the application of the technologies in the analysis fleet. In regard to ACEEE's comment on SAX penetration in the analysis fleet, for the NPRM and final rule analysis, the agencies considered all 4WD vehicles to have the capability manually to disconnect either the front or rear wheel axle and associated rotating components, thus shifting to a 2WD mode. When 4WD operation is required for safety and utility, the consumer can enable this feature. As stated above, this capacity to shift between 2WD and 4WD modes is another form of SAX. For AWD vehicles, publicly available manufacturer information was reviewed to identify the specific vehicles that have SAX technology. Based on market observations and feedback from OEMs, the entire analysis fleet for NPRM and the final rule was considered to have a basic level of improved accessories (comparable to what Draft TAR referred to as IACC1). The application of IACC in the NPRM and final rule analysis fleets represents further improvements to accessories such as electric water pumps and higher efficiency alternators with mild regeneration capacity.

The following distribution of technologies in the analysis fleet from the NPRM to the final rule analysis shows a slight decrease in the portion of total vehicles produced that have EPS

and IACC, a very slight increase in the portion of total vehicle production that have LDB, and a slight increase in the portion of 4WD/AWD vehicles with SAX technology.

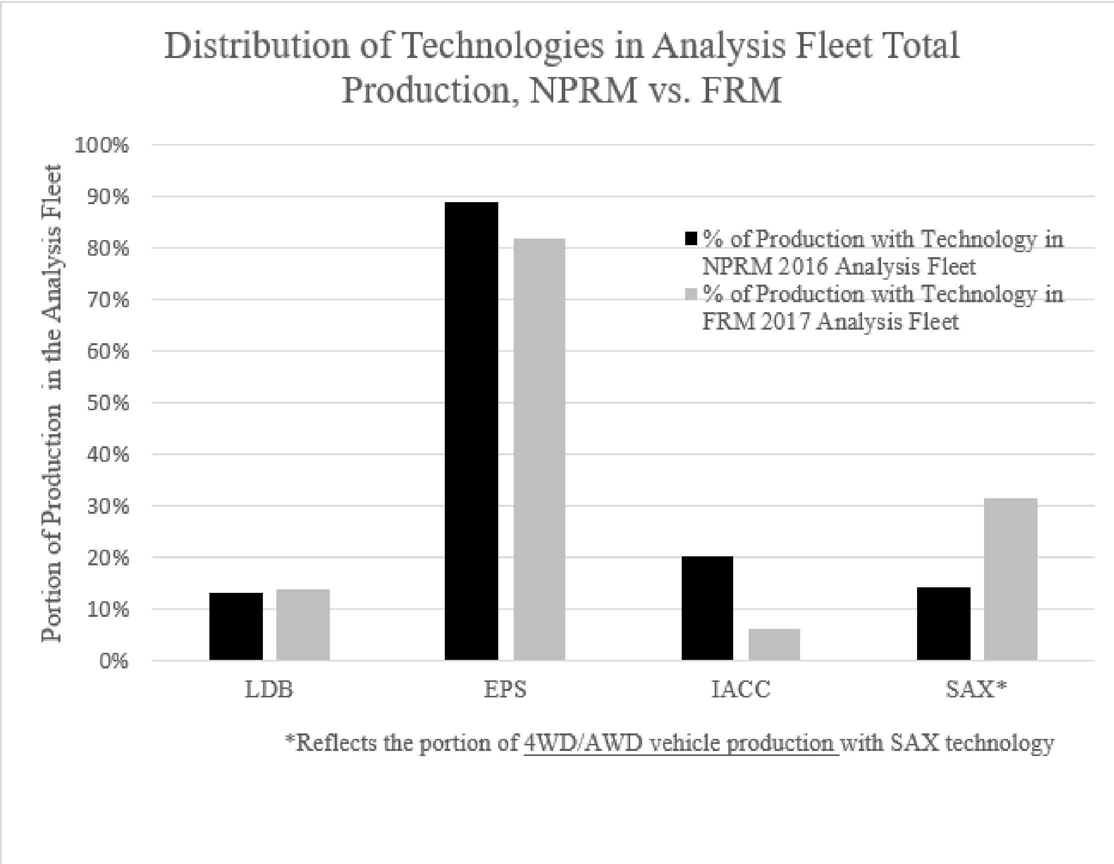

Figure VI-112 – Distribution of Technologies in Analysis Fleet Production

f) Effectiveness Estimates for Other Vehicle Technologies

The effectiveness estimates for these four technologies rely on previous work published as part of the rulemaking process, both for the 2012 rule for MYs 2017-2025 and the Draft TAR. The effectiveness values are unchanged from the Draft TAR.

The effectiveness of both EPS and EHPS is derived from the decoupling of the pump from the crankshaft, and is considered to be practically the same for both. Thus, a single effectiveness value is assigned to all vehicles in the analysis fleet that possess either EPS or EHPS, and the “EPS” designation is applied.

For the Draft TAR analysis, two levels of IACC were offered as a technology path (a low improvement level and a high improvement level). Since much of the market has incorporated some of these technologies in the baseline MY 2016 and 2017 fleets, the NPRM and final rule analyses assumed all vehicles have incorporated what was previously the low level, so only the high level remained as an option for vehicles. The figure above shows the distribution of IACC for NPRM and FRM, which is the equivalent type of technology as the high-level IACC in the DRAFT TAR.

The NPRM analysis carried forward work on the effectiveness of SAX systems conducted in the Draft TAR and EPA Proposed Determination. This work involved gathering information by monitoring press reports, holding meetings with suppliers and OEMs, and attending industry technical conferences. The resulting effectiveness estimates used in the Draft TAR, NPRM, and this final rule are shown below.

Table VI-169 – Fuel Consumption Improvement Values for Other Vehicle Technologies

g) Cost Estimates and Learning Rates for Other Vehicle Technologies

The cost estimates for these technologies rely on previous work published as part of the rulemaking process, both for the 2012 rule for MYs 2017-2027 and the Draft TAR. The cost values are from the same sources as the Draft TAR and were updated to 2016 dollars for the NPRM and 2018 dollars for the final rule analysis. Learning rates for these technologies are also unchanged since the NPRM, and can be seen in Section VI.B.4.d)(4) Cost Learning as Applied in the CAFE Model.

CARB noted that the IACC costs in Tables 6-32 and 6-33 of the PRIA did not align with the Technologies central analysis input file.[1638] HDS commented, as part of its comparison of IACC penetration in the analysis fleet from the Draft TAR to NPRM, that IACC costs were based on the difference between IACC1 and IACC2 costs and this appeared to be inconsistent with the cost of accessory electrification which is more expensive.[1639]

[1638] CARB, Docket No. NHTSA-2018-0067-12428, at 21.
[1639] H-D Systems, “HDS final report,” Docket No. NHTSA-2018-0067-11985, at 21.

In the PRIA, the cost of IACC was reported in some tables as an absolute cost (the cost of adding IACC to a base vehicle), while the NPRM Technologies central analysis input file showed IACC cost incremental to EPS. This was necessary in the model input file because the accounting method of the NPRM CAFE model utilized incremental costs. In contrast, a change in the CAFE model accounting method for this final rule allows all costs in the input file to be reported as absolute costs, incremental to a base vehicle. It was assumed that EPS must be present on a vehicle in order for it to adopt IACC, and as such the cost of IACC includes the cost of EPS. For further detail on the use of absolute costs in place of incremental costs, see Section VI.C.7.g). Although HDS commented that accessory electrification has a higher cost than what is being used in the analysis, no specific additional input was given; the cost of IACC, as was done for Draft TAR (where it was referred to as IACC2), was taken from the 2015 NAS Report.[1640]

Table VI-170 below shows the absolute costs for these technologies for select model years. The FRM Technologies central analysis input file shows the costs for all model years.

Table VI-170 – Final Rule Absolute Costs for Other Vehicle Technologies, including Learning Effects and Retail Price Equivalent (2018$)

Technology	**2017**	**2021**	**2025**	**2029**
EPS	$133.23	$124.42	$117.28	$111.97
IACC	$196.39	$163.40	$146.67	$136.96
LDB	$92.08	$84.60	$78.35	$73.97
SAX	$97.41	$86.69	$80.34	$75.98

8. Simulating Off-Cycle and A/C Efficiency Technology Adjustments

Off-cycle and air conditioning (A/C) efficiency technologies can provide fuel economy improvements in real-world vehicle operation, but that benefit cannot be adequately captured by the 2-cycle test procedures used to demonstrate compliance with fuel economy and CO_2 emissions standards.[1641] Off-cycle technologies include technologies like high efficiency alternators and high efficiency exterior lighting.[1642] A/C efficiency technologies operate mainly by reducing the operation of the compressor, which pumps A/C refrigerant around the system loop. The less the compressor operates or the more efficiently it operates, the less load the compressor places on the engine, resulting in better fuel efficiency and lower CO_2 emissions.

Vehicle manufacturers have the option to generate credits for off-cycle technologies and improved A/C systems under the EPA's CO_2 program and receive a fuel consumption improvement value (FCIV) equal to the value of the benefit not captured on the 2-cycle test under NHTSA's CAFE program. The FCIV is not a credit in the NHTSA CAFE program, but the FCIVs increase the reported fuel economy of a manufacturer's fleet, which is used to determine compliance. EPA applies FCIVs during determination of a fleet's final average fuel economy reported to NHTSA.[1643] FCIVs are only calculated and applied at a fleet level for a manufacturer and are based on the volume of the manufacturer's fleet that contain qualifying technologies.[1644]

As discussed further in Section IX.D Compliance Issues that Affect Both the CO2 and CAFE Programs, three pathways can be used to determine the value of A/C efficiency and off-cycle adjustments. First, manufacturers can use a predetermined list or "menu" of credit values established by EPA for specific off-cycle technologies.[1645] Second, manufacturers can use 5-cycle testing to demonstrate and justify off-cycle CO_2 credits;[1646] the additional tests allow emission benefits to be demonstrated over some elements of real-world driving not captured by the 2-cycle compliance tests, including high speeds, rapid accelerations, and cold temperatures. Third, manufacturers can seek EPA approval, through a notice and comment process, to use an

[1644] 40 CFR 600.510-12(c)

[1645] *See* 40 CFR 86.1869-12(b). The Technical Support Document (TSD) for the 2012 final rule for MYs 2017 and beyond provides technology examples and guidance with respect to the potential pathways to achieve the desired physical impact of a specific off-cycle technology from the menu and provides the foundation for the analysis justifying the credits provided by the menu. The expectation is that manufacturers will use the information in the TSD to design and implement off-cycle technologies that meet or exceed those expectations in order to achieve the real-world benefits of off-cycle technologies from the menu.

[1646] *See* 40 CFR 86.1869-12(c). EPA proposed a correction for the 5-cycle pathway in a separate technical amendments rulemaking. *See* 83 FR 49344 (Oct. 1, 2019). EPA is not approving credits based on the 5-cycle pathway pending the finalization of the technical amendments rule.

alternative methodology other than the menu or 5-cycle methodology for determining the off-cycle technology improvement values.[1647]

The agencies have been collecting data on the application of these technologies since implementing the programs.[1648] Most manufacturers are generating A/C efficiency and off-cycle credits; in MY 2017, 15 manufacturers generated A/C efficiency credits and 15 manufacturers generated off-cycle credits, through the level of deployment varies by manufacturer.[1649]

a) Air Conditioning Efficiency Technologies

Air conditioning (A/C) is a virtually standard automotive accessory, with more than 95 percent of new cars and light trucks sold in the United States equipped with mobile air conditioning (MAC) systems. Most of the additional air conditioning related load on an engine is due to the compressor, which pumps the refrigerant around the system loop. The less the compressor operates or the more efficiently it operates, the less load the compressor places on the engine and the better fuel consumption will be. This high penetration means A/C systems can significantly impact energy consumed by the light duty vehicle fleet.

Vehicle manufacturers can generate credits for improved A/C systems under EPA's GHG program, and receive a fuel consumption improvement values (FCIV) equal to the value of the benefit not captured on the 2-cycle test under NHTSA's CAFE program[1650]. Table VI-172 provides a "menu" of fuel economy improvement values in grams per mile is available for qualifying A/C technologies, with the magnitude of each value estimated based on the expected reduction in CO_2 emissions from the technology.[1651] NHTSA converts the improvement in grams per mile to a fuel economy improvement value for each vehicle for purposes of measuring CAFE compliance.

The 2012 final rule for MYs 2017 and later outlined two test procedures to determine eligibility for A/C efficiency menu credits, the idle test and the AC17 test. The idle test, performed while the vehicle is at idle, determined the additional CO_2 generated at idle when the A/C system is operated.[1652] The AC17 test is a four-part performance test that combines the existing SC03 driving cycle, the fuel economy highway test cycle, and a pre-conditioning cycle and solar soak period.[1653] Manufacturers could use the idle test or AC17 test to determine

improvement values for MYs 2014-2016, while for MYs 2017 and later, the AC17 test is the exclusive test that manufacturers can use to demonstrate eligibility for menu A/C improvement values.

In MYs 2020 and later, manufacturers will use the AC17 test to demonstrate eligibility for A/C credits, and also to partially quantify the amount of the credit earned. AC17 test results equal to or greater than the menu value will allow manufacturers to claim the full menu value for the credit. A test result less than the menu value will limit the amount of credit to that demonstrated on the AC17 test. In addition, for MYs 2017 and beyond, A/C fuel consumption improvement values will be available for CAFE calculations, whereas efficiency credits were previously only available for GHG compliance. The agencies proposed these changes in the 2012 final rule for MYs 2017 and later largely as a result of new data collected, as well as the extensive technical comments submitted on the proposal.[1654]

The pre-defined technology menu and associated car and light truck credit value is shown in Table VI-172 below. The regulations include a definition for each technology that must be met for eligibility for the menu credit.[1655] To use the pre-defined credit value, manufacturers are not required to submit any other emissions data, or information, beyond meeting definition and useful life requirements.[1656] Manufacturers' use of menu-based credits for A/C efficiency is subject to a regulatory cap; 5.7 g/mi for cars and trucks through MY 2016 and separate caps of 5.0 g/mi for cars and 7.2g/mi for trucks for later MYs.[1657]

In the 2012 final rule for MYs 2017 and later, the agencies estimated that manufacturers would employ significant advanced A/C technologies throughout their fleets to improve fuel economy, and this was reflected in the stringency of the standards.[1658] Many manufacturers have since incorporated A/C technology throughout their fleets, and the utilization of advanced A/C technologies has become significant contributor to industry compliance plans. As summarized in the EPA Manufacturer Performance Report for the 2016 model year,[1659] 15 auto manufacturers included A/C efficiency credits as part of their compliance demonstration in the 2016 MY. These amounted to more than 12 million Mg of fuel consumption improvement values of the total net fuel consumption improvement values reported. This is equivalent to approximately four grams per mile across the 2016 fleet. Accordingly, a significant amount of new information about A/C technology and the efficacy of test procedures has become available since the 2012 final rule for MYs 2017 and beyond.

Oil Separator (internal or external to compressor)	10	0.5	0.7	0.000056	0.000079

(1) A/C Efficiency Technology Valuation Through the Off-Cycle Program

The A/C technology menu, discussed at length above, includes several A/C efficiency-improving technologies that were well defined and had been quantified for effectiveness at the time of the 2012 final rule for MYs 2017 and beyond.[1660] Manufacturers claimed the vast majority of A/C efficiency credits to date by utilizing technologies on the menu; however, the agencies recognize that manufacturers will develop additional technologies that are not currently listed on the menu. These additional A/C efficiency-improving technologies are eligible for fuel consumption improvement values on a case-by-case basis under the off-cycle program. Approval under the off-cycle program also requires "A-to-B" comparison testing under the AC17 test, that is, testing substantially similar vehicles in which one has the technology and the other does not.

To date, the agencies have received one type off-cycle application for an A/C efficiency technology. In December 2014, General Motors submitted an off-cycle application for the Denso SAS A/C compressor with variable crankcase suction valve technology, requesting an off-cycle GHG credit of 1.1 grams CO_2 per mile.[1661] EPA, in consultation with NHTSA, evaluated the applications and found methodologies described therein were sound and appropriate. In December 2017, BMW of North America, Ford Motor Company, Hyundai Motor Company, and Toyota petitioned and received approval to receive the off-cycle improvement value for the same A/C efficiency technology.[1662,]

The agencies received additional stakeholder comments on the off-cycle approval process as an alternate route to receiving A/C technology credit values. The Alliance requested that EPA "simplify and standardize the procedures for claiming off-cycle credits for the new MAC technologies that have been developed since the creation of the MAC indirect credit menu."[1663] Other commenters noted the importance of continuing to incentivize further innovation in A/C efficiency technologies as new technologies emerge that are not listed on the menu, or when manufacturers begin to reach regulatory caps. The commenters suggested that EPA should consider adding new A/C efficiency technologies to the menu and/or update the fuel consumption improvement values for technology already listed on the menu, particularly in cases where manufacturers can show through an off-cycle application that the technology actually deserves more credit than that listed on the menu. For example, Toyota commented that "the incentive values for A/C efficiency should be updated along with including new technologies being deployed."[1664]

[1663] Alliance TAR comments at.

[1664] Toyota TAR comments at p. 23.

The agencies note that some of these comments are directed towards the off-cycle technology approval process generally, which is described in more detail in IX.D. Regarding the A/C technology menu specifically, the agencies do anticipate that new A/C technologies not currently on the menu will emerge over the time frame of the MY 2021-2026 standards. At the time of this proposal, the agencies are proposing to add one additional A/C technology to the menu—the A/C compressor with variable crankcase suction valve technology, discussed in Section VI.C.8.a)(2), below (and also one off-cycle technology, discussed in Section VI.C.8.b), below). The agencies also request comment on whether to change any fuel economy improvement values currently assigned to technologies on the menu.

Next, as mentioned above, the menu-based improvement values for A/C efficiency established in the 2012 final rule for MYs 2017 and by end are subject to a regulatory cap. The rule set a cap of 5.7 g/mi for cars and trucks through MY 2016 and separate caps of 5.0 g/mi for cars and 7.2g/mi for trucks for later MYs.[1665] Several commenters asked EPA to reconsider the applicability of the cap to non-menu A/C efficiency technologies claimed through the off-cycle process and questioned the applicability of this cap on several different grounds. These comments appear to be in response to a Draft TAR passage that stated: "Applications for A/C efficiency credits made under the off-cycle credit program rather than the A/C credit program will continue to be subject to the A/C efficiency credit cap" (Draft TAR, p. 5-210). The agencies considered these comments and present clarification below.

As additional context, the 2012 TSD states[1666]: "...air conditioner efficiency is an off-cycle technology. It is thus appropriate [...] to employ the standard off-cycle credit approval process [to pursue a larger credit than the menu value]. Utilization of bench tests in combination with dynamometer tests and simulations [...] would be an appropriate alternate method of demonstrating and quantifying technology credits *(up to the maximum level of credits allowed for A/C efficiency)* [emphasis added]. A manufacturer can choose this method even for technologies that are not currently included in the menu." This suggests the concept of placing a limit on total A/C fuel consumption improvement values, even when some are granted under the off-cycle program, is not entirely new and that EPA considered the menu cap as being appropriate at the time.

Regulatory caps specified under 40 CFR 86.1868-12(b)(2) apply to menu-based improvement values and are not part of the off-cycle regulation (40 CFR 86.1869-12). However, it should be noted that off-cycle applications are decided individually on merits through a process involving public notice and opportunity for comment. In deciding whether to approve or deny a request, the agencies may take into account any factors deemed relevant, including such issues as the realization of claimed fuel consumption improvement value in real-world use. Such considerations could include synergies or interactions among applied technologies, which could potentially be addressed by application of some form of cap or other applicable limit, if warranted. Therefore, applying for A/C efficiency fuel consumption improvement values

[1665] See 40 CFR 86.1868-12(b)(2).
[1666] See p. 5-58 2012 Final Rule TSD.

through the off-cycle provisions in 40 CFR Part 86.1869-12 should not be seen as a route to unlimited A/C fuel consumption improvement values.

Going forward, the agencies are not changing the cap for total A/C efficiency fuel consumption improvement values whether granted through 40 CFR Parts 86.1868-12 or 86.1869-12. That is, the agencies are likely to specify total A/C efficiency fuel consumption improvement values be capped in an appropriate manner. At this time, agencies believe that, unless information pertinent to a specific application causes a different conclusion, the caps specified in 40 CFR Part 86.1868-12 are appropriate for this purpose. Applicants can present, as part of the analysis supporting their application, evidence that a different conclusion should apply to the application in question.

(2) Addition of A/C Compressor with variable crankcase suction valve technology to menu list

For this NPRM, the agencies requested comments on the addition of a new menu item for A/C efficiency improvement. The new technology incorporates a variable crankcase suction valve into the A/C compressor.[1667] The agencies are proposing a 1.1 g/mile CO_2 equivalent fuel economy improvement value for this technology. This technology improves the internal valve system within the compressor to reduce the internal refrigerant flow necessary throughout the range of displacements the compressor may use during its operating cycle. The addition of a variable crankcase suction valve allows a larger mass flow under maximum capacity and compressor start-up conditions (when high flow is ideal), and then it can reduce to smaller openings with reduced mass flow in mid- or low-capacity conditions. The refrigerant exiting the crankcase is thus optimized across the range of operating conditions, reducing energy consumption of the A/C system. As discussed in section for A/C Conditioning above, multiple manufacturers demonstrated additional A/C efficiency improvement from this technology.

Denso, a component supplier of A/C compressors with variable crankcase suction valves, conducted an engineering analysis using bench testing per SAE J2765[1668] for compressor and Life Cycle Climate Performance (LCCP) analysis[1669] to determine CO_2 effects. Denso's analysis compared a fixed crankcase variable valve versus the variable crankcase valve, and this comparison resulted in 1.1 g/mile improvement in CO_2 using bench testing and the LCCP analysis.

Data from GM, Ford, Hyundai, and Toyota's AC17 vehicle testing also showed similar benefits for the variable crankcase suction valve. Specific vehicles selected for the AC17 test included the 2014 MY Toyota Corolla, 2014 Cadillac ATS, Hyundai Sonata, and BMW 3-series. All manufacturer AC17 tests for the SAS compressor showed benefits above those found in Denso's engineering analysis; compared to Denso's 1.1 g/mile improvement, BMW showed the

[1667] Such as with the Denso SAS compressor.
[1668] SAE J2765: Procedure for Measuring System COP [Coefficient of Performance] of a Mobile Air Conditioning System on a Test Bench.
[1669] LCCP analysis is a method to estimate CO_2 effects of MAC systems.

least improvement with a 1.2 g/mile improvement, and Ford showed the highest improvement with a 1.5 g/mile improvement.

The vehicle test data from manufacturers confirms the benefits of the variable crankcase suction valve compressor technology and agrees with on-vehicle tests. As a result, the agencies added the technology to the A/C efficiency menu at 1.1 g/mile CO_2 equivalent fuel economy improvement value based on the LCCP analysis using bench test data, which reflects the annual U.S. average performance for an air conditioning system.

b) Off Cycle Technologies

Off-cycle" emission reductions and fuel consumption improvements can be achieved by employing off-cycle technologies resulting in real-world benefits but where that benefit is not adequately captured on the test procedures used to demonstrate compliance with fuel economy emission standards. EPA initially included off-cycle technology credits in the MY 2012-2016 rule and revised the program in the MY 2017-2025 rule.[1670] NHTSA adopted equivalent off-cycle fuel consumption improvement value for MYs 2017 and later in the MY 2017-2025 rule.[1671]

The intent of the off-cycle provisions is to provide a flexibility for manufacturers to use off-cycle technologies that improve real world fuel economy and CO_2 for compliance, which provides an expanded array of technologies that may be used for compliance and expands the range of operating conditions in which fuel economy is improved. The preamble to the 2012 final rule for MYs 2017 and beyond provided a detailed discussion of eligibility for off-cycle credits.[1672] NHTSA further discussed technologies that might otherwise be implemented through its safety regulations.[1673] Technologies that are integral or inherent to the basic vehicle design including engine, transmission, mass reduction, passive aerodynamics, and base tires are not eligible and are accounted for in 2-cycle test procedures. EPA established this approach believing the use of 2-cycle technologies would be driven by standards, and no additional improvement values would be necessary or appropriate.

Manufacturers can demonstrate the value of off-cycle technologies in three ways: first, they may select fuel economy improvement values and CO_2 credit values from a pre-defined "menu" for off-cycle technologies that meet certain regulatory specifications. As part of a manufacturer's compliance data, manufacturers will provide information about which off-cycle technologies are present on which vehicles.

The pre-defined list of technologies and associated off-cycle light-duty vehicle fuel economy improvement values and GHG credits is shown in Table VI-173 and

---

[1673] 40 CFR 86.1869-12.

Table VI-174 below.[1674] A definition of each technology equipment must meet to be eligible for the menu credit is included at 40 CFR 86.1869-12(b)(4). Manufacturers are not required to submit any other emissions data or information beyond meeting the definition and useful life requirements to use the pre-defined credit value. Credits based on the pre-defined list are subject to an annual manufacturer fleet-wide cap of 10 g/mile.

Table VI-173 - Off-Cycle Fuel Consumption Improvement Value Menu Technologies for Light Duty Vehicles

Technology	**CAFE Value for Cars**	**CAFE Value for Light Trucks**
	g/mi (gallons/mi)	**g/mi (gallons/mi)**
High Efficiency Exterior Lighting (at 100W)	1.0 (0.000113)	1.0 (0.000113)

Solar Roof Panels (for 75 W, active cabin ventilation plus battery charging)	2.5 (0.000282)	2.5 (0.000282)
Active Aerodynamic Improvements (scalable)	0.6 (0.000068)	1.0 (0.000113)
Engine Idle Start-Stop w/ heater circulation system	2.5 (0.000282)	4.4 (0.000496)
Engine Idle Start-Stop without/ heater circulation system	1.5 (0.000169)	2.9 (0.000327)
Active Transmission Warm-Up	1.5 (0.000169)	3.2 (0.000361)
Active Engine Warm-Up	1.5 (0.000169)	3.2 (0.000361)
Solar/Thermal Control	Up to 3.0 (0.000338)	Up to 4.3 (0.000484)

[1674] For a description of each technology and the derivation of the pre-defined credit levels see Chapter 5 of "Joint Technical Support Document: Final Rulemaking for 2017-2025 Light-duty Vehicle Greenhouse Gas Emission Standards and Corporate Average Fuel Economy," EPA-420-R-12-901, August 2012.

Table VI-174 - Off-Cycle Fuel consumption improvement value Menu Technologies for Solar/Thermal Control Technologies for light Duty Vehicles

Thermal Control	**CAFE Value (CO2 g/mi)**	
Technology	Car	Truck
Glass or Glazing	Up to 2.9 (0.000326)	Up to 3.9 (0.000439)
Active Seat Ventilation	1.0 (0.000113)	1.3 (0.000146)
Solar Reflective Paint	0.4 (0.00005)	0.5 (0.00006)
Passive Cabin Ventilation	1.7 (0.000191)	2.3 (0.000259)
Active Cabin Ventilation	2.1 (0.000236)	2.8 (0.000315)

Manufacturers can also perform their own 5-cycle testing and submit to the agencies with a request explaining the off-cycle technology and the test results. The additional 3 test cycles have different operating conditions including high speeds, rapid accelerations, high temperature with A/C operation and cold temperature, enabling improvements to be measured for technologies that do not impact operation on the 2-cycle tests. Credits determined according to this methodology do not undergo public review.

The third pathway allows manufacturers to seek EPA approval to use an alternative methodology for determining the value of an off-cycle technology. This option is only available if the benefit of the technology cannot be adequately demonstrated using the 5-cycle methodology. Manufacturers may also use this option to demonstrate reductions that exceed those available via use of the predetermined menu list. The manufacturer must also demonstrate that the off-cycle technology is effective for the full useful life of the vehicle. Unless the manufacturer demonstrates that the technology is not subject to in-use deterioration, the manufacturer must account for the deterioration in their analysis.

Manufacturers must develop a methodology for demonstrating the benefit of the off-cycle technology, and EPA makes the methodology available for public comment prior to an EPA and NHTSA determination whether or not to allow the use of the methodology to measure improvement values and credits. The data needed for this demonstration may be extensive.

Several manufacturers have requested and been granted use of an alternative test methodologies for measuring improvements and credits. In the fall of 2013, Mercedes requested off-cycle credits for the following off-cycle technologies in use or planned for implementation in the 2012-2016 model years: stop-start systems, high-efficiency lighting, infrared glass glazing, and active seat ventilation. EPA approved methodologies for Mercedes to determine these off-cycle credits in September 2014.[1675] Subsequently, FCA, Ford, and GM requested off-cycle credits under this pathway. FCA and Ford submitted applications for off-cycle credits from high

[1675] "*EPA Decision Document: Mercedes-Benz Off-cycle Credits for MYs 2012-2016*," U.S. EPA-420-R-14-025, Office of Transportation and Air Quality, September 2014. https://www.epa.gov/vehicle-and-engine-certification/mercedes-benz-compliance-materials-light-duty-greenhouse-gas-ghg.

efficiency exterior lighting, solar reflective glass/glazing, solar reflective paint, and active seat ventilation. Ford's application also demonstrated off-cycle benefits from active aerodynamic improvements (grill shutters), active transmission warm-up, active engine warm-up technologies, and engine idle stop-start. GM's application described real-world benefits of an air conditioning compressor with variable crankcase suction valve technology. EPA approved the credits for FCA, Ford, and GM in September 2015.[1676] Although EPA granted the use of alternative methodologies to determine credit values, manufacturers have yet to report credits to EPA based on those alternative methodologies.

As discussed below, all three methods have been used by manufacturers to generate off-cycle improvement values and credits.

(1) Use of Off-Cycle Technologies to Date

Manufacturers used a wide array of off-cycle technologies in MY2016 to generate off-cycle GHG credits using the pre-defined menu. Table VI-175 below shows the percent of each manufacturer's production volume using each menu technology reported to EPA for MY 2016 by manufacturer. Table VI-176 shows the g/mile benefit each manufacturer reported across its fleet from each off-cycle technology. Like Table 25, Table VI-175 provides the mix of technologies used in MY 2016 by manufacturer and the extent to which each technology benefits each manufacturer's fleet. Fuel consumption improvement values for off-cycle technologies were not available in the CAFE program until MY 2017, and therefore only GHG off-cycle credits have been generated by manufacturers thus far.

[1676] "*EPA Decision Document: Off-cycle Credits for Fiat Chrysler Automobiles, Ford Motor Company, and General Motors Corporation*," U.S. EPA-420-R-15-014, Office of Transportation and Air Quality, September 2015. Note: "0.0" indicates the manufacturer implemented that technology, but the overall penetration rate was not high enough to round to 0.1 g/mi whereas a dash indicates no use of a given technology by a manufacturer.

In 2016, manufacturers generated the vast majority of credits using the pre-defined menu.[1677] Although MY2014 was the first year that manufacturers could generate credits using pre-defined menu values, manufacturers have acted quickly to generate substantial off-cycle improvements. FCA and Jaguar Land Rover generated the most off-cycle credits on a fleet-wide basis, reporting credits equivalent to approximately 6 g/mile and 5 g/mile, respectively. Several other manufacturers report fleet-wide credits in the range of approximately 1 to 4 g/mile. In

[1677] Thus far, the agencies have only granted one manufacturer (GM) off-cycle credits for technology based on 5-cycle testing. These credits are for an off-cycle technology used on certain GM gasoline-electric hybrid vehicles, an auxiliary electric pump, which keeps engine coolant circulating in cold weather while the vehicle is stopped and the engine is off, thus allowing the engine stop-start system to be active more frequently in cold weather.

MY2016, the fleet total across manufacturers equaled approximately 2.5 g/mile. The agencies expect that as manufacturers continue expanding their use of off-cycle technologies, the fleet-wide effects will continue to grow with some manufacturers potentially approaching the 10 g/mile fleet-wide cap.

(2) Addition of high efficient alternator technology to off-cycle menu list

During the MY 2017-2025 rulemaking process, the agencies received several comments from the automobile industry associations, individual manufacturers, and suppliers requesting the agencies include high efficiency alternators on the off-cycle defined technology list.[1678] The agencies agreed that high efficiency alternators have the potential to reduce electrical load, resulting in lower fuel consumption and CO_2 emissions. However, at that time, the agencies lacked supporting data across a range of vehicle categories and range of technology implementation strategies. The agencies asked manufacturers to consider two items: first, the amount of credit that the agencies should give for levels of alternator efficiency, and second, how manufacturers could ensure proper accounting of efficiency with different vehicle components, accessories, and associated loads.

Based on data acquired since the 2012 rulemaking, the agencies are now proposing to add high efficiency alternators to the off-cycle menu list with value of 0.16 g/mile per percent efficient improvement from 68 percent VDA.[1679] Since the 2012 final rule for MYs 2017 and later, the agencies have received three off-cycle requests from Ford, GM, and FCA using an alternative methodology to demonstrate the off-cycle benefit of high efficiency alternators.[1680] Each request provided in-use data for average accessories load and levels of improvement in alternator improvement from baseline of average.

Ford conducted lab and in-use testing of two different vehicles to assess the electrical loads. Ford stated that standard 2-cycle testing could measure some benefits of a high efficiency alternator; however, on-road driving conditions frequently demand a higher vehicle electrical load than observed in the test cycle. To show the difference between the standard 2-cycle test and on-road driving conditions, Ford measured alternator loads from 47 unique MY 2014 and MY 2015 Ford Fusions and F150s. The test results showed the difference in electrical power between 72 percent VDA efficient alternator and 67 percent VDA efficient alternator between 2-cycle tests and on-road driving. The benefits of the high efficiency alternator were derived based on 2012 TSD Table 5-18[1681] that identified what the average fuel consumption improvement average value is for 100-watt power reduction in electrical load. Ford requested an approval of

---

[1678] Federal Register Vol. 77, No.199, Oct 5, 2012 Page 62730.

[1679] The VDA (Verband der Automobilindustirie) efficiency rating is the weighted average of the alternator efficiencies measured in component bench tests at four different alternator speeds.

[1680] "*Compliance Information for Light-Duty Greenhouse Gas (GHG) Standards,"* https://www.epa.gov/vehicle-and-engine-certification/compliance-information-light-duty-greenhouse-gas-ghg-standards Access March 9, 2018.

[1681] "*Joint Technical Support Document: Final Rulemaking for 2017-2025 Light-Duty Vehicle Greenhouse Gas Emission Standards and Corporate Average Fuel Economy Standards,*" Page 5-66, EPA-420-R-12-901 (August 2012) an off-cycle improvement value of 0.8 grams/mile CO_2 for a 5 percent alternator efficiency increase from 67% to 72%.

GM also conducted lab and in-use testing to assess the potential difference in fuel consumption improvement values from alternators with varying efficiencies. GM analyzed different efficiency alternators across multiple vehicle classes using its GM Unified Model software. GM requested approval of an off-cycle improvement value of 0.16 grams/mile CO_2 for each 1 percent VDA efficiency improvement above a 67 percent efficiency baseline rating.

FCA's request for high efficiency alternator credit considered alternative methodologies in comparing different brand alternator efficient using EPA's Alpha 2.0 model. FCA modeled multiple vehicle configurations with alternator efficiencies of 67%, 73%, and 80% VDA at two electrical loads.[1682] FCA determined the environmental and base vehicle electrical load by testing a fleet of fourteen vehicles. These vehicles included MY 2014-2016 small, medium and large cars, as well as light duty trucks and SUVs, in varying trim levels and accessory configurations. FCA's petition requested approval of an off-cycle improvement value of 0.14 grams/mile CO_2 for each 1 percent VDA efficiency improvement above a 67 percent efficiency baseline rating.

The agencies believe that appropriate data – from both in-use testing of different vehicle classes and impact of different VDA efficiencies – has been provided to propose adding high efficiency alternators to the off-cycle menu list. For this final rule making, the agencies are adding high efficiency alternators to the off-cycle menu list with a value of 0.14 g/mile per percent efficient improvement from baseline of 68 percent VDA.

c) A/C and Off-Cycle Effectiveness Modeling

The NPRM analysis used the off-cycle FCIVs and credits earned by each manufacturer in MY 2016 and carried these forward at the same levels for future years for the CO_2 analysis and beginning in MY 2017 for the CAFE analysis. The 2016 values for off-cycle FCIVs for each manufacturer and fleet, denominated in grams CO_2 per mile,[1683] are provided in Table VI-177.[1684] Additional off-cycle FCIVs were added in future years if a manufacturer applied a technology that was explicitly simulated in the analysis and also was an off-cycle technology

---

[1683] For the purpose of estimating their contribution to CAFE compliance, the grams CO_2/mile values in Table VI-177 are converted to gallons/mile and applied to a manufacturer's 2-cycle CAFE performance. When calculating compliance with EPA's CO_2 program, there is no conversion necessary (as standards are also denominated in grams/mile).
[1684] 2016 GHG Manufacturer Performance Report. EPA-420-R-18-002. January 2018.
https://nepis.epa.gov/Exe/ZyPDF.cgi?Dockey=P100TGIA.pdf. Last Accessed Nov. 14, 2019.
2016 Report Tables for the GHG Manufacturer Performance Report. January 2018.
https://www.epa.gov/sites/production/files/2018-01/ghg-report-2016-data-tables.xlsx. Last Accessed Nov. 14, 2019.

listed on the predefined menu.[1685] Technologies explicitly simulated in the analysis that are also on the off-cycle menu include start-stop systems that reduce fuel consumption during idle and active grille shutters that improve aerodynamic drag at highway speeds, among others. Any off-cycle adjustments that accrued as the result of applying these technologies were calculated dynamically in each model year the technology was applied, with adjustments accumulating up to the 10 g/mi cap. As a practical matter, most of the adjustments for which manufacturers can claim off-cycle FCIVs exist outside of the CAFE model technology tree so the off-cycle menu cap was rarely reached for the NPRM analysis.

The agencies sought comment on both the A/C and off-cycle data that was used for the NPRM analysis as well as the assumptions for applying those technologies.

[1685] For more details, see Section IX.D Compliance Issues that Affect Both the CO_2 and CAFE Programs and Section IX.D.3 Flexibilities for Off-Cycle Technologies.

Table VI-177 – NPRM Base Off-Cycle CO_2 Adjustments for MY 2016 and Later Model Years[1686]

Manufacturer	**Off-Cycle Adjustment per Vehicle (g CO_2/mile)**	
	PC	**LT**
BMW	1.70	2.60
Daimler	1.60	0.50
FCA	2.90	7.30

SUBARU	-	-
Tesla	-	-
TOYOTA	0.60	2.80
Volvo	-	-
VWA	-	-

Universally, stakeholders believed the application of off-cycle adjustments in the analysis was too conservative. Stakeholders believed the A/C and off-cycle technologies would be rapidly deployed and manufacturers would reach the cap values within the rulemaking timeframe.

The Institute for Policy Integrity (IPI) questioned the position the agencies assumed in the NPRM analysis, and suggested the agencies "assume that manufacturers will efficiently deploy all cost-saving offset opportunities, especially in the face of increasingly stringent standards."[1687]

ICCT stated "far greater use of the off-cycle provisions will occur by 2025" and emphasized that off-cycle technologies are "highly cost-effective and being deployed in greater

---

[1686] *See* 83 FR 43159-60 ("…this analysis uses the off-cycle credits submitted by each manufacturer for MY 2017 compliance and carries these forward to future years with a few exceptions.").
[1687] Comments from Institute from Policy Integrity, Attachment 1, NPRM Docket No. NHTSA-2018-0067-12213, at 20-21.

sales penetrations than many of the test-cycle efficiency technologies that the agencies are analyzing."[1688] ICCT supported manufacturers maximizing the use of off-cycle technologies, and supported the analysis estimating "fleetwide off-cycle credit use at over 10 g/mile by 2020," and further suggested fleetwide achievement of 15 g/mile by 2025.[1689]

FCA, General Motors and the Auto Alliance all provided similar observations, stating "[m]anufacturers have rapidly deployed technology in response to this all new regulatory mechanism." Each of the commenters provided support for an argument of rapid off-cycle technology adoption, stating "[i]n the MY2021-2026 timeframe of the proposed rule, it is likely that manufacturers will hit the existing 10 g/mi cap."[1690]

The DENSO Corporation further supported the increased use of off-cycle technologies, commenting that "[a]vailable data on OEM off-cycle technology credit utilization within the past few years demonstrates that the use of off-cycle technologies is expected to grow—particularly technologies on the credit menus."[1691]

However, Toyota Motors North America asked for constraints on considerations of off-cycle technology in the analysis.[1692] Toyota expressed concern for over-reliance on off-cycle technologies to provide flexibilities for compliance, as "most of the technologies provide little tangible value proposition for customers." In additional comments, Toyota repeated the concern noting, "most of these technologies lack consumer demand." Finally, Toyota specifically cautioned against overusing off-cycle technologies in the analysis, stating "[t]he suggested pursuit of maximum credits overlooks the associated costs and market acceptance challenge for certain off-cycle technologies." Toyota listed costs versus risk of customer acceptance and agency approval as factors that "introduce a high level of uncertainty for an auto manufacturer's planning and make investments in off-cycle technologies risky and less appealing."

After carefully considering the comments, the agencies agree that A/C and off-cycle technologies are likely to be more broadly applied by manufacturers within the rulemaking timeframe. The final rule analysis has been updated to reflect an increased application of the technologies. Similar to the NPRM, the final rule analysis used the A/C and off-cycle FCIVs earned by each manufacturer in the baseline fleet (MY 2017 for the final rule analysis) as a

---

[1688] Comments from ICCT, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11741, at I40 – I41.

[1689] Note there is a regulatory "cap" on menu technologies of 10 g/mi (see Section IX for further discussion of the cap), however a manufacturer can receive additional off-cycle credit/FCIV by using the pathways described above to petition for off-menu technologies. ICCT's comment suggests that manufacturers will reach the regulatory menu cap and apply additional technologies to get an additional 5 g/mi credit above the menu cap.

[1691] Comments from DENSO Corporation, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11880, at 6.

[1692] Comments from Toyota Motors North America, Attachment 1, NHTSA Docket No. NHTSA-2018-0067-130798, at 9-10; Supplemental Comments from Toyota Motors North America, Attachment 1, NHTSA Docket No. NHTSA-2018-0067-12150, at 24; Supplemental Comments from Toyota Motors North America, Attachment 1, NHTSA Docket No. NHTSA-2018-0067-12376, at 4-5.

starting point. However, the final rule analysis increased these values in subsequent model years. In addition to the dynamic application of off-cycle FCIVs, as in the NPRM, each manufacturer's fleet FCIVs were increased by extrapolating the manufacturers' historical rate of FCIV application through 2017.[1693] In line with most commenters, the agencies increased the FCIVs for each manufacturer such that the maximum value of 10 g/mi will be reached by MY 2023. For manufacturers who did not reach maximum values prior to 2023 through data extrapolation, a linear increase to the cap was assumed. The agencies believe this approach balances a greater application of FCIV technologies across the fleet, while avoiding uncertain over-reliance on flexibilities for the analysis.

The agencies disagreed with the proposal to model the application of 15 g/mi of FCIVs universally in the rulemaking timeframe. Based on historical data and industry comments from both manufacturers and suppliers, the agencies expect there will be an increase in off-cycle technology application. However, there are two issues with assuming manufacturers will exceed the existing off-cycle caps. First, only a few manufacturers approached the cap limit in MY 2018, and the fleet average menu credit was 4.7 grams/mile, less than half the cap value.[1694] Second, new off-cycle technologies may address the same inefficiencies as menu technologies, rather than work in conjunction. Accordingly, the agencies believe there is a reasonable basis for assuming manufacturers could, and would only achieve 10 g/mi on average by MY 2023, and used that assumption for the final rule analysis.

Table VI-178 shows passenger car values for FCIVs and Table VI-179 shows light truck values for FCIVs applied for the final rule analysis.

d) A/C Efficiency, A/C Leakage and Off-Cycle Costs

As discussed above, the only A/C efficiency and off-cycle technologies applied dynamically in the NPRM analysis were explicitly simulated technologies like stop-start systems and active aerodynamic technologies. The NPRM analysis fully accounted for both the effectiveness and cost of these technologies and therefore separate cost accounting was not needed. For example, when stop-start or active aerodynamics technology was added by the model to a vehicle, the corresponding off-cycle FCIVs were applied and the technology costs were captured the same as every other technology on the decision trees.

For the final rule analysis, A/C and off-cycle technologies are applied independently of the decision trees using the extrapolated values, so it is necessary to account for the costs of those technologies independently. Table VI-180 shows the costs used for A/C and off-cycle FCIVs the final rule analysis. The costs are shown in dollars per gram of CO_2 per mile ($ per g/mile). The A/C costs and off-cycle technology costs are the same costs used in the EPA Proposed Determination and described in the EPA Proposed Determination TSD.[1695]

Table VI-180 – A/C and Off-Cycle FCIV Costs for this final rulemaking in dollars per gram of CO_2 per mile ($2018)

D. Impacts that Result From Simulating Manufacturer Compliance with Regulatory Alternatives

1. Simulating Economic Impacts of Regulatory Alternatives

a) What Economic Impacts Occur When Vehicle Manufacturers Comply with Different CAFE and CO_2 Standards?

(1) The NPRM Framework for Analyzing Economic Impacts

In the proposed rule, the agencies noted the importance of identifying the mechanisms by which vehicle manufacturers' compliance with different CAFE and CO_2 standards generated impacts on manufacturers, owners of new and used vehicles, and the remainder of the U.S. The agencies organized the analysis of alternative standards using a framework that clarified the economic impacts on vehicle producers, illustrated how costs were transmitted to buyers of new vehicles, highlighted the collateral economic effects on owners of used vehicles, and identified how these responses created various indirect costs and benefits. Throughout the analysis, the agencies stressed the distinction between the proposal's economic consequences for private businesses and households, and its "external" economic impacts—those ultimately borne by the rest of the U.S. economy.

To clarify the framework used in the proposal, the agencies used Table VI-181 below (which is based on Tables II-25 to II-28 from the NPRM)[1696] to report costs and benefits and to trace how they pass through the economy. As the table shows, the economic impacts of standards initially fall on vehicle manufactures, but ultimately are borne by consumers who

[1695] EPA PD TSD. EPA-420-R-16-021. November 2016. At 2-423 – 2-245. https://nepis.epa.gov/Exe/ZyPDF.cgi?Dockey=P100Q3L4.pdf . Last accessed Nov.14, 2019.
[1696] *See* 83 FR at 43062-66.

purchase and drive new models. Smaller, indirect economic effects of the proposal would be borne by owners of used cars and light trucks (vehicles produced during model years prior to those affected by the proposal, but still in use) as well as by the general public and government agencies. On balance, the agencies projected that most of the proposal's economic effects would fall on private businesses and households, with the remainder of the U.S. economy bearing much smaller impacts.

Table VI-181 – Benefits and Costs Resulting from Proposed CAFE Standards

Line	**Affected Party**	**Source**	**Private Benefits and (Costs)**
1	Vehicle Manufacturers	CAFE model	Savings in technology costs to increase fuel economy
2			Reduced fine payments for non-compliance
3		assumed = -(1+2)	Net loss in revenue from lower vehicle prices
4		net = 1+2+3	Net benefits to manufacturers
5	New Vehicle Buyers	assumed = 3	Lower purchase prices for new vehicles
6		CAFE model	Reduced injuries and fatalities from higher vehicle weight
7			Higher fuel costs from lower fuel economy (measured using retail fuel prices)
8			Inconvenience from more frequent refueling
9			Lost mobility benefits from reduced driving
10		net = 5+6+7+8+9	Net benefits to new vehicle buyers
11	Used Vehicle Owners	CAFE model	Reduced costs for injuries and property damage costs from driving in used vehicles
12	All Private Parties	net = 4+10+11	Net private benefits
Line	Affected Party	Source	External Benefits and (Costs)
13	Rest of U.S. Economy	CAFE Model	Increase in climate damages from added CO_2 Emissions
14			Increase in health damages from added emissions of air pollutants
15			Increase in economic externalities from added petroleum use
16			Reduction in civil penalty revenue
17			Reduction in external costs from lower vehicle use
18			Increase in Fuel Tax Revenues
19		net = 13+14+15+16+17+18	Net external benefits
Line	Affected Party	Source	Economy-Wide Benefits and (Costs)
20	Entire U.S. Economy	total = 1+2+5+6+11+17+18	Total benefits

Line	Affected Party	Source	Private Benefits and (Costs)
21		total = 3+7+8+9+13+14+15+16	Total costs
22		net = 20+21 (also =12+19)	Net Benefits

More specifically, the agencies' analysis showed that the proposal would initially have saved manufacturers the costs of adding the technologies that would otherwise have been necessary to enable their new cars and light trucks to comply with the baseline fuel economy and CO_2 emissions regulations, with the estimated dollar value of those savings shown in line 1 of Table VI-181. The proposal also enabled some manufacturers to make lower civil penalty payments for failing to comply with the more demanding standards that were supplanted (line 2), although these savings would have been exactly offset by lower civil penalty revenue to the Federal Government (line 16). The analysis assumed that manufacturers would have the ability, in a competitive market, to pass their savings in technology costs and any reduction in civil penalties paid on to buyers, by charging lower prices for new vehicles. Although lower prices reduced their revenues (line 3), on balance, their savings in compliance costs, reduced civil penalty payments, and lower sales revenue were assumed to leave manufacturers financially unaffected (shown by the zero entry in line 4 of the table).

Under the proposal, the analysis showed that buyers of new cars and light trucks benefited directly from those vehicles' lower purchase prices and financing costs (line 5). They also avoided the increased risk of crash-related injuries that would have resulted from reductions in the weight of some new models, as manufacturers attempted to improve fuel economy to comply with the baseline standards. The economic value of this reduction in risk represented an additional benefit from the proposal to reducing the stringency of the standards vis-à-vis the baseline (line 6).

At the same time, however, the lower fuel economy that some new cars and light trucks were expected to offer with less stringent standards in place would have imposed various additional costs on their buyers and users. Drivers experienced higher fuel costs as a consequence of new vehicles' increased fuel consumption (line 7), as well as the added time and inconvenience of having to make more frequent refueling stops required by reduced driving range (line 8). They also forfeited some mobility benefits as they drove newly-purchased cars and light trucks less in response to their higher fuel costs (line 9). On balance, the agencies' analysis of the proposal showed that buyers of new cars and light trucks produced during the model years it affected would experience significant economic benefits (line 10).

A novel feature of the agencies' evaluation of the proposal showed that lowering prices for new cars and light trucks, some owners of used vehicles retired them from service earlier than they otherwise would have done. In combination with increased sales of new models, this transferred some driving that would have occurred with used cars and light trucks to newer and safer models, thus reducing the total costs of fatalities and injuries sustained in motor vehicle crashes.[1697] In the proposal, this reduction in injury risks provided benefits to owners and drivers of older cars and light trucks that had not been recognized or quantified in its analyses of previous CAFE and CO_2 standards (line 11).

Table VI-181also showed that the changes in fuel consumption and vehicle use resulting from the proposal would in turn generate both benefits and costs to the remainder of the U.S. economy. The analysis described these as "external" effects, in the sense that they were by-products of households' choices among new vehicle models, decisions about keeping older cars and light trucks in service, and allocations of driving across the fleet that were experienced broadly throughout the U.S. economy, rather than by the individuals making such decisions. The largest of these was additional refining and consumption of petroleum-based fuel and the associated increases in emissions of carbon dioxide and other gases, which were projected to increase the cost of economic damages inflicted on the U.S. economy by future changes in the global climate (line 13). Added fuel production and use under the proposal also led to higher emissions of localized air pollutants, and the resulting increase in the U.S. population's exposure and its adverse effects on health imposed additional external costs (line 14).

Increased consumption of petroleum-derived fuel also imposed higher external costs on the U.S. economy, in the form of potential losses in economic output and costs to businesses and households for adjusting to any sudden changes in energy prices (line 15 of the table). Reduced driving by buyers of new cars and light trucks in response to their higher operating costs also reduced the external costs from their contributions to traffic delays and noise, benefits that were expected to be experienced throughout the U.S. economy (line 17). Finally, some of the higher fuel costs to buyers of new cars and light trucks will consist of increased fuel taxes; this increase in revenue was projected to enable Federal and State government agencies to improve upkeep of roads and highways, fund increases in other services, or reduce other tax burdens (line 18).[1698]

The net economic effect (line 22) of the proposal consisted of the benefits and costs imposed directly on car and light truck manufacturers, accompanying indirect effects on buyers of new vehicles and owners of used ones, external costs driving decisions generated throughout the U.S. economy, and changes in revenue to government agencies. The agencies' organization was intended to convey the causal connections among these impacts, by highlighting how the proposed change in fuel economy standards faced by manufacturers would set in motion the sequence of behavioral responses that determined its economy-wide costs and benefits. This contrasted with the way benefits and costs of previous proposals to establish CAFE and CO_2 standards were analyzed and presented, which obscured their sequence and causal connections.

In those previous analyses, most economic effects other than manufacturers' costs to comply with proposed standards and anticipated changes in fuel consumption were grouped

---

[1697] This improvement in safety resulted from the fact that cars and light trucks have become progressively more protective in crashes over time (and also slightly less prone to certain types of crashes, such as rollovers). Thus, shifting some travel from older to newer models reduced injuries and damages sustained by drivers and passengers because they were traveling in inherently safer vehicles, rather than because of changes to driver risk profiles.

[1698] In some States, levies on gasoline include both general sales taxes as well as excise taxes, and not all proceeds are dedicated to transportation purposes.

together and reported as "co-benefits." This obscured how these various consequences arose from the proposed standards, providing no information about who would ultimately experience the costs of complying with the standards, or who would experience their direct and indirect benefits. In contrast, the recent analysis spelled out how each category of benefits and costs resulted from the proposed change in standards, identified the mechanisms that translated direct economic impacts into indirect costs and benefits, and distinguished between those arising from changes in fuel consumption, and safety consequences of changes in vehicle use. The proposal's framework also clarified who would bear each category of impacts, distinguishing between the proposal's economic impacts on private actors—vehicle manufacturers, new car and light truck buyers, and owners of used vehicles—and the external economic consequences for the general public and government agencies that stem indirectly from such private impacts.

(2) Final Rule Framework

While the agencies received several comments about which economic effects are included in the analysis, the agencies received no comments about the specific structure of the framework. Substantive comments about individual effects are addressed over the next several sections.

The agencies have expanded the accounting framework for benefits and costs shown in Table VI-181 above to include two additional entries, as well as to distinguish financial impacts on government agencies from externalities borne broadly across the remainder of the U.S. economy. The revised accounting framework for costs and benefits is shown in Table VI-182, below. Line 6 of the revised table reports the change in consumer surplus experienced by buyers of new cars and light trucks when prices and sales of those vehicles adjust in response to changes in CAFE and CO_2 standards. The gain in consumer surplus that occurs when production costs and prices for vehicles fall and sales increase in response represents a benefit to buyers, while any loss in consumer surplus that occurs when more stringent standards increase costs and prices and cause sales to decline appears as a loss to new car and light truck buyers.

Line 7 of Table VI-182 reports the estimated value of changes to attributes of new cars and light trucks other than fuel economy that their manufacturers make to comply with changes in CAFE and CO_2 standards. In the case where standards are less stringent, manufacturers are able to employ many of the same resources they would have deployed to increase fuel economy for the alternative purpose of improving other attributes of vehicles that their potential buyers value more highly than the forgone improvements in fuel economy. This response provides an additional benefit to purchasers of new cars and light trucks that was not recognized in the agencies' analysis of the proposal, but is included in the analysis of this final rule. Of course, if CAFE and CO_2 standards are made more stringent, manufacturers employ those technologies to increase fuel economy, thus sacrificing potential improvements in competing attributes—those that entail tradeoffs with higher fuel economy—and the value of improvements in those other attributes that is sacrificed or forgone represents an opportunity cost to those buyers. This implicit opportunity cost is analyzed in a sensitivity analysis and is not included in the primary analysis.

Finally, the agencies revised the framework for reporting costs and benefits of changes in CAFE and CO_2 standards to identify government agencies separately from the entry previously labeled “Rest of U.S Economy.” This minor revision is intended to distinguish more clearly between changes in external costs imposed by externalities that result from fuel production and use, and the revenue effects on government agencies from changes in tax and civil penalty payments. While both effects ultimately result from manufacturers’ compliance with revised standards and the resulting changes in fuel consumption, externalities represent real economic costs; in contrast, changes in tax revenues received by government agencies are financial transfers, whose offsetting effects on manufacturers and vehicle buyers are also recognized elsewhere in the accounting framework.

Table VI-182 – Benefits and Costs of Final CAFE and CO_2 Standards

Line	Affected Party	Source	Private Benefits and (Costs)
1	Vehicle Manufacturers	CAFE model	Savings in technology costs to increase fuel economy
2			Reduced penalties for non-compliance
3		assumed = -(1+2)	Net loss in revenue from lower vehicle prices
4		net = 1+2+3	Net benefits to manufacturers
5	New Vehicle Buyers	assumed = 3	Lower purchase prices for new vehicles
6		CAFE model	Gain in consumer surplus from lower vehicle prices
7			Im (sensitivity analysis case only)
8			Reduced injuries and fatalities from higher vehicle weight
9			Higher fuel costs from lower fuel economy (measured using retail fuel prices)
10			Time and inconvenience from more frequent refueling
11			Loss in mobility benefits from reduced driving
12		net = 5+6+8+9+10+11	Net benefits to new vehicle buyers
13	Used Vehicle Owners	CAFE model	Reduced costs for injuries and property damage costs from driving in used vehicles
14	All Private Parties	net = 4+12+13	Net private benefits
15	Government agencies	CAFE Model	Reduction in revenue from civil penalties
16			Increase in fuel tax revenue
17		Net=15+16	Net effect on government agency revenue
18	Rest of U.S. Economy	CAFE Model	Increase in climate damages from added CO_2 Emissions
19			Increase in health damages from added emissions of air pollutants
20			Increase in economic externalities from added petroleum use
21			Reduction in external costs from lower vehicle use
22		net = 18+19+20+21	Net external benefits
23	Entire U.S. Economy	total = 1+2+5+6+8+13+16+21	Total benefits
24		total = 3+7+9+10+11+15+18+19+20	Total costs
25		net = 21+22 (also =14+17+22)	Net Benefits

b) Economic Assumptions

The agencies' analysis of CAFE and CO_2 standards for the model years covered by this final rule rely on a range of forecast information, estimates of economic, safety, and environmental variables, and input parameters. While the analysis accompanying the proposal largely resembled previous CAFE and CO_2 analyses, the agencies updated many of the underlying inputs and assumptions—based on the most up-to-date data—and expanded the central analysis to account for changes in new vehicle sales and the retirement of older vehicles.

EDF, UCS, CARB and others commented that the agencies acted arbitrarily and capriciously by changing inputs and assumptions from previous analyses, and argued that the agencies failed to provide "good reasons" for the changes.[1699] In the following sections, the agencies will respond directly to these comments. However, the agencies note that it would be uncommon to retain inputs and assumptions from prior analyses—which are typically informed by transitory empirical observations—on the basis of precedent. The agencies are "neither required nor supposed to regulate the present and the future within the inflexible limits of yesterday."[1700]

The agencies also received a number of comments focused on the agencies' attempt to incorporate the effects of changes in new vehicle prices on new vehicle sales, retirement rates of used vehicles, and the resulting "turnover" of the vehicle fleet. Some comments endorsed the agencies' more comprehensive analysis, although many of those same commenters later disagreed with aspects of the results. For example, RFF noted that "Incorporating sales and scrappage effects represents a step in the right direction for modeling the effects of the regulation."[1701] Similarly, NRDC stated that "it is reasonable and appropriate to develop a mechanism for estimating future vehicle populations, and the NPRM documents appropriately present considerable discussion on the topic and the derivation of the utilized algorithm."[1702] One commenter explicitly recognized that the narrower analysis utilized in previous rules likely led to incorrectly estimating costs and benefits, and endorsed the broader approach used by the proposal. Specifically, American Fuel & Petrochemical Manufacturers stated that the absence of scrappage in prior rules "likely led to a significant overestimation of the existing standard's benefits with respect to fuel and air pollutant emission reductions and an underestimation of safety risks and societal costs." FCA also expressed general support for the agency's expanded analysis.[1703]

In contrast, some commenters objected to the inclusion of 'new' impacts, including the effect of fuel economy regulations on new vehicle prices, the resulting changes in their sales, and retirement rates for used cars. Workhorse Group, Inc. noted that the agencies "made novel

[1703] FCA, NHTSA-2018-0067-12078.

assumptions about the safety impacts of consumers delaying vehicle purchases due to the increased costs of fuel economy improvements that contradicts the analytical approach NHTSA has followed in all prior safety and CAFE rulemakings."[1704] Honda agreed "that significantly higher-priced new vehicles have the potential to depress the new vehicle market and thus increase the fleet of used vehicles, with concomitant increased safety risks associated with driving greater numbers of older vehicles in lieu of newer ones," but found it "premature and ill-advised" to model the impact of fleet turnover.[1705] CBD et. al. argued that the sales and scrappage effects were too uncertain to include in the analysis and cited EPA's 2016 proposed determination as stating, "a reasonable qualitative assessment is preferable to a quantitative estimate lacking sufficient basis, or (due to uncertainties like those here) having such an enormous range as to be without substantial value."[1706]

As was done repeatedly throughout the proposal, the agencies acknowledge that dynamically modeling fleet turnover is new for this rulemaking; however, the agencies disagree that the analysis relied on 'novel' assumptions or contradicted previous analyses. The agencies have described the sales and scrappage responses similarly in prior rulemakings,[1707] and have expressed an interest in quantitatively measuring them.[1708] The agencies agree with commenters that—like many of the effects included in today's analysis—there remains a degree of uncertainty about the magnitude of the sales and scrappage responses. However, *CBD v. NHTSA* stressed that a variable should not be excluded from the analysis simply because it is uncertain when the effect is quantifiable, "certainly not zero," and the analysis "monetize[s] other uncertain benefits."[1709] As discussed in the coming sections, the agencies are confident that (a) changes in new vehicle prices impact the volume of new vehicle sales and rate of retirement of older vehicle, (b) of the direction of those effects, and (c) their ability to reasonably estimate the impacts. As such, the agencies strongly believe that including the sales and scrappage responses improves the thoroughness of the analysis, is consistent with case law, and is necessary to comprehensively analyze the cost-benefits of the rule.

The following subsections briefly describes the sources of the agencies' estimates of each of the economic, environmental, and safety estimates. In reviewing these variables and the agencies' estimates of their values for purposes of this final rule, NHTSA and EPA considered comments received in response to the proposed rule and, in response, made several changes to the economic assumptions used for the final analysis.

(1) Macroeconomic Assumptions that Affect the Agencies' Analysis

As the proposed rule noted, the more comprehensive economic impact analysis of CAFE and CO_2 included in this rulemaking requires a more detailed and explicit explanation of the

macroeconomic context in which regulatory alternatives are evaluated. The agencies continued to rely on projections of future fuel prices to evaluate manufacturers' use of fuel-saving technologies, the resulting changes in fuel consumption, and various other benefits. Furthermore, the agencies expanded the scope of their analysis to include projecting future sales of new cars and light trucks, as well as the retirement of used vehicles under each regulatory alternative. In addition to projections of future fuel prices, constructing these forecasts requires explicit projections of macroeconomic variables, including U.S. Gross Domestic Product (GDP), labor force participation (the number of persons employed or actively seeking employment), and bellwether interest rates, which are likely to vary according to roughly the same pattern as interest rates on new car loans.

The analysis presented in the proposal as well as the accompanying RIA and EIS employed forecasts of future fuel prices developed by the agencies using the U.S. Energy Information Administration's (EIA's) National Energy Model System (NEMS). An agency within the U.S. Department of Energy (DOE), EIA collects, analyzes, and disseminates independent and impartial energy information to promote sound policymaking, efficient markets, and public understanding of energy and its interaction with the economy and the environment. EIA uses NEMS to produce its Annual Energy Outlook (AEO), which presents forecasts of future fuel prices, among many other energy-related variables. AEO projections of energy prices and other variables are not intended as predictions of what will happen; rather, they are projections of the likely course of these variables that reflect their past relationships, specific assumptions about future developments in global energy markets, and the forecasting methodologies incorporated in NEMS. Each AEO includes a "Reference" case as well as a range of alternative scenarios that each incorporate somewhat different assumptions from those underlying the Reference Case.

For the proposal, the agencies used the AEO2017 version of NEMS, as this was the most current version of the model that was available at the time. Using this version of NEMS, the agencies reevaluated the "Reference," "Low Oil Price," and "High Oil Price" cases described in AEO2017, by setting aside their assumption that mandates by California and other States to sell "Zero Emission Vehicles" (ZEVs) would be enforced. The agencies used the resulting modified Reference case fuel prices as inputs to the proposal's central case results, and used the modified "Low Oil Price" and "High Oil Price" case fuel prices, which were generated using NEMS, as inputs to several of the sensitivity analysis cases that were presented in the proposal. The sensitivity analysis also included a case that applied the Reference case fuel prices from the then recently issued AEO2018, which did not reflect the modification of EIA's forecasting model to set aside state mandates for ZEV sales.[1710]

The analysis supporting the proposed rule simulated the economic impacts of car and light truck manufacturers' compliance with alternative CAFE and CO_2 standards through model year 2032, and in doing so estimated the number of vehicles originally produced and sold in each model year that would remain in service during each year of their useful lives (assumed to extend

[1710] The results of these and other sensitivity analyses were reported in NHTSA and EPA, "Notice of Proposed Rulemaking: The Safer Affordable Fuel-Efficient (SAFE) Vehicles Rule for Model Years 2021–2026 Passenger Cars and Light Trucks," Federal Register Vol. 83, No. 165, August 24, 2018, Tables Vii-90 to Vii-98, pp. 43353-69.

for a maximum of 40 years), as well as their usage, fuel consumption, and safety performance. This required the forecasts of macroeconomic variables that affect vehicle sales, use, and retirement rates, which include U.S. Gross Domestic Product (GDP), the size of the domestic labor force, and key interest rates, to extend well beyond calendar year 2050. One of the few sources that provides forecasts of these variables spanning such a long time horizon was the 2017 OASDI Trustees Report from the U.S. Social Security Administration, and the analysis supporting the proposed rule relied on this source for forecasts of these key macroeconomic measures.[1711]

(a) Comments on the Fuel Price Forecasts and Macroeconomic Assumptions Used in the NPRM Analysis

The agencies received relatively few comments on the projections of fuel prices and macroeconomic variables that were used in their analysis supporting the proposed rule, virtually all of them focused on the fuel price projections the agencies employed. While only one comment questioned the agencies' use of price projections that rely on EIA's methodology and assumptions, a few commenters called attention to the unreliability of price projections reported in earlier editions of AEO. Other comments noted the importance of updating projections used to analyze the proposal to reflect more recent developments in energy markets, without necessarily questioning the reliability of EIA's fuel price projections. Several comments emphasized the implications for the agencies' analysis of the wide variation in alternative fuel price projections reported in both EIA's 2017 and 2018 Annual Energy Outlooks, with most stressing the possibility that future prices might be above even those projected in their High Oil Price cases. Only a single comment identified a potential alternative source of fuel price projections, but noted that it was within the range of projections the agencies considered.

One commenter claimed that AEO's projections of fuel prices are "inappropriate" for the agencies to employ in analyzing the consequences of CAFE and CO_2 standards; because EIA "does not speculate on changes in international policy or geopolitics," which contribute to the uncertainty surrounding future prices.[1712] However, this commenter did not identify an alternative source for fuel price projections that reflect such considerations; and because projections of fuel prices are a central element in the agencies' evaluation of alternative future standards, the observation that EIA's projections do not incorporate some sources of uncertainty is unhelpful by itself.

Some commenters asserted that by relying on the AEO2017 Reference Case projections of fuel prices in their central analysis of the proposed rule while considering the significantly higher fuel prices projection in the AEO High Oil Price scenario only in the accompanying

---

[1711] Social Security Administration, *The 2017 Annual Report of the Board of Trustees of the Federal Old-Age and Survivors Insurance and Federal Disability Insurance Trust Funds*, available at https://www.ssa.gov/OACT/TR/2017/.

[1712] NHTSA-2018-0067-11837, Alliance to Save Energy, p. 2 ("EIA takes a transparently conservative approach in modeling future oil prices, and does not speculate on changes in international policy or geopolitics. As a result, their projections are an inappropriate measure of future fuel prices.").

sensitivity analyses, the agencies inadequately considered the possible effect of higher fuel prices on the estimated economic benefits from alternatives that would have relaxed the augural standards, including the preferred alternative.[1713] Surprisingly, none of these comments acknowledged that the fuel price projections reported in the High Oil Price cases accompanying past editions of the Annual Energy Outlook have so far proven to be significantly above actual prices, or that EIA has consistently lowered its fuel price projections in more recent editions of the AEO. In any case, supplemental material included in the NPRM regulatory docket showed that the ranking of regulatory alternatives by their estimated net economic benefits remained unchanged from the central analysis in the sensitivity analysis that substituted the AEO2017 High Oil Price case projection of fuel prices.

None of the commenters who argued that the agencies inadequately considered the possibility of higher fuel prices observed that the agencies' analogous use of lower fuel price projections from the AEO2017 Low Oil Price case only in their sensitivity analyses inadequately considered the possibility that future fuel prices might prove to be *lower* than projected in the AEO2017 Reference Case, and its potential effect on the proposal's estimated benefits. Nor did any of the commenters offer substantive guidance about how the agencies might revise their analysis to accord greater emphasis to fuel price projections above (or below) those from the AEO Reference Case.[1714]

Other comments stressed the fact that EIA's current projections of future fuel prices are significantly lower than those the agencies relied on when they established CAFE standards through model year 2021 and introduced the augural standards for subsequent model years in the rulemaking they conducted in 2012, citing this as support for the agencies' reconsideration of the augural standards in the current rulemaking.[1715]

One comment compared the range of fuel price projections spanned by the High and Low Oil Price cases from AEO2017 and AEO2018 to the range of future prices spanned by another widely-recognized and relied-upon projection, concluding that the alternative scenarios included in AEO2017 incorporated an even wider range of uncertainty about future prices, and noted that the net economic benefits of the preferred alternative were positive over this entire range of alternative future fuel prices. This same commenter noted that by combining high and low fuel

---

[1713] *See e.g.*, Securing America's Future Energy (SAFE), NHTSA-2018-0067-11981, pp. 12 & 30 and Institute for Policy Integrity, NHTSA-2018-0067-12213, p. 31.

[1714] One commenter did refer to guidance to EPA contained in a National Research Council report on incorporating and conveying uncertainty about key inputs directly into that agency's estimates of benefits from reducing air pollution, rather than simply recognizing it in supplemental sensitivity analyses. This was presumably intended as potential guidance to the agencies about how they might do so in their evaluations of fuel economy and CO_2 standards, although that was not stated explicitly. *See* American Fuel & Petrochemical Manufacturers, NHTSA-2018-0067-12078, p. 19, citing National Research Council(2002), *Estimating the Public Health Benefits of Proposed Air Pollution Regulations,* 2002, available at https://www.nap.edu/catalog/10511/estimating-the-public-health-benefits-of-proposed-air-pollution-regulations.

[1715] For example, Fiat Chrysler Automobiles (FCA) pointed out that the AEO 2017 Reference Case forecast of gasoline prices through 2025 is approximately 36% lower than that in the AEO 2012 Reference Case, which the agencies relied on in the analysis supporting that earlier rulemaking; *see* NHTSA-2018-0067-11943, p. 33.

price projections with alternative assumptions about other key economic variables (such as GDP growth) and parameter assumptions (principally payback period), the agencies' sensitivity analyses captured potentially important interactions between uncertainty regarding fuel prices and other key economic inputs.[1716]

(b) Macroeconomic Assumptions Used to Analyze Economic Consequences of the Final Rule

After considering these comments, the agencies have concluded that there is no convincing reason to rely on sources other than EIA's NEMS model to project future energy prices, or to rely on alternatives to the Reference Case scenario in the current edition of AEO as their basis for using NEMS. The agencies agree that the resulting projections will be uncertain, but note that EIA regularly publishes retrospective analyses comparing past Reference case projections to subsequent market price outcomes, thus enabling an assessment of this uncertainty. Although EIA does not identify its Reference case as a "most likely" outcome, in the agencies' judgment that case's design—which assumes future trends are consistent with historical and current market behavior—makes it a reasonable and appropriate basis for projecting fuel prices to use in the agencies' central analysis of alternative CAFE and CO_2 standards.

The agencies also conclude that the wide range of uncertainty about future petroleum prices encompassed in EIA's "Low Oil Price" and "High Oil Price" cases means that including them in the accompanying sensitivity analyses provides a meaningful basis for assessing the potential economic consequences of future energy prices that prove to be considerably lower or higher than those reflected in the Reference case. Although these alternative cases do not incorporate unbridled speculation regarding hypothetical changes in "international policy or geopolitics," the agencies believe that this restraint means that relying on them produces a more, rather than less, meaningful test of the effect of the inherent uncertainty surrounding projections of fuel prices.

For today's final rule, the agencies have therefore used the AEO2019 version of NEMS to develop projections of future prices for transportation fuels, as this was the most current version available when this analysis was conducted. Using this version of NEMS, the agencies modified EIA's AEO2019 Reference case by (1) setting aside presumed enforcement by California and other States of any mandates to sell "Zero Emission Vehicles" (ZEVs), (2) setting aside post-2020 increases in the stringency of CAFE and CO_2 standards, and (3) modifying inputs regarding battery costs, in order to bring those costs down to levels more consistent with battery cost estimates applied in the CAFE model analysis.[1717] All other NEMS inputs used to develop the AEO2019 Reference case were left unchanged in this analysis.

[1716] *See* Alliance of Automobile Manufacturers, NHTSA-2018-0067-1207, p. 108.

[1717] These inputs are all contained in the "trnldvx.xlsx" NEMS input file. The input file utilized for today's analysis is available in regulatory docket NHTSA-2018-0067, https://www.regulations.gov/docket?D=NHTSA-2018-0067 (see Supporting Documents), as is the corresponding output file from which reference case fuel and electricity prices

Setting aside enforcement of state mandates to sell ZEVs makes the supporting analysis consistent with the agencies' recent One National Program Action,[1718] under which EPA withdrew aspects of a Clean Air Act Preemption waiver previously granted to California, and NHTSA concluded that EPCA expressly and implied preempted State ZEV mandates. Setting aside the post-2020 increase in the stringency of CAFE and CO_2 standards ensures that the fuel prices used in the agencies' analysis are at least as high as those that would prevail under the least stringent regulatory alternative considered, since that alternative produces the highest level of fuel consumption and thus the highest fuel prices.

Figure VI-113 and Figure VI-114 below show the resulting modified projections of BEV prices and sales, and compare them to the projections reported in EIA's AEO2019 Reference case. As they illustrate, the combination of these modifications led NEMS to project significantly lower BEV prices and correspondingly higher BEV sales volumes. Figure VI-115 and Figure VI-116 show the modified projections of gasoline and electricity prices, and again compare these to the projections reported in EIA's AEO2019 Reference case. As those figures indicate, the agencies' modifications to NEMS did not significantly affect its projections of future prices for transportation fuels.

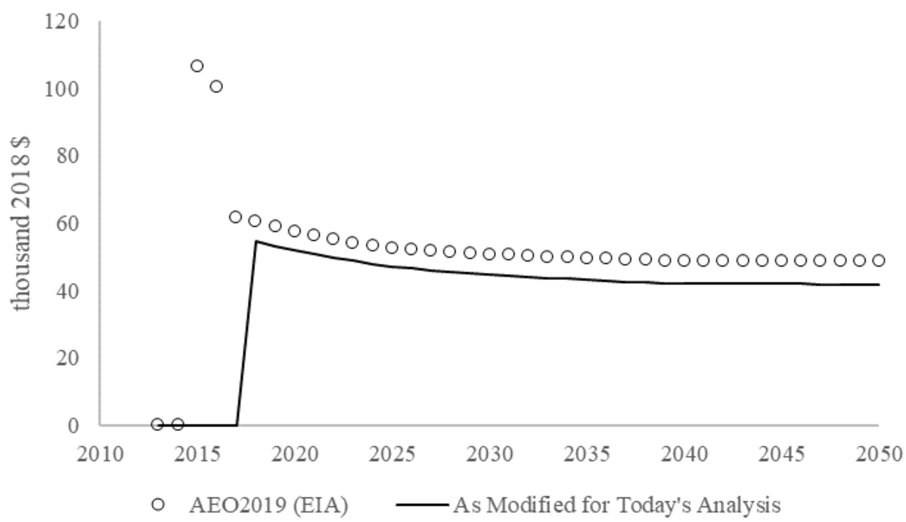

Figure VI-113 – NEMS-Based BEV Prices (Showing 300-Mile Midsize Car)

were obtained to be used as inputs to the CAFE model. The version of NEMS utilized for today's analysis is available at https://www.eia.gov/outlooks/aeo/info_nems_archive.php,

[1718] 84 FR 51310.

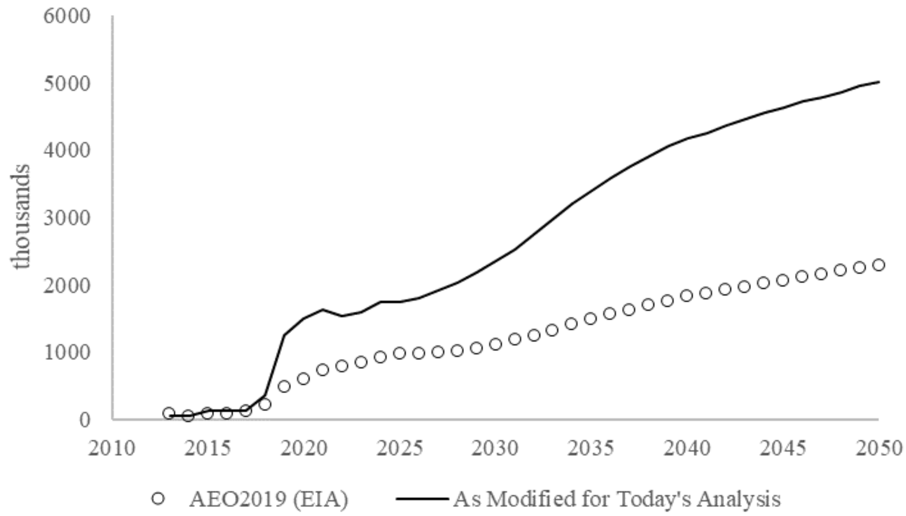

Figure VI-114 – NEMS-Based BEV Sales

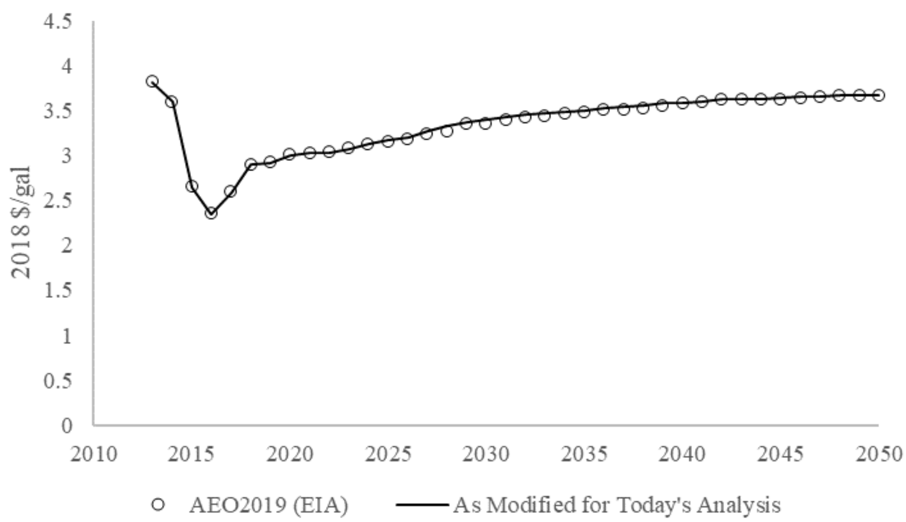

Figure VI-115 – NEMS-Based Gasoline Prices

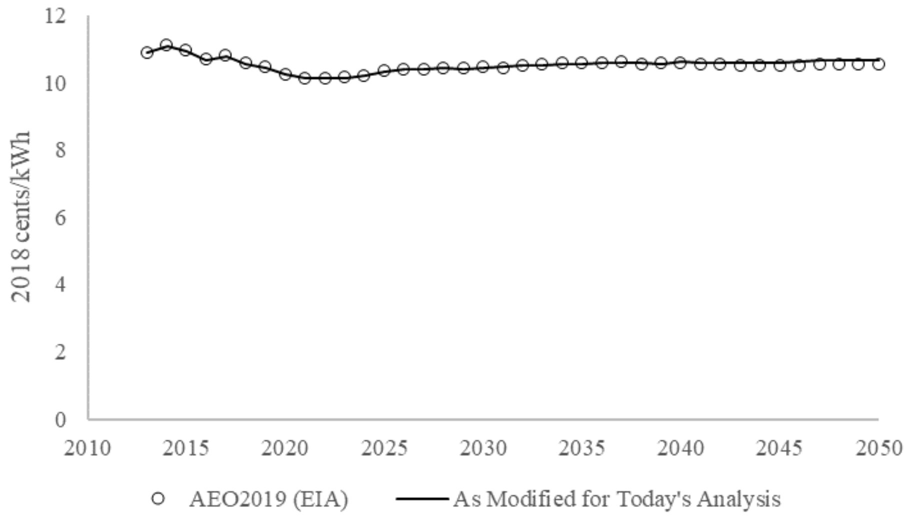

Figure VI-116 – NEMS-Based Electricity Prices (Average to All Users)

The agencies used the resulting Reference case fuel prices as inputs to the rule's central analysis. The agencies also used the as-published (by EIA) "Low Oil Price" and "High Oil Price" case fuel prices as inputs to several of the cases included in the sensitivity analysis.

For the projections of macroeconomic variables used in the analysis supporting this rule, the agencies elected to rely on different sources from those that informed their analysis of the proposed rule. Specifically, the agencies rely on projections of future growth in U.S. GDP reported in AEO2019 to support their central analyses of the final rule's impacts on new car and light truck sales and the retirement of used vehicles. These incorporate underlying projections generated using the IHS Markit Global Insight long-term macroeconomic model, as modified via this model's interaction with NEMS' representation of global energy markets and their future outcomes. The alternative projections of future growth in GDP used in the agencies' sensitivity analyses are drawn from the AEO2019 High Economic Growth and Low Economic Growth cases. These reflect alternative future trends in U.S. labor force and productivity growth, and are also consistent with the energy market outcomes projected by NEMS under the resulting future performance of the U.S. economy.

For estimates of the number of U.S. households during future years, which influence the projections of new car and light truck sales used in the analysis, the agencies rely on projections of new household formation developed the Harvard University Joint Center for Housing Studies.[1719] These are consistent with the most recent projections of future growth in the nation's population prepared by the U.S. Bureau of the Census.[1720]

[1719] *See* Harvard University Joint Center for Housing Studies, Updated Household Growth Projections: 2018-2028 and 2028-2038, December 18, 2018, available at https://www.jchs.harvard.edu/sites/default/files/Harvard_JCHS_McCue_Household_Projections_Rev010319.pdf.
[1720] *Ibid*., pp. 2-5.

(2) Approach to Estimating Sales Response Under Different Standards

Prior to the NPRM, all previous CAFE and CO_2 rulemaking analyses used static fleet forecasts that were based on a combination of manufacturer compliance data, public data sources, and proprietary forecasts (or product plans submitted by manufacturers). When simulating compliance with regulatory alternatives, those analyses projected identical sales across the alternatives, for each manufacturer down to the make/model level—where the exact same number of each model variant was assumed to be sold in a given model year under both the least stringent alternative (typically the baseline) and the most stringent alternative considered (intended to represent "maximum technology" scenarios in some cases). To the extent that an alternative matched the assumptions made in the production of the proprietary forecast, using a static fleet based upon those assumptions may have been warranted. However, a sales forecast is unlikely to be representative of a broad set of regulatory alternatives with significant variation in the cost of new vehicles. A number of commenters on previous regulatory actions encouraged consideration of the potential impact of fuel efficiency standards on new vehicle prices and sales, and the changes to compliance strategies that those shifts could necessitate.[1721] In particular, the continued growth of the utility vehicle segment creates compliance challenges within some manufacturers' fleets as sales volumes shift from one region of the footprint curve to another, or as mass is added to increase the ride height of a vehicle on a sedan platform to create a crossover utility vehicle, which exists on the same place of the footprint curve as the sedan upon which it might be based.

However, some NPRM commenters referenced the agencies' previous omission of this effect as justification to continue ignoring this issue in the current rulemaking. EDF commented,[1722] "use of a sales response model constitutes an unexplained reversal in the agency's position on the feasibility of doing so." To say that the agencies never used a model is a misrepresentation. Assuming that sales never change in any model year, even at the individual nameplate level, regardless of the stringency of fuel economy regulations or the technology costs required to comply with those regulations, is, itself, a model. It is a model that implicitly asserts that, while fuel economy regulation impacts vehicle prices, such regulations have no impact on the quantity or mix of new vehicle sold, regardless of stringency. This is an implicit argument that new vehicle demand is perfectly inelastic—and that no change in vehicle prices can impact the number of cars consumers will buy. Logically, however, there must exist a level of stringency that would have a negative impact on new sales. Picking an extreme example to prove the point, if the agencies set standards at an extraordinarily stringent level that forced all vehicles into battery electric propulsion systems next year, sales would obviously be impacted. The increase in new vehicle price or changes to other relevant attributes like range, refueling time, or operating cost would surely affect the decisions of some buyers. But, by arguing that the agencies should continue to model new vehicle sales as if they are entirely unaffected by standards, commenters are effectively asking the agencies to assume that the alternatives considered in this rule are insufficiently stringent to affect the market. By endorsing the

[1721] *See, e.g.*, Alliance of Automobile Manufacturers, Comment, EPA-HQ-OAR-2015-0827-4089, at 115-16.
[1722] EDF, Appendix B, NHTSA-2018-0067-12108, at 37-38.

approach from the 2012 final rule, which assumed no impact on the new vehicle market from standards as stringent as 7 percent increase, year-over-year, beginning in 2017, commenters are suggesting that even *those* standards would have no impact on new vehicle sales. Manufacturers have asserted in their comments that fuel economy regulations change both the cost of producing new vehicles and consumer demand for them. In the recent peer review of the NPRM release of the CAFE model, all reviewers encouraged the inclusion of a sales response to fuel economy regulations (albeit not necessarily the version of the response model that appeared in the NPRM).[1723] Based on earlier comments and the agencies' own analysis, the agencies were persuaded to include a sales response mechanism in the NPRM, and do so again in this final rule.

While several commenters (CARB, NCAT, CBD, Aluminum Association) discouraged the agencies from attempting to account for the effect of regulations on new vehicle sales, other commenters stated that the NPRM analysis was improved by explicitly considering this effect (RFF, Toyota, the Alliance of Automobile Manufacturers). CBD cited EPA's 2016 proposed determination, stating "[a] reasonable qualitative assessment is preferable to a quantitative estimate lacking sufficient basis, or (due to uncertainties like those here) having such an enormous range as to be without substantial value."[1724] However, RFF supported the inclusion of the effect (with caveats about the specific implementation, for which they suggested alternative approaches), stating "[i]ncorporating sales and scrappage effects represents a step in the right direction for modeling the effects of the regulation.[1725] It is reasonable to conclude that regulations as transformative as fuel economy standards will impact the market for new vehicles, and excluding the effect (as CBD and others suggested) is equivalent to stating that it does not exist.

The NPRM version of the sales response relied on differences in the average price of new vehicles to produce sales differences between regulatory alternatives. Some commenters (ACEEE, IPI, CBD, UCS, Aluminum Association, and Alliance to Save Energy) argued that new vehicle prices do not increase with the addition of technology required to comply with fuel economy regulations. Some argued that manufacturers will choose not to "pass through" the full incremental cost of fuel saving technologies to consumers, instead absorbing those costs into their profit margin.[1726] The question of cost pass-through is one that academic and industry researchers have considered for decades—and two of the agencies' recent peer reviewers addressed this issue in their comments.

Dr. John D. Graham, one of the peer reviewers, argued that the assumption of complete cost pass-through is defensible, and more likely in the long-run than the short-run.[1727] The reviewer also suggested that changes to the CAFE (and subsequent CO_2) program that base a manufacturer's standard on the mix of vehicle footprints in each fleet more equitably spreads the impact of the standards across the industry, and that industry shifts toward increasingly competitive market models (rather than the oligopolistic models that existed earlier in the last century) both act to increase the likelihood that manufacturers will pass regulatory costs through to consumers. In particular, this reviewer stated:[1728]

> In a classic study, Gron and Swenson (2000) examined list prices of automobiles at the model level in the US from 1984 to 1994 coupled with data on production, vehicle characteristics, foreign versus domestic firm ownership, wages of employees, exchange rates, imported parts content, tariffs and other variables. Although their work rejects the hypothesis of 100% pass through of cost to consumer price, they find higher rates of pass through than previous studies, and much of the incomplete pass through occurs when cost increases impact only a few models or firms. Confirming earlier studies, they show that US auto manufacturers engage in more aggressive pass-through pricing than Asian and European manufacturers (greater than 100% in some specifications), possibly due to the eagerness of importers to enlarge market share in lieu of recovering regulatory costs, at least in the short run (see Dinopolous and Kreinin, 1988;[1729]; Froot, 1989[1730]). This study helps explain why pass-through pricing is a more viable hypothesis in the long run than in the short run.
>
> The original design of the CAFE program is a contrasting case where pass-through pricing was difficult for some automakers. All auto makers, regardless of their product mix, were subject to the same fleet-wide average CAFE standard, such as 27.5 miles per gallon for cars in 1990. In practice, those standards impacted only three high-volume companies (General Motors, Ford and Chrysler) because the Big Three produced a higher proportion of large and performance-oriented vehicles than did Japanese companies. As a result, manufacturers such as Toyota and Honda consistently surpassed the federal fleet-wide standard for cars without any regulatory cost (i.e., partly due to their smaller product mix). In the 1975-2007 period, the Big Three were not able to pass on all of their

compliance costs to consumers and thus experienced some declines in profitability due to CAFE (Kleit, 1990;[1731] Kleit, 2004;[1732] Jacobsen, 2013[1733]).

When the CAFE program was reformed for light trucks in 2008 (and for cars in 2011) on the basis of vehicle size (the so-called "footprint" adjustments to CAFE stringency), the, the technology costs of CAFE standards were spread more evenly among automakers, although the overall societal efficiency of the regulation diminished due to the removal of downsizing as a compliance option .[1734] Given that the size-based fuel economy programs are not concentrating the costs of compliance on one or two automakers, it is reasonable to predict a fairly high degree of pass-through pricing for the 2021-2025 fuel economy standards. In related literature on manufacturer pricing responses to a national carbon tax, Bento and Jacobsen (2007)[1735] and Bento (2013)[1736] report high rates of pass-through pricing (on the order of 85%). Carbon taxes are more efficient than footprint-based CAFE standards, but both instruments are likely to impact a wide range of companies in the auto sector and result in a high degree of pass-through pricing by impacted companies.

Also, it should be noted that the US automotive industry is much more competitive today than it was from 1970 to 2000. The market share of General Motors, once the dominant, majority producer in the U.S. market, has declined dramatically, and a variety of Japanese and Korean companies have captured substantial market share. Moreover, the rise of startups (e.g., Tesla and other electric vehicle start-ups) and ride-sharing services (e.g., Uber) are adding a new competitive dimension in the U.S. industry. As a result, some of the most recent auto regulatory studies have given more emphasis to analytic results based on competitive models than oligopolistic models (see, e.g., Davis and Knittel (2016)[1737]).

Another peer reviewer, Dr. James Sallee, suggested that costs would pass through to new vehicle buyers to different degrees, depending upon the stringency of the standards.[1738] The reviewer argued that more stringent standards, which result in larger increases to the cost of

production, are likely to induce greater degrees of pass-through than less stringent standards, which automakers may, as some commenters have suggested, be able to absorb in the form of lost profit. If the degree of cost pass-through should vary by the stringency of the alternative, the agencies are underestimating the difference in price between the most and least stringent alternatives—which would favor alternatives with higher stringency.

Other commenters argued that manufacturers are able to compensate fully for the costs of fuel economy standards by increasing the prices of luxury vehicles—which would increase the average new vehicle price, but leave large sections of the market unaffected by the increased cost of producing fleets that comply with the standards. While it seems likely that manufacturers employ pricing strategies that push regulatory costs (as well as increases in costs like pension obligations and health care costs for employees) into the prices of models and segments with less elastic demand, the extent to which any OEM is able to succeed at this is unknown by the agencies. At some point, however, price increases on even luxury models will merely price more and more purchasers out of the market, and make competition with other manufacturers and market segments that much more difficult. And the more that avoided price increases for lower ends of the vehicle market are subsidized by luxury vehicles, the more either prices for luxury models would need to be increased, or (if moderately increasing prices) more of those luxury models would need to be sold. It is worth noting that luxury vehicles tend to be more powerful and content-rich, and often have fuel economy levels below (or CO_2 levels above) their targets on the curves—so that selling more of them to compensate for lost profit elsewhere further erodes the compliance levels of the fleets in which they reside.

While manufacturers could conceivably push some small cost increases into the prices of their vehicle segments that have less elastic demand to cover accordingly small increases in stringency, larger stringency increases would exhaust the ability of such segments to absorb additional costs. In addition, the agencies do not attempt to adjust the mix of vehicle models based on their own price elasticity of demand; doing so would require a pricing model that takes the compliance cost for each manufacturer (which the agencies' model estimates dynamically) and apportions that cost to the prices of individual nameplates and trim levels. The agencies have experimented with pricing models (when integrating vehicle choice models, pricing models are a necessity), but each manufacturer almost certainly has a unique pricing strategy that is unknown to the agencies, and involves both strategic decisions about competitive position within a segment and the volumes needed fully to amortize fixed costs associated with production. To the extent that the agencies assume all regulatory costs are passed through and affect the average regulatory cost of each vehicle instead of being priced in a fashion to minimize the impact on aggregate sales, the agencies note that—more stringent alternatives are provided an artificial analytical advantage because manufacturers are better positioned to incorporate smaller price adjustments into their current strategic pricing models. The agencies opted to take the conservative approach instead of speculating on manufacturer's private business models.

Finally, some commenters have argued that, even if regulations *do* increase the cost of producing vehicles and those costs *are* passed on to new vehicle buyers, it does not matter because sales have increased in recent years under both rising standards and rising prices. EDF, CARB, Aluminum Association, SAFE, CBD, and CA et al. and Oakland et al., all make some version of this argument in their comments.[1739] The commenters are confusing correlation with causation and failing to consider the counterfactual case. Higher prices of new vehicles certainly did not cause sales to increase since 2012. Sales increased over that period, in large part, as a result of economic expansion following the great recession.[1740] The statistical model used in the NPRM attempted to isolate the effect of average price on new vehicle sales, independent of the overall health of the US economy which plays an obviously important role. That model showed a negative relationship between sales and price (albeit a modest one), and positive relationships with GDP and employment. Even under the most stringent alternative in the NPRM, sales increased over time. However, in other alternatives, where the same macroeconomic conditions prevailed but average new vehicle prices were lower, sales increased relative to the baseline. That is the counterfactual case that is relevant for regulatory analysis—it attempts to answer the question, "would sales have been even higher if average prices had been lower?"

As discussed below, identifying the independent contribution of price to new vehicle sales is econometrically challenging. In the NPRM, the agencies stated that the simultaneous nature of price and sales—where transaction prices are higher in periods of higher demand, because the market will bear them, and lower in periods of lower demand, because the market will not, for an otherwise identical vehicle—creates a form of reverse causality. As commenters suggested, in recent years sales have increased along with average transaction price increases—and transaction price increases will occur when regulation forces manufacturers to add content, and their corresponding costs, to the vehicles they sell. Thus, it is understandable that some commenters could interpret the recent increase in new vehicle sales following the recession as evidence that standards (and maybe prices) have no impact on new sales. However, that view confuses correlation for causation (or lack thereof, in this case).

In response to these comments, the agencies have modified their approach to modeling the sales impacts of regulatory alternatives. In order to isolate the impact of the standards, the agencies have broken the sales response module into two discrete components. The first captures the effects of broader economic forces such as GDP growth. The second measures how changes in vehicle prices influence sales. As elaborated in more detail in the following passages, the agencies considered alternative approaches and specific changes suggested by commenters, but concluded that the comments either lacked enough information to implement a change, failed to remedy identified alleged weaknesses of the NPRM model, or created new limitations for which there were no practical solutions. Furthermore, the two-pronged approach addresses many of the concerns raised by commenters better than any specific modeling alteration. First, the structural changes to the model address many of the econometric concerns raised by commenters. Second, by modeling sales in the first step as a function of macroeconomic conditions, and then applying an independent own-price elasticity to estimate the change in sales

[1740] Table VI-183 below shows a large and statistically significant effect of GDP on sales.

across alternatives, the agencies are able to more clearly distinguish between demand-side and supply-side impacts on prices, the issue that appears to have tripped up some of the commenters.

Comments on the econometric model used in the NPRM

Any model of sales response must satisfy two requirements: it must be appropriate for use in the CAFE model, and it must be based in both sound economic theory and appropriate empirical analysis. The first of these requirements implies that forecasts of any variable used in the estimation of the econometric model must also be available as a forecast throughout the duration of the years covered by the simulations (this analysis explicitly simulates compliance through MY 2050). Some values the model calculates endogenously, making them available in future years for sales estimation, but others must be known in advance of the simulation. As the CAFE model simulates compliance, it accumulates technology costs across the industry and over time. By starting with the last known average transaction price (associated with MY 2016, in this analysis) and adding accumulated regulatory costs to that value, the model is able to represent an estimated average selling price in each future model year, assuming that manufacturers are able to pass their compliance costs on to buyers of new vehicles. Other variables used in the estimation can be entered into the model as inputs prior to the start of the compliance simulation.

The NPRM analysis was based on an econometric model that attempted to estimate the price elasticity of aggregate demand for new light-duty vehicles based on exogenous factors, intended to represent (1) macroeconomic forces that influence demand for new vehicles, and (2) average new vehicle price, intended to represent the impact of regulation. A number of commenters voiced opposition to the approach. Some disagreed with the theoretical framing of the issue—arguing that the model of sales response should have acknowledged the relevance of other vehicle attributes, included consumer valuation of fuel savings for new vehicles, based the response on something other than price, and considered the effect at a lower level of aggregation, rather than average price across the industry.

In the NPRM, the agencies relied upon an autoregressive distributed lag (ARDL) statistical model to estimate the impact of price differences between regulatory alternatives and to produce a time series of total new vehicle sales in each year of the analysis. The statistical model estimated new vehicle sales per year based on two lagged variables of new sales (new sales in the previous period, and the period before that), GDP and lagged GDP, and labor force participation and lagged labor force participation. The model used quarterly data and seasonally adjusted annual rates to increase the number of observations over the sample period for which reliable sales data existed (1978-2015). The ARDL model used in the NPRM was chosen to address sales impacts at a high level of aggregation, namely the total new vehicle market (across all vehicle brands and body styles), and to resolve the econometric issues associated with the time series data related to total new vehicle sales.

Stock et al. commented at length on the econometric specification of the NPRM sales response model, identifying limitations and suggesting alternative approaches.[1741] In particular,

[1741] EPA–HQ–OAR–2018–0283 and NHTSA–2018–0067.

they argued that the length of the response to price shocks should dissipate faster than the NPRM model allows—an artifact of using quarterly data and seasonally adjusted annual rates to estimate the effect and implementing it on an annual basis in the CAFE model. The agencies agree that this was a flaw in the implementation of the NPRM model. While this approach produced the correct units (i.e., annual sales) the response to changes in price should have dissipated at a quarterly rate, rather than an annual rate. As a result, a single price shock, which appears in one year and disappears the next, was projected to have a longer impact on sales in future years than was appropriate given the specification. The sales response in the final rule corrects for this objective error and takes a more conservative approach to price shocks.

Stock et al. commented that "it is important to estimate the dynamic effect on sales of a price increase, that is, the causal effect on current and future demand of a price increase" because "it allows the response to an intervention—here, a one-time price increase or sequence of such increases—to evolve over time."[1742] The comment suggests that the agencies should include future responses in sales to a one-time price increase that exists for a single period and then disappears. In our analytical framework, this implies that a price difference between any alternative and the baseline that causes a difference in sales in that year should also produce a difference in sales in the following year (and possibly subsequent years), though of smaller magnitude, even if the price difference only exists for a single period. The Stock et al. comment illustrates a quickly diminishing response to a single price shock. The final rule assumes (more conservatively) that each price shock lasts only for a single year, and produces no future "ripple" effects in the new vehicle market in subsequent years. Furthermore, the regulatory alternatives considered in this analysis do not produce single period price shocks (in the form of price differences between alternatives), but rather persistent price differences between alternatives that result from continued differences in stringency. The persistent nature of the price differences resulting from fuel economy and CO_2 regulations further reduce the importance of capturing these multi-period effects caused by single-period price shocks.

Stock et al. also objected to the use of an ARDL model to estimate the impact of price on new vehicle sales. In order for the estimation of causality to be valid in a time series model, the current price movements must be uncorrelated with unobserved demand shocks in the past, present, and future; so-called strict exogeneity. The commenters argue that the NPRM fails this test because actions taken in the market (by both buyers and sellers) can influence the response to price changes in the next period. They suggest the use of a vector autoregression (VAR) model to address the relationship between past demand disturbances and current prices to address the temporal exogeneity issues they identify. However, an important caveat is that this approach still does not resolve the largest econometric challenge—that of contemporaneous endogeneity between price and sales (in the same period). To address that challenge, one needs to employ instrumental variable methods.

The agencies attempted several modifications to the statistical model developed for the NPRM based on the Stock et al. comment. The agencies reviewed the initial approach and attempted several specifications that would explicitly address the temporal endogeneity bias

[1742] *Ibid*.

identified in the comment. In particular, the agencies addressed data limitations that were raised by Stock et al. (and also by EDF), who encouraged us to reconsider the quarterly specification and to use quality-adjusted price data for new vehicles in order to ensure a more consistent definition of the average vehicle over the time series, as the "average vehicle" has consistently improved in a myriad of ways over successive model years. The quarterly price series was statistically interpolated in the NPRM to increase the number of observations,[1743] but represented a less-than-ideal solution. The interpolating process may have impacted the underlying quarterly data generating process, resulting in unreliable, or potentially biased, regression results. This issue was remedied by sourcing both vehicle sales and price data from IHS Markit, which provides these data at the same base frequency (quarterly) and obviates the need for any interpolation. In addition, the macroeconomic data used in the model specification were also sourced from IHS, which provides consistency between historical and forecast data (i.e., forecasts of sales, price, personal income, etc., were all based on a consistent set of input assumptions and modeling framework during testing).

Historical quarterly series for new light vehicle average price and total sales are presented in Figure VI-117 below. Due to the lack of data availability for business investment in light vehicles, the historical series for average vehicle price begins in 1987. Average prices were transformed into quality adjusted real terms using the CPI for new motor vehicles, and both series were seasonally adjusted.[1744] Quality adjusted prices have risen overtime, while total sales have remained relatively flat in recent years with the major exception being the significant economic downturn of 2008-2009. The difference in these trends suggests that the number of vehicles purchased per household does not necessarily change, or grow, over time, as income grows, but rather households adjust the "amount" of new vehicle they are willing to purchase (i.e., switching from sedan to an SUV).[1745] Moreover, while disposable income has steadily increased during this period, sales have not seen the same type of upward trend, and instead only returned to its pre-recession average of around 17 million annual sales.

[1743] Interpolation is the practice of adding unobserved data points based on observed trends to provide more observations to a limited data set.
[1744] Seasonal adjustment was made using X.12 in EViews.
[1745] Aggregate light duty vehicle sales data does not allow for observing the distribution of vehicles being sold, which will have an effect on the average price.

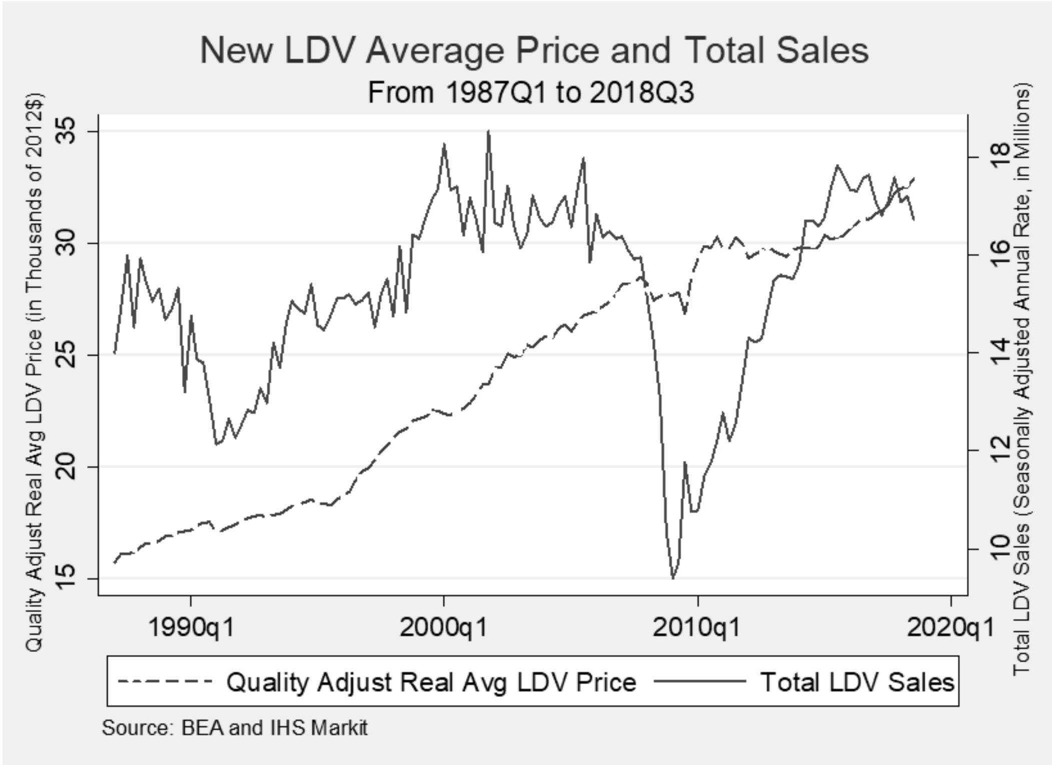

Figure VI-117 – New Light Duty Vehicle Average Price and Total Sales

Even as real disposable income has risen since 2000, and outside of the great recession, new vehicle sales have remained relatively steady. This, in turn, suggests there are other economic, or behavioral, factors beyond disposable income influencing the decision to purchase a new vehicle. Given the significant cost to purchase a new vehicle, and the long multiyear timeframe over which they are typically financed, households' forward-looking view on the health of the economy likely plays a role in their willingness to purchase a new vehicle. Put differently, households may delay their purchasing decisions if their view outlook on the economy sours, regardless of income level. These observations are consistent with the framework of the NPRM model, and Figure VI-118 presents the consumer sentiment index and total new sales, with both series exhibiting similar trends over this period. Some commenters advocated that consumer sentiment (also known as consumer confidence) should be included in the sales forecast. For example, the Aluminum Association indicated that prior sales models have shown consumer behavior to be "highly sensitive to macroeconomic conditions, consumer confidence and employment levels." While consumer sentiment was not included in the NPRM model, it was included in specifications that the agencies tested and considered and is a component of the forecasting model used in the final rule.[1746]

[1746]Commenters mentioned consumer confidence as a predictor of consumer behavior. For instance, the Aluminum Association indicated that prior sales models have shown consumer behavior to be "highly sensitive to macroeconomic conditions, consumer confidence and employment levels." Comments, NHTSA-2018-0067-11952, at 14.

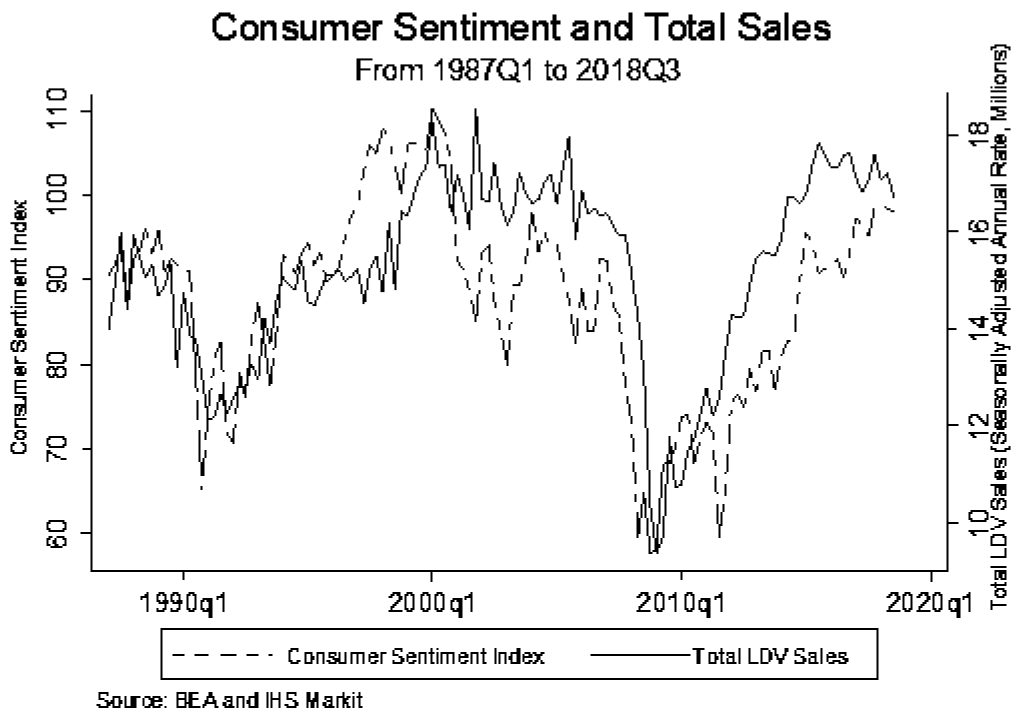

Figure VI-118 – Consumer Sentiment and Total Sales

All macroeconomic data were sourced from IHS including real disposable income, number of US households, and the University of Michigan's consumer sentiment index. The summary statistics for all series are presented below in Table VI-183.

Table VI-183 – Summary Statistics

Variable	Obs.	Mean	Std.	Min	Max
Quality Adjusted Real Avg. LDV Price (Thousands, 2012$)	127	24.13	5.29	15.74	32.89
Total LDV Sales (SA Annual Rate, Millions)	127	15.23	1.93	9.38	18.53
Real Disposable Income (Billions, 2012$)	127	9,979.94	2,432.22	6,113.99	14,358.03
Number of Households (Millions)	127	110.36	9.19	93.53	126.35
Consumer Sentiment Index	127	87.66	11.68	57.67	110.13

Each series was transformed into natural logarithms and tested for stationarity using the modified Dicky-Fuller test.[1747] Results presented in Table VI-184 indicate each variable containing contained a unit-root, while being differenced stationary (i.e. integrated of order one).

Table VI-184 – Modified Dickey-Fuller Test (1 lag)

	DF-GLS Test Stat.	**1% Critical Value**	**5% Critical Value**	**10% Critical Value**
NL Quality Adjusted Real Avg. LDV Price	-1.224	-3.548	-2.995	-2.704
Δ NL Quality Adjusted Real Avg. LDV Price	-5.803	-3.549	-2.996	-2.706
NL Total LDV Sales	-1.841	-3.548	-2.995	-2.704
Δ NL Total LDV Sales	-6.352	-3.549	-2.996	-2.706
NL Total LDV Sales per Household	-1.855	-3.548	-2.995	-2.704
Δ NL Total LDV Sales per Household	-6.375	-3.549	-2.996	-2.706
NL Real Disposable Income	-0.855	-3.548	-2.995	-2.704
Δ NL Real Disposable Income	-4.593	-3.549	-2.996	-2.706
NL Real Disposable Income per Household	-1.091	-3.548	-2.995	-2.704
Δ NL Real Disposable Income per Household	-4.589	-3.549	-2.996	-2.706
NL Consumer Sentiment Index	-2.332	-3.548	-2.995	-2.704
Δ NL Consumer Sentiment Index	-8.991	-3.549	-2.996	-2.706

Two separate variables lists were then tested for the existence of one or more cointegrating relationships, with results from the Johansen test presented in Table VI-185.[1748] In each set of variables, both total LDV sales and disposable income were converted to household units as a means to control for the growth in US households and the possible decision making process of buying/consuming a new unit of LDV. The results show that 4 out of the 5 lag length selections for both variable sets conclude there being one cointegrating relationship (rank I(1)) among them.

Table VI-185 – Johansen Test for Cointegration

Series	**Lags**	**Max** Rank	**Trace Stat.**	**5% Critical Value**
NL LDV Sales per HH, NL PDI per HH, NL Avg. LDV Price	2	1	9.9139	15.41
	3	0	28.6582	29.68
	4	1	8.8639	15.41

[1747] Using nonstationary variables would generate unreliable estimates of their influence, as prior values of those variables are correlated with their future values, and this violates the assumption that values variables take on are independent over time.
[1748] The number of lag lengths were also tested formally, with general consensus between 2 and 6 lags as being optimal. Test results are available upon request, however, the final lag length selection was determined on the full set of VAR and VECM output that includes satisfying time series conditions such as no presence of autocorrelation and plausible interpretability of the estimated output.

Series	Lags	**Max** Rank	Trace Stat.	5% Critical Value
	5	1	7.9938	15.41
	6	1	12.6687	15.41
NL LDV Sales per HH, NL PDI per HH, NL Avg. LDV Price, NL JCSM	2	2	10.2220	15.41
	3	1	25.8108	29.68
	4	1	29.2521	29.68
	5	1	21.7739	29.68
	6	1	27.1268	29.68
Note: NHH, PDI, and JCSM refer to households, real personal disposable income, and consumer sentiment, respectively. All tests include an unrestricted constant. Alternative tests were conducted to include restricted trend or constant terms, but are not presented here for brevity as our preferred specification only includes an unrestricted constant term in the model.				

Taken together, these tests confirm the need to address the time series properties of each variable in any modeling framework. This will become especially important when discussing the correct modeling approach, as The pre-modeling tests provide evidence against running a simple OLS regression or VAR in first differences, because doing so would have the potential outcome of excluding important long-run information.

Furthermore, the endogeneity between vehicle sales and price is another element that needs to be considered for model specification. The IHS historical series for average price of a new light duty vehicle is defined as a function of business and private residential spending on light vehicles divided by total new light vehicle sales; from this identity, the average price represents the nominal price per new unit of light duty vehicle sold. This definition supports the existence of an endogenous relationship between vehicle price and sales that needs to be accounted for when developing an econometric estimation of the influence of new vehicle price on sales. This is consistent with economic theory, whereby vehicle sales and price are simultaneously determined in the market, and therefore should be included together when specifying a forecasting equation.[1749] This restriction holds even if nominal vehicle price is transformed into a quality adjusted real dollar series, as some commenters (EDF, Stock et al) proposed.[1750]

Models

Faced with the simultaneity problem associated with price and sales, several specifications were reviewed to determine the best method for addressing this issue. An Instrumental Variable (IV) method was deemed the most direct approach, with the advantage of preserving the initial model's autoregressive distributed lag structure. In order to obtain consistent estimates of the price elasticity of demand, a suitable instrument that is correlated with average LDV price but uncorrelated with the error term is needed in the first stage. A suitable instrument must also make economic sense and have a plausible causal relationship. In theory,

---

[1749] Endogeneity results in correlation between an independent variable in a regression and the error term leading to biased coefficient estimates.
[1750] For reference on how the BLS measures quality adjustments in vehicles: https://www.bls.gov/cpi/factsheets/new-vehicles.htm.

instruments that satisfy all three conditions (exogeneity, causality, and non-weak correlation) should exist. In practice, however, it is often prohibitively difficult to find a viable instrument. Both Stock et al. and CARB suggested instrumenting to resolve the endogeneity issue in the NPRM model, but neither suggested specific candidates for instrumental variables.

For the purposes of modeling vehicle sales, candidate IVs would reflect the price of inputs to production that are broad enough, so that the underlying behavior of the variable is not deterministic of LDV sales. Examples of candidate variables include producer price indices (PPIs) of auto or other related manufacturing, cost of capital required for production, labor market data, energy costs, technology changes, and exogenous shocks to price, production, labor, or policy changes.

The lack of data availability and quality concerns reduced the primary list of candidate IVs to relatable PPIs such as for manufacturing and automobile primary products. Even the most "promising" candidate IVs, however, proved to be poor instruments, with counterintuitive signs, lack of statistical significance, and poor overall first stage F-statistics (even by relatively lenient weak instrument test standards).

The lack of reasonable results from the IV approach led to testing vector autoregressive (VAR) and vector error correction (VECM) models. Relaxing the strict exogeneity assumption needed under an ARDL framework is the main advantage of modeling price, sales, and macroeconomic variables as a system of equations where the feedback from previous period shocks affect both price and sales.[1751] In addition, a VAR or VECM can also adequately handle the time series and nonstationary properties discussed above. For both the VAR and VECM, a parsimonious specification was preferred with either a three or four variable system using the variables discussed above.

We first estimated a simple VAR using a Wold causal ordering of real disposable income per household, average price of new LDV, and new total sales of LDVs per household.[1752] The alternative specification included the consumer sentiment variable in the ordering the consumer sentiment variable after income and before price. This ordering assumes that households' disposable income (and consumer sentiment) do not respond to shocks to auto prices and sales within the same quarter. It also assumes that prices are contemporaneously exogenous of sales (demand), since the MSRPs are set in advance. Lastly, sales are able to respond to unexpected changes in price in the same quarter. The alternative ordering of placing sales before average price was deemed unrealistic as it would presume sales responding independently to an unexpected change in prices.

[1751] Strict exogeneity requires there to be past, contemporaneous, and future exogeneity between the variables of interest.

[1752] The Wold causal ordering creates a lower triangular matrix for our shocks, so by construction these shocks are orthogonal to each other to allow for causal inference. This recursive or Wold ordering technique should be predetermined and based on economic theory as the causal interpretation of the impulse responses are dependent on the correct/plausible ordering of variables.

In the first specification, all variables were transformed to first differences to ensure stationarity, while ignoring any possible long-run information (for the moment). A combination of post-estimation tests for autocorrelation and stability conditions were considered along with impulse response functions to gauge the model performance. The preferred model was estimated with five lags, and the impulse response functions (IRF) of a 1 percent shock to price on sales for the two specifications are presented in Figure VI-119.

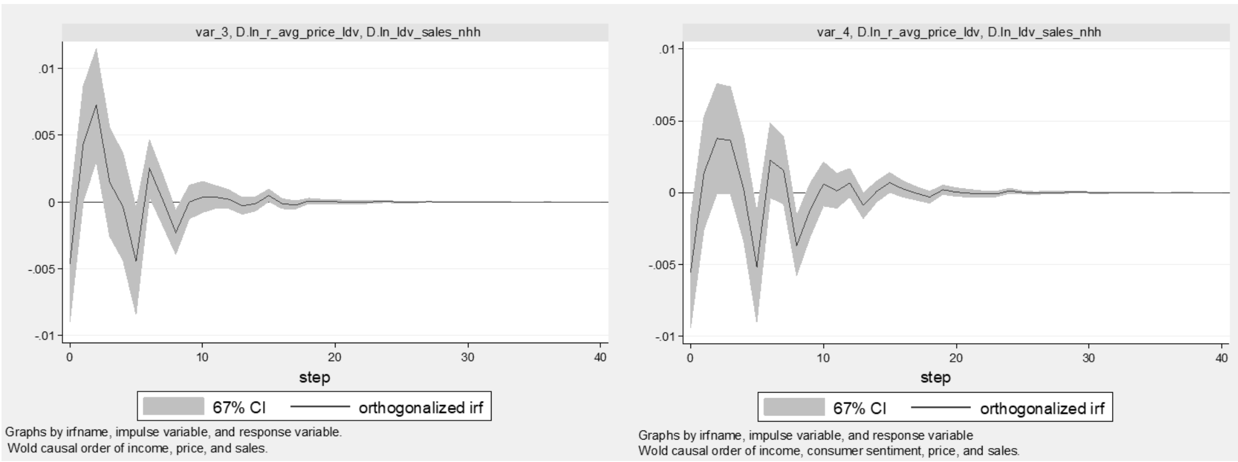

Figure VI-119 – Impulse Response Functions of Price on Sales from First Difference VARs

Both figures show a similar trend of the response in sales oscillating from negative to positive before ultimately returning to zero 12 quarters out. The three variable VAR sees a positive response in the first few periods, while the four variable VAR manages to dip below zero briefly after 4 periods out. This behavior, which by definition is short-run due to the differencing of the variables, could be representing auto dealerships' attempts to pull sales back to its equilibrium level after the price shock pushes sales negative, implying some level of over compensation during this process. Nonetheless, despite the model showing there is some evidence of an immediate and negative price elasticity, the overly simplified VAR model is missing key long run information (as identified in the cointegration tests), creating some reservations about the results. It is also worth noting that the lagged positive response in sales from an unexpected price shock is persistent regardless of the lag length selection, and in many cases even more pronounced.

A number of preliminary conclusions can be drawn from the IRF results shown in Figure VI-119. First, at least at this level of aggregation, any short-run and immediate effect of a price increase on total LDV sales is relatively small in nature. This does not suggest, however, that the price elasticity of demand is zero. Instead, what may be the case is that when faced with an unexpected change in price, consumers will choose to purchase a less expensive car with fewer features as opposed to no car at all. In other words, the level of aggregation being used, total car sales, removes important variation between the type of vehicle being sold and consumer purchasing decisions from the data; what is left is a clouded version of the true relationship between price and sales. Second, this type of VAR ignores and throws out any long run information that may exist, which would create omitted variable bias if such a cointegrated relationship exists.

Based on the conclusions from the Johansen cointegration test, the next step involved estimating the system as a VECM. As with the VAR models, the VECM employs either a three or four variable system with five lag lengths and an unconstrained constant in the model (no trend in either the first differenced or cointegrating equations). In each model, the cointegrating vector is normalized around sales (i.e. the sales' coefficient is set to 1), and the model results indicate strong evidence of a cointegrating relationship between the variables.

Aside from general agreement on a cointegrating relationship, the VECM performance was weak in nearly every specification attempted, with implausible magnitudes for the long-run coefficient estimates and insignificant short-run dynamics. Moreover, the adjustment coefficient for the sales equation is particularly weak and insignificant.[1753] The limitations of the VECM could be rooted in the system being normalized around sales, which lacks significant variation, correlation, or possibly true causation with the other variables.

As with the VAR analysis, a similar focus is placed on the IRFs presented inFigure VI-120. Here a one percent shock in price on LDV sales shows a similar response between the two specifications, with an increase during the first several periods before returning to a negative and permanent long-run effect. This response is erroneous in two ways: first, the sharp positive response during the first 8 to 10 quarters defies economic logic as an increase in the price of a normal good should not induce an increase in sales. Second, the permanent and negative effect is equally as confounding because it rules out the ability for dealerships or auto manufacturers to adjust prices or supply.[1754]

The updated econometric models of light duty vehicle sales (described above) thus did not provide clear, significant or robust insight into the magnitude of the price elasticity of demand. While the VAR model specification points to an immediate short-run negative price elasticity of demand (i.e., sales fall in the face of an immediate price shock), this relationship is relatively small. In addition, the fact that this specification excludes the identified cointegration between the variables suggests that it is not robust or unbiased. In short, the VECM and IV approaches were unable to provide reasonable and meaningful results.

These results strongly suggest that the relationship between sales and price is not adequately estimated with the macro-level data used in this analysis. Recent peer reviewers of the CAFE model had similar concerns. In particular, these data are insufficient to explain the individual consumer (micro-) level decision making process of purchasing a new LDV. Aggregating the sales response to the national level reduces the useful variation in the decision making process to levels unsuitable for estimation. Commenters generally agreed with this conclusion.

[1753] The lack of a statistically significant adjustment variable could be an indication of weak exogeneity. In this case that would not be plausible given the clear endogeneity between price and sales, and is more likely an indication of poor data and the absence of reliable modelling approaches.

[1754] Note that error bounds cannot be generated for VECM IRFs using most statistical packages, so determining statistical significance is difficult. Given the change from positive to negative and the low magnitude of the response, it is quite possible that this effect is indistinguishable from zero.

Even assuming a theoretically and econometrically correct model was possible, this relationship is impossible to evaluate at the current data aggregation level. Future research may focus on constructing an aggregate price elasticity of demand from consumer level data utilizing discrete choice modeling or something similar. However, constructing such models and integrating them into the simulations of the final rule are beyond the scope of this analysis.

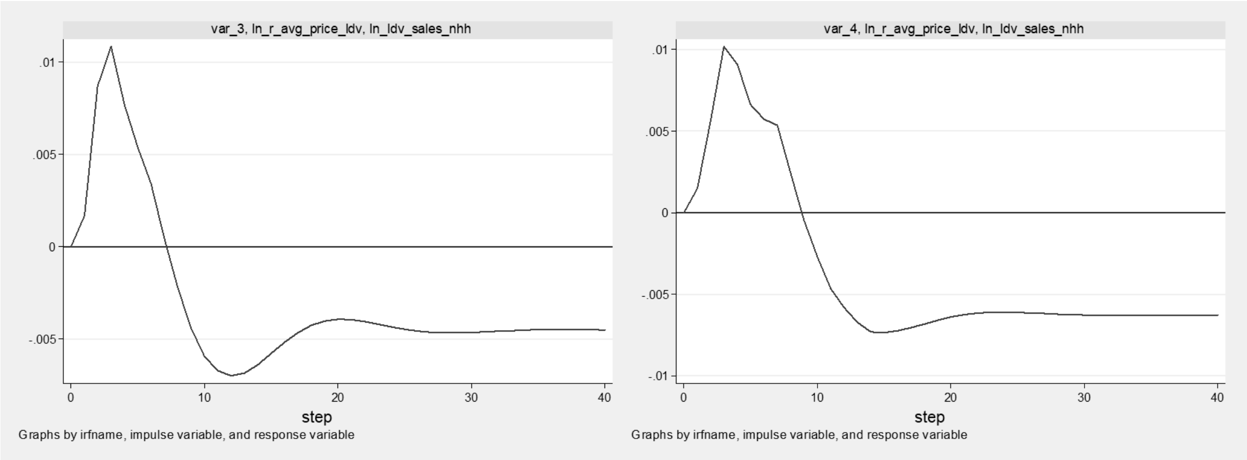

Figure VI-120 – Impulse Response Functions of Price on Sales from VECMs

Many commenters suggested that the NPRM model was unable to find a statistically significant influence of fuel economy on sales because the model was too highly aggregated, as the agencies found with the econometric experimentation to estimate a price response. EDF, CARB, and CA et al. and Oakland et al. expressed concern that using industry averages eliminated the variation needed to detect consumer valuation of fuel economy in new vehicle purchases. The agencies noted a similar concern in the NPRM, citing the level of aggregation as the most likely reason that the average fuel economy of a new vehicle was not a statistically significant explanatory variable in the ARDL model. The approach for the final rule includes an average value of improved fuel economy in the sales response, as commenters suggested it should.

(a) How do Car and Light Truck Buyers Value Improved Fuel Economy?

Many commenters (CARB, CA et al. and Oakland et al., NRDC, EDF, CBD, North Carolina Department of Environmental Quality, IPI, EPA Science Advisory Board, Stock et al.) stated that the agencies should explicitly consider fuel savings, and the value that consumers ascribe to it, in addition to changes in price when estimating the response of new vehicle sales to different regulatory alternatives. NRDC stated, "The decision between new vehicle purchase alternatives must consider both differential costs and differential benefits. The CAFE model sales algorithm considers only differential costs and is, therefore, flawed."[1755] The agencies agree that the degree to which new vehicle buyers value improvements in fuel economy is an

[1755] NRDC, Attachment 3, NHTSA-2018-0067-11723, at 4.

important consideration when estimating the response of new vehicle sales to potential standards. The effect of vehicle prices on sales is difficult to detect at the aggregate level because price movements are correlated with the current strength of the economy, which can appear as a positive price elasticity when modeling sales, and there are various technical econometric difficulties in identifying the effect of price on sales (simultaneity, cointegration, etc., addressed above). The sales response model in the final rule accounts for fuel savings realized by buyers of new vehicles.

Some commenters and EPA's Science Advisory Board noted that the sales response equation omitted any value of fuel savings to new vehicle buyers, while other elements of the analysis—notably the technology application algorithm—assumed that buyers would demand fuel economy technologies that "pay back" within the first 2.5 years of ownership (as a result of avoided fuel costs), and manufacturers would supply fuel economy at those levels even in the absence of standards. This observation was made in comments by CARB, CBD, and IPI—the last of which stated that 2.5 year payback assumption "clashes directly with the contradictory assumption that the agencies rely on in the model's sales module, where they implicitly assume that customers entirely disregard fuel efficiency in their purchasing decisions."[1756] The agencies agree that this represented an internal inconsistency. The sales model used to analyze the final rule includes the estimated value of fuel savings to vehicle buyers, and is consistent with other assumptions throughout the analysis about the "pay back" period.

How potential buyers value improvements in the fuel economy of new cars and light trucks is an important issue in assessing the benefits and costs of government regulation. If buyers fully value the savings in fuel costs that result from higher fuel economy, manufacturers will presumably supply any improvements that buyers demand, and vehicle prices will fully reflect future fuel cost savings consumers would realize from owning—and potentially re-selling—more fuel-efficient models. If consumers internalize fuel savings this case, more stringent fuel economy standards will impose net costs on vehicle owners and can only result in social benefits through correcting externalities, because consumers would already fully incorporate private savings into their purchase decisions, as discussed further below. If instead consumers systematically undervalue some market failure such as an information asymmetry leads to an underinvestment in fuel-saving technology, the cost savings generated by improvements in fuel economy when choosing among competing models, more stringent fuel economy standards will also lead manufacturers to adopt improvements in fuel economy that buyers might not choose despite the cost savings they offer and improve consumer welfare.

The potential for car buyers voluntarily to forego improvements in fuel economy that offer savings exceeding their initial costs is one example of what is often termed the "energy-efficiency gap." This appearance of such a gap, between the level of energy efficiency that would minimize consumers' overall expenses and what they actually purchase, is typically based on engineering calculations that compare the initial cost for providing higher energy efficiency to the discounted present value of the resulting savings in future energy costs.

[1756] IPI, Appendix, NHTSA-2018-0067-12213, at 16.

There has long been an active debate about why such a gap might arise and whether it actually exists. Economic theory predicts that individuals will purchase more energy-efficient products only if the savings in future energy costs they offer promise to offset their higher initial costs. However, the additional up-front cost of a more energy-efficient product includes more than just the cost of the technology necessary to improve its efficiency; because consumers have a scarcity of resources, it also includes the opportunity cost of any other desirable features that consumers give up when they choose the more efficient alternative. In the context of vehicles, whether the expected fuel savings outweigh the opportunity cost of purchasing a model offering higher fuel economy will depend, among other things, on how much its buyer expects to drive, his or her expectations about future fuel prices, the discount rate he or she uses to value future expenses, the expected effect on resale value, and whether more efficient models offer equivalent attributes such as performance, carrying capacity, reliability, quality, or other characteristics.

Published literature has offered little consensus about consumers' willingness-to-pay for greater fuel economy, and whether it implies over-, under- or full-valuation of the expected discounted fuel savings from purchasing a model with higher fuel economy. Most studies have relied on car buyers' purchasing behavior to estimate their willingness-to-pay for future fuel savings; a typical approach has been to use "discrete choice" models that relate individual buyers' choices among competing vehicles to their purchase prices, fuel economy, and other attributes (such as performance, carrying capacity, and reliability), and to infer buyers' valuation of higher fuel economy from the relative importance of purchase prices and fuel economy.[1757] Empirical estimates using this approach span a wide range, extending from substantial undervaluation of fuel savings to significant overvaluation, thus making it difficult to draw solid conclusions about the influence of fuel economy on vehicle buyers' choices.[1758] Because a vehicle's price is often correlated with its other attributes (both measured and unobserved), analysts have often used instrumental variables or other approaches to address endogeneity and other resulting concerns.[1759]

Despite these efforts, more recent research has criticized these cross-sectional studies; some have questioned the effectiveness of the instruments they use,[1760] while others have observed that coefficients estimated using non-linear statistical methods can be sensitive to the optimization algorithm and starting values.[1761] Collinearity (i.e., high correlations) among vehicle attributes—most notably among fuel economy, performance or power, and vehicle size—and between vehicles' measured and unobserved features also raises questions about the reliability and interpretation of coefficients that may conflate the value of fuel economy with other attributes (Sallee, et al., 2016; Busse, et al., 2013; Allcott & Wozny, 2014; Allcott & Greenstone, 2012; Helfand & Wolverton, 2011).

[1757] In a typical vehicle choice model, the ratio of estimated coefficients on fuel economy — or more commonly, fuel cost per mile driven — and purchase price is used to infer the dollar value buyers attach to slightly higher fuel economy.
[1758] *See* Helfand & Wolverton (2011) and Green (2010) for detailed reviews of these cross-sectional studies.
[1759] *See, e.g.*, Barry, et al. (1995).
[1760] *See* Allcott & Greenstone (2012).
[1761] *See* Knittel & Metaxoglou (2014).

In an effort to overcome shortcomings of past analyses, three studies published fairly recently rely on panel data from sales of individual vehicle models to improve their reliability in identifying the association between vehicles' prices and their fuel economy (Sallee, et al. 2016; Allcott & Wozny, 2014; Busse, et al., 2013). Although they differ in certain details, each of these analyses relates changes over time in individual models' selling prices to fluctuations in fuel prices, differences in their fuel economy, and increases in their age and accumulated use, which affects their expected remaining life, and thus their market value. Because a vehicle's future fuel costs are a function of both its fuel economy and expected gasoline prices, changes in fuel prices have different effects on the market values of vehicles with different fuel economy; comparing these effects over time and among vehicle models reveals the fraction of changes in fuel costs that is reflected in changes in their selling prices (Allcott & Wozny, 2014). Using very large samples of sales enables these studies to define vehicle models at an extremely disaggregated level, which enables their authors to isolate differences in their fuel economy from the many other attributes, including those that are difficult to observe or measure, that affect their sale prices.[1762]

These studies point to a somewhat narrower range of estimates than suggested by previous cross-sectional studies; more importantly, they consistently suggest that buyers value a large proportion—and perhaps even all—of the future savings that models with higher fuel economy offer.[1763] Because they rely on estimates of fuel costs over vehicles' expected remaining lifetimes, these studies' estimates of how buyers value fuel economy are sensitive to the strategies they use to isolate differences among individual models' fuel economy, as well as to their assumptions about buyers' discount rates and gasoline price expectations, among others. Since Anderson et al. (2013) found evidence that consumers expect future gasoline prices to resemble current prices, the agencies use this assumption to compare the findings of the three studies and examine how their findings vary with the discount rates buyers apply to future fuel savings.[1764]

[1762] These studies rely on individual vehicle transaction data from dealer sales and wholesale auctions, which includes actual sale prices and allows their authors to define vehicle models at a highly disaggregated level. For instance, Allcott & Wozny (2014) differentiate vehicles by manufacturer, model or nameplate, trim level, body type, fuel economy, engine displacement, number of cylinders, and "generation" (a group of successive model years during which a model's design remains largely unchanged). All three studies include transactions only through mid-2008 to limit the effect of the recession on vehicle prices. To ensure that the vehicle choice set consists of true substitutes, Allcott & Wozny (2014) define the choice set as all gasoline-fueled light-duty cars, trucks, SUVs, and minivans that are less than 25 years old (i.e., they exclude vehicles where the substitution elasticity is expected to be small). Sallee et al. (2016) exclude diesels, hybrids, and used vehicles with less than 10,000 or more than 100,000 miles.

[1763] Killian & Sims (2006) and Sawhill (2008) rely on similar longitudinal approaches to examine consumer valuation of fuel economy except that they use average values or list prices instead of actual transaction prices. Since these studies remain unpublished, their empirical results are subject to change, and they are excluded from this discussion.

[1764] Each of the studies makes slightly different assumptions about appropriate discount rates. Sallee et al. (2016) use five percent in their base specification, while Allcott & Wozny (2014) rely on six percent. As some authors note, a five to six percent discount rate is consistent with current interest rates on car loans, but they also acknowledge that borrowing rates could be higher in some cases, which could be used to justify higher discount

As Table VI-183 indicates, Allcott & Wozny (2014) found that consumers incorporate 55% percent of future fuel costs into vehicle purchase decisions at a six percent discount rate, when their expectations for future gasoline prices are assumed to reflect prevailing prices at the time of their purchases. With the same expectation about future fuel prices, the authors report that consumers would fully value fuel costs only if they apply discount rates of 24 percent or higher. However, these authors' estimates are closer to full valuation when using gasoline price forecasts that mirror oil futures markets, because the petroleum market expected prices to fall during this period (this outlook reduces the discounted value of a vehicle's expected remaining lifetime fuel costs). With this expectation, Allcott & Wozny (2014) find that buyers value 76 percent of future cost savings (discounted at six percent) from choosing a model that offers higher fuel economy, and that a discount rate of 15 percent would imply that they fully value future cost savings. Sallee et al. (2016) begin with the perspective that buyers fully internalize future fuel costs into vehicles' purchase prices and cannot reliably reject that hypothesis; their base specification suggests that changes in vehicle prices incorporate slightly more than 100 percent of changes in future fuel costs. For discount rates of five to six percent, the Busse et al. (2013) results imply that vehicle prices reflect 60 to 100 percent of future fuel costs. As Table VI-186 suggests, higher private discount rates move all of the estimates closer to full valuation or to over-valuation, while lower discount rates imply less complete valuation in all three studies.

Table VI-186 – Percent of Future Fuels Costs Internalized in Used Vehicle Purchase Price using Current Gasoline Prices to Reflect Expectations (for Base Case Assumptions)

Authors (Pub. Date)	**Discount rate**			
	3%	5%	6%	10%
Busse, et al. (2013)*	54%-87%	60%-96%	62%-100%	73%-117%
Allcott & Wozny (2014)	48%		55%	65%
Sallee, et al. (2016)		101%		142%

*Note: The ranges in the Busse et al. estimates depend on which quartiles of the fuel economy distribution are compared. With no prior on which quartile comparison to use, this analysis presents the full quartile comparison range.

The studies also explore the sensitivity of the results to other parameters that could influence their results. Busse et al. (2013) and Allcott & Wozny (2014) find that relying on data that suggest lower annual vehicle use or survival probabilities, which imply that vehicles will not

rates. Rather than assuming a specific discount rate, Busse et al. (2013) directly estimate implicit discount rates at which future fuel costs would be fully internalized; they find discount rates of six to 21 percent% for used cars and one to 13 percent% for new cars at assumed demand elasticities ranging from -2 to -3. Their estimates can be translated into the percent of fuel costs internalized by consumers, assuming a particular discount rate. To make these results more directly comparable to the other two studies, we assume a range of discount rates and uses the authors' spreadsheet tool to translate their results into the percent of fuel costs internalized into the purchase price at each rate. Because Busse et al. (2013) estimate the effects of future fuel costs on vehicle prices separately by fuel economy quartile, these results depend on which quartiles of the fuel economy distribution are compared; our summary shows results using the full range of quartile comparisons.

last as long, moves their estimates closer to full valuation, an unsurprising result because both reduce the changes in expected future fuel costs caused by fuel price fluctuations. Allcott & Wozny's (2014) base results rely on an instrumental variables estimator that groups miles-per-gallon (MPG) into two quantiles to mitigate potential attenuation bias due to measurement error in fuel economy, but they find that greater disaggregation of the MPG groups implies greater undervaluation (for example, it reduces the 55 percent estimated reported in Table VI-183 to 49 percent). Busse et al. (2013) allow gasoline prices to vary across local markets in their main specification; using national average gasoline prices, an approach more directly comparable to the other studies, results in estimates that are closer to or above full valuation. Sallee et al. (2016) find modest undervaluation by vehicle fleet operators or manufacturers making large-scale purchases, compared to retail dealer sales (i.e., 70 to 86 percent).

Since they rely predominantly on changes in vehicles' prices between repeat sales, most of the valuation estimates reported in these studies apply most directly to buyers of used vehicles. Only Busse et al. (2013) examine new vehicle sales; they find that consumers value between 75 to 133 percent% of future fuel costs for new vehicles, a higher range than they estimate for used vehicles. Allcott & Wozny (2014) examine how their estimates vary by vehicle age and find that fluctuations in purchase prices of younger vehicles imply that buyers whose fuel price expectations mirror the petroleum futures market value a higher fraction of future fuel costs: 93 percent% for one- to three-year-old vehicles, compared to their estimate of 76 percent% for all used vehicles assuming the same price expectation.[1765]

Accounting for differences in their data and estimation procedures, the three studies described here suggest that car buyers who use discount rates of five to six percent value at least half—and perhaps all—of the savings in future fuel costs they expect from choosing models that offer higher fuel economy. Perhaps more important in assessing the case for regulating fuel economy, one study (Busse et al., 2013) suggests that buyers of *new* cars and light trucks value three-quarters or more of the savings in future fuel costs they anticipate from purchasing higher-mpg models, although this result is based on more limited information.

In contrast, previous regulatory analyses of fuel economy standards implicitly assumed that buyers undervalue even more of the benefits they would experience from purchasing models with higher fuel economy, so that, without increases in fuel economy standards, little improvement would occur, and the entire value of fuel savings from raising CAFE standards represented private benefits to car and light truck buyers themselves. For instance, in the EPA analysis of the 2017-2025 model year CO_2 standards, fuel savings alone added up to $475 billion (at three percent discount rate) over the lifetime of the vehicles, far outweighing the compliance costs: $150 billion). The assertion that buyers were unwilling to take voluntary advantage of this opportunity implies that collectively, they must have valued less than a third ($150 billion/$475 billion = 32 percent%) of the fuel savings that would have resulted from those standards. In fact,

[1765] Allcott & Wozny (2014) and Sallee, et al. (2016) also find that future fuel costs for older vehicles are substantially undervalued (26-30%). The pattern of Allcott and Wozny's results for different vehicle ages is similar when they use retail transaction prices (adjusted for customer cash rebates and trade-in values) instead of wholesale auction prices, although the degree of valuation falls substantially in all age cohorts with the smaller, retail price based sample.

those earlier analyses assumed that new car and light truck buyers attach relatively little value to higher fuel economy, since their baseline scenarios assumed that fuel economy levels would not increase in the absence of progressively tighter standards, despite increasing fuel prices. The evidence reviewed here makes that perspective extremely difficult to justify and would call into question any analysis that claims to show large private net benefits for vehicle buyers attributable to increases in fuel economy standards.

What analysts assume about consumers' vehicle purchasing behavior, particularly about potential buyers' perspectives on the value of increased fuel economy, clearly matters a great deal in the context of benefit-cost analysis for fuel economy regulation. In light of this recent evidence on this question, warrants a more nuanced approach that is more nuanced than merely assuming that buyers drastically undervalue benefits from higher fuel economy, (and that, as a consequence, these benefits are unlikely to be realized without stringent fuel economy standards,) seems warranted. One possible approach would be to use a baseline scenario where fuel economy levels of new cars and light trucks reflected full (or nearly so) valuation of fuel savings by potential buyers in order to reveal whether setting fuel economy standards above market-determined levels could produce net social benefits. Another might be to assume that, unlike in the agencies' previous analyses, where buyers were assumed to greatly to undervalue higher fuel economy under the baseline but to value it fully under the proposed standards, buyers value improved fuel economy identically under both the baseline scenario and with stricter CAFE standards in place.

The agencies requested comment on the consumer valuation of fuel economy and its use in the NPRM analysis. CBD and the North Carolina Department of Environmental Quality took issue with the agencies' characterization of the literature on the value of fuel economy, citing EPA's previous determination that the estimates in the literature represented too large a range, and the degree of uncertainty made including a value of fuel economy challenging. This final rule analysis accounts for the value of fuel economy in several places, though it uses a more conservative value than is suggested by the literature summarized above. Manufacturers have consistently told the agencies that new vehicle buyers will pay for about 2 or 3 years' worth of fuel savings before the price increase associated with providing those improvements begins to impact affect sales. The agencies have assumed the same valuation, 2.5 years, in all components of the analysis that reflect consumer decisions regarding vehicle purchases and retirements.[1766] This analysis explicitly assumes that: 1) consumers are willing to pay for fuel economy improvements that pay back within the first 2.5 years of vehicle ownership (at average usage rates); 2) manufacturers know this and will provide these improvements even in the absence of regulatory pressure; 3) potential buyers weigh these savings against increases in new vehicle prices when deciding to retire a vehicle; and 4) the amount of technology for which buyers will pay rises (or falls) with rising (or falling) fuel prices.[1767] Excluding the value of fuel economy

---

[1766] When accounting for social benefits and costs associated with an alternative, the full lifetime value of fuel savings is included.

[1767] NADA, the Alliance of Automobile Manufacturers, and American Fuel and Petrochemical Manufacturers argued that CAFE/CO_2 standards have already reached the point where the price increases necessary to recoup manufacturers' increased costs for providing further increases in fuel economy outweigh the value of fuel savings, entirely from these calculations does not remove it from the analysis; it merely imposes an implausibly low value on the desired payback period of new vehicle buyers and manufacturers—regardless of fuel prices or technology costs. And while the agencies acknowledge the uncertainty around the estimates in the literature, zero is far removed from the lower bounds of any study.

CARB asserted that the various market failures suggested by the agencies in past rules (lack of information about fuel savings from higher MPG, inability to calculate cost savings from higher MPG, loss aversion, first-mover disadvantage), together with advertising that only emphasizes fuel economy during periods of high fuel prices, leads buyers to undervalue fuel economy. [1768] In contrast, CARB (and others—such as SCAQMD, Alliance to Save Energy, Save EPA, AAA, Environmental group coalition, Consumers Union, EDF, and IPI) argues elsewhere that new vehicle buyers *do* value fuel economy highly, and nearly fully once fuel prices return to "normal" levels.[1769] The agencies' payback period assumption, and the matching adjustment it makes to changes in new car prices to account for accompanying changes in fuel economy, recognizes that on average potential car buyers value a significant share of lifetime cost savings resulting from higher fuel economy. The agencies considered longer payback periods along the lines suggested by Consumer Federation of America (CFA),[1770] but chose 2.5 years as a conservative approach. Our assumption is consistent with survey evidence cited by the commenters, but at odds with their assertions that this program is necessary to save buyers from their own limited ability to make decisions in their best interest.

(b) Representing Sales Responses in CAFE/ CO_2 Analysis

The approach used in the NPRM relied on a single model to produce the total number of new vehicle sales in each calendar year for a given regulatory scenario. Many commenters expressed reservations about the predictive capabilities of the model (CARB, North Carolina Department of Environmental Quality, EDF, Aluminum Association). As the Aluminum Association commented, "[D]eveloping a model to predict consumer reaction to changes in prices is complicated and highly sensitive to macroeconomic conditions, consumer confidence and employment levels." [1771] As discussed above, the agencies agree that development of such a

---

and requiring further increases in fuel economy will reduce new vehicle sales. The sales response in the final rule recognizes and incorporates the effect of fuel prices and fuel economy on new vehicle purchases. *See* NADA, NHTSA-2018-0067-12064, at 11; Auto Alliance, Full Comment Set, NHTSA-2018-0067-12073 at 163-64; AMFP, Comments, NHTSA-2018-0067-12078-29,at 3.

model is complicated, and the agencies have elected to simplify the approach for the final rule. For the purposes of regulatory evaluation, the relevant sales metric is the difference between alternatives rather than the absolute number of sales in any of the alternatives. As such and in response to these comments and others previously addressed, the agencies divided the sales response model for the final rule into two parts: a nominal forecast that provides the level of sales in the baseline (based primarily upon macroeconomic inputs), and a price elasticity that creates sales differences relative to that baseline in each year. The nominal forecast does not include price, and is merely a (continuous) function of several macroeconomic variables that are provided to the model as inputs. While the statistical model used in the NPRM attempted to account for the influence of these other factors in estimating the price elasticity, the forecast in this analysis separates the two completely (as described further below). The price elasticity is also specified as an input, but this analysis assumes a unit elastic response of -1.0—meaning that a one percent increase in the average price of a new vehicle produces a one percent decrease in total sales.[1772]

The revised sales model features three broad changes: 1) it uses the change in average vehicle price net of fuel costs instead of vehicle prices on their own, 2) it uses macroeconomic factors to project baseline sales without considering vehicle prices, and 3) it assesses the change in sales across the various regulatory alternatives considered using an own-price elasticity from the literature. These changes were made in response to comments that consumers are willing to pay for some level of fuel economy and vehicle prices and sales are simultaneously and jointly determined (e.g. endogenous). This section discusses these three broad changes, as well as other more technical and minor changes.

The first component of the new sales response model is the nominal forecast, which is a function (with a small set of inputs) that determines the size of the new vehicle market in each calendar year in the analysis for the baseline. It leverages some of the same structure of the statistical model used in the NPRM, though the dependent variable and some of the explanatory variables have changed. It is of some relevance that this statistical model is intended only as a means to project a baseline sales series. Some commenters raised econometric objections about the NPRM specification's ability to isolate the causal effect of new vehicle prices on new vehicle sales. The agencies note that the nominal forecast model does not include prices and is not intended for statistical inference.

The forecast is derived from a statistical model that accounts for a similar set of exogenous factors related to new light-duty vehicle sales. In particular, the model accounts for the number of households in the U.S., recent number of new vehicles sold, GDP, and consumer confidence. The structure of the forecast model is similar to the NPRM model, which also used a ARDL specification, but even the variables that are common between the two models have different structural forms in the final rule version. In particular, the dependent variable has been transformed to reflect the fact that, as some commenters suggested, households are an important

[1772] The "price increase" in this case represents the new vehicle price net of a portion of fuel savings, described further in this section.

component of demand for new vehicles. As such, the dependent variable is defined as new vehicles sold per household.[1773] While this variable still exhibits the cyclic behavior that new vehicle sales exhibit over time, the trend shows the number of new vehicles sold per household declining since the 1970's, as shown in Figure VI-121, where the dotted line is the trend over time. As this time series is non-stationary,[1774] a lagged variable (the value in the previous year) is included on the right-hand side of the regression equation. In addition, the model includes a lagged variable that represents the three-year running sum of new vehicle sales, divided by the number of households in the previous year. This variable represents the saturation effect, where the existing number of households can only buy so many new vehicles before a significant number of households already have one (and do not need to buy another). As vehicle durability and cost has increased over time, and average length of initial ownership has increased similarly, this variable acts to put downward pressure on sales after successive years of high sales (particularly during extrapolation).

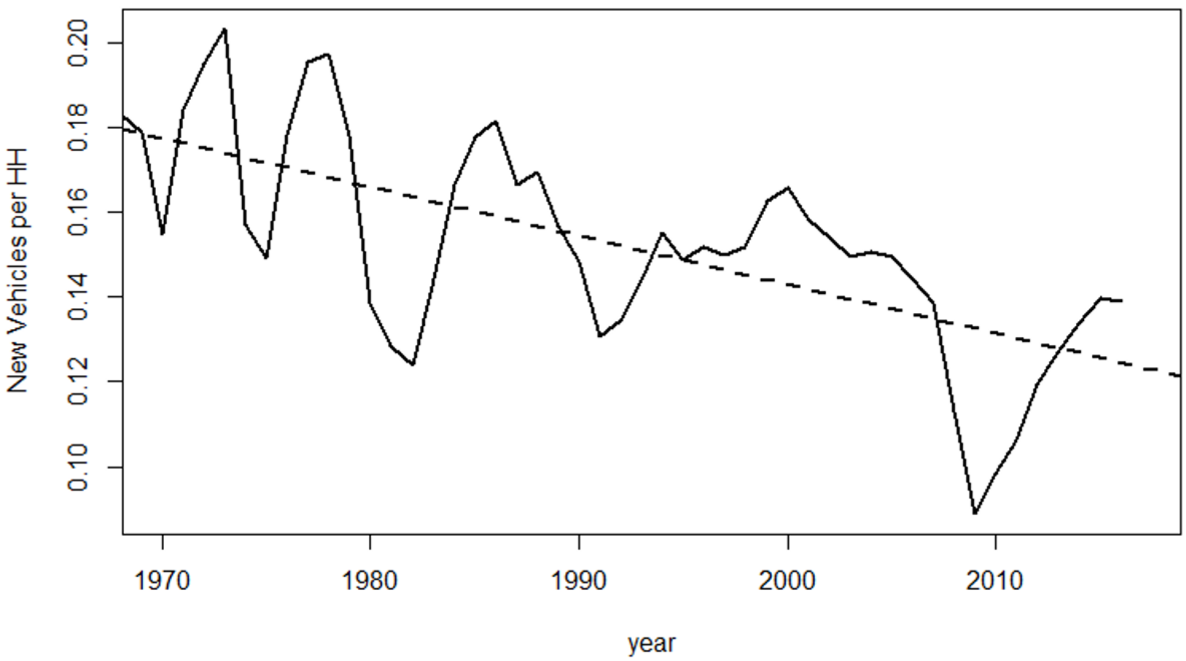

Figure VI-121 – New Light-Duty Vehicle Sales per Household in the United States, 1970 – 2016

Similar to the NPRM model, the forecast model includes real U.S. GDP,[1775] but in natural logarithm form (as some commenters suggested was more appropriate).[1776] The final variable is consumer sentiment, as measured by the University of Michigan survey of consumers.[1777] As

---

[1773] Number of U.S. households is taken from Federal Reserve Economic data, https://fred.stlouisfed.org/series/TTLHH.
[1774] Stationary refers to whether a time series statistical properties are constant over time. Since car sales are increasing over time, the time series non-stationary.
[1775] Federal Reserve Economic Data, available at https://fred.stlouisfed.org/series/GDPC1#0.
[1776] EPA-HQ-OAR-2018-0283-6220-1.
[1777] http://www.sca.isr.umich.edu/tables.html.

both of these series are non-stationary (determined by applying augmented Dickey-Fuller unit root tests to the time series), lagged versions of the variables are included to ensure stationarity in the residuals. The functional form appears below in Equation 2.

Equation 2 – Statistical Model Used to Generate Nominal Forecast

$$New\_Veh\_per\_HH_t = C + \beta_1 New\_Veh\_per\_HH_{t-1} + \beta_2 3YrSumPerHH_{t-1} + \beta_3 LN(GDP_t) + \beta_4 LN(GDP_{t-1}) + \beta_5\, Consumer\_sentiment_t + \beta_6 Consumer\_sentiment_{t-1}$$

The model fit is described in Table VI-187. The included lag term of the dependent variable and both GDP variables are statistically significant at nearly zero, while both the lagged three year sum term and consumer sentiment are both marginally significant. Being a time series model, the agencies also computed the Durbin-Watson test statistic for autocorrelation (1.77) and the Breusch-Godfrey test for serial correlation (0.65) at order 1. The signs of the coefficients are all correct, in the sense that they are consistent with our expectations.

Table VI-187 – Summary of Forecast Regression Function

	new.veh.per.HH		
Predictors	Estimates	CI	p

Observations	47		
R2 / R2 adjusted	0.919 / 0.907		

Because the dependent variable is the number of new vehicles sold per household, it is necessary to multiply by the number of households to produce an estimate of new vehicle sales. This model is used to produce a forecast of new vehicle sales out to 2050, so it is necessary to have projections of each variable used in Equation 2 through calendar year 2050. In an effort to be consistent with other inputs to the analysis, the projection of U.S. GDP is taken from the 2019 AEO. The forecast of households in this analysis comes from the Harvard Joint Center for Housing Studies 2018 Household projections.[1778] The consumer confidence forecast is taken

[1778] https://www.jchs.harvard.edu/research-areas/working-papers/updated-household-growth-projections-2018-2028-and-2028-2038.

directly from the University of Michigan index for 2017 and 2018, and from the Global Insight forecast of consumer confidence for all subsequent years.

While the analysis could have relied on a forecast of new vehicle sales taken from a published source (the 2019 AEO, for example), using a function is an attractive option because it allows the CAFE Model dynamically to adjust the forecast in response to input changes. If a sensitivity case requires a forecast that is consistent with a set of specific, possibly unlikely, assumptions, a forecast of new vehicle sales that is consistent with those assumptions may not exist in the public domain, for example low GDP growth sensitivity cases. As implemented in this rulemaking, using a functional form allows the user to vary some of the assumptions to the analysis without creating inconsistencies with other elements of the analysis. However, it is incumbent upon the analyst to ensure that any set of assumptions that deviate from the central analysis are logically consistent.

This function, and the set of assumptions contained in the central analysis, produces a projection that is comparable in magnitude to the forecast in the 2019 AEO reference case, though there are differences. The two forecasts, and the percentage difference relative to the AEO 2019, appear in Table VI-188, as does a recent forecast published by the Center for Automotive Research.[1779] The reader will notice that even 2017 shows a discrepancy of nearly 7 percent between the final rule forecast and the Annual Energy Outlook, one of the larger differences between annual forecasts. However, the final rule analysis is based upon the certified production volumes of MY2017, which exceed 17 million units. So, while the difference may seem significant, the final rule volumes in 2017 represent the ground truth for model year production.[1780] The CAR forecast, while shorter in length, is consistently higher than both the AEO and final rule forecasts—though likely also includes class 2b (and possibly class 3) pickup trucks in its light vehicle forecast. Finding a public forecast that explicitly excludes light-duty vehicles exempt from these regulations is challenging. However, all three forecasts exhibit similar trends—decreases in sales starting in 2019 that last for a few years before ticking up again slowly. As commenters observed, all forecasts are almost guaranteed to have some errors, and projections out to 2050 should be taken as potential future projections limited by our knowledge at the time, rather than an ironclad prediction of the future.

Table VI-188 – Comparison of AEO2019 Projection to Final Rule (Million Vehicles)

Year	**AEO 2019**	**Final Rule**	**Percent difference (AEO, final rule)**	**CAR**
2017	15.95	17.01	6.6	17.2
2018	15.69	17.10	9.0	17.2
2019	15.66	17.07	9.0	16.8
2020	15.54	16.61	6.8	16.5

2048	16.70	15.87	-5.0	
2049	16.72	15.80	-5.5	
2050	16.72	15.72	-6.0	

Although the forecast produces the total number of new vehicle sales in the baseline, an elasticity is imposed on price differences to produce sales changes between alternatives. The NPRM version of the model considered only differences in average new vehicle prices between alternatives, and the agencies received a number of comments (from CBD, IPI, EDF, CARB, CA et al., and Oakland et al., as well as recent peer reviewers) encouraging the agencies to account for some component of fuel savings associated with those price changes. In their comment, California et al. and Oakland et al. stated the model failed "to consider how consumers will respond to the reduced cost of operating the vehicle from better gas mileage and therefore inaccurately predicts a decline in vehicle sales under the existing standards."[1781] The agencies agree that price is not the only consideration, and that the value of fuel savings to new vehicle buyers is also relevant to the purchase decision.

In previous rules, while the agencies produced analyses that qualitatively considered sales and employment impacts, the agencies acknowledged that fuel economy and CO_2 standards were likely to increase vehicle prices, while simultaneously reducing operating costs, and that estimating how consumers would choose to balance those two factors in the new vehicle market was challenging.[1782] Furthermore, the agencies recognized that there is a broad consensus in the economic literature that the price elasticity of demand for automobiles is approximately –1.0.[1783] The agencies feel that a unit elasticity of -1.0 is still a reasonable estimate.[1784]

Because the elasticity assumes no perceived change in the quality of the product, and the vehicles produced under different regulatory scenarios have inherently different operating costs, the price metric must account for this difference. As commenters suggested is appropriate, the price to which the unit elasticity is applied in this analysis represents the residual price change *between scenarios* after accounting for 2.5 years' worth of fuel savings to the new vehicle buyer. This approach is consistent with the 2012 FRIA analysis of sales impacts, that which considered several payback periods over which the value of fuel savings was subtracted from the change in average new vehicle price.

Similar to the NPRM, the price elasticity is applied to the percentage change in average price (in each year). However, the average price to which the elasticity is applied is calculated differently in the final rule in response to comments. As discussed below the price change does not represent an increase/decrease over the last observed year, but rather the percentage change relative to the baseline. In the baseline, the average price is defined as the observed new vehicle price in 2017 plus the average regulatory cost associated with the alternative. In the case of CO_2 standards, the regulatory cost is equivalent to the retail equivalent price of technology improvements. In the case of CAFE standards, the regulatory cost includes both technology

[1782] Final Regulatory Impact Analysis, Corporate Average Fuel Economy for MY 2017-MY 2025 Passenger Cars and Light Trucks, August 2012, at 821
[1783] *See, e.g.*, Kleit, A.N., "The Effect of Annual Changes in Automobile Fuel Economy Standards," Journal of Regulatory Economics, Vol. 2 (1990), at pp 151-72; Bordley, R., "An Overlapping Choice Set Model of Automotive Price Elasticities," Transportation Research B, Vol. 28B no. 6 (1994), at pp 401-408; and McCarthy, P.S. "Market Price and Income Elasticities of New Vehicle Demands," The Review of Economics and Statistics, Vol. LXXVII no. 3 (1996), at pp. 543-547.
[1784] For example, a recent review of 12 studies examining vehicle price elasticities conducted by the Center of Automotive Research ("CAR") found an "average short-run elasticity of -1.09" and focusing "only those models which also employ time series methods, the average short-run own-price elasticity is higher yet, at -1.25." CAR's own analysis found a -.79 short-run elasticity. Appendix II of the CAR report shows that the long-run elasticities ranged from -.46 and -1.2 with an average of -.72. In sum, a -1.0 elasticity is well-aligned with the totality of research. McAlinden Ph.D, Sean P., Chen, Yen, Schultz, Michael, Andrea, David J., The Potential Effects of the 2017-2025 EPA/NHTSA GHG/Fuel Economy Mandates of the US Economy, Center for Automotive Research, Ann Arbor, MI (Sept. 2016), available at https://www.cargroup.org/wp-content/uploads/2017/02/The-Potential-Effects-of-the-2017_2025-EPANHTSA-GHGFuel-Economy-Mandates-on-the-US-Economy.pdf.

costs and civil penalties paid for non-compliance in a model year. So the change in sales for alternative *a* in year *y* is:

Equation 3 – Calculation of Change in Sales

$$\Delta Sales_{y,a} = \frac{(\Delta RegCost_{y,a-0} - \Delta FuelCosts_{t,a-0})}{34449 + RegCost_{y,0}} \cdot PriceElasticity \cdot NominalSales_{y}$$

ΔRegCost is the difference in average regulatory cost between alternative *a* and the baseline scenario in year *y* to make a vehicle compliant with the standards, $34,449 is the average transaction price of a new vehicle in 2016, *NominalSales* is the forecasted sales (in the baseline) in year *y*, ΔFuelCosts is the change in average fuel costs over 2.5 years relative to the baseline in year *y* and *PriceElasticity* is -1.0:

Equation 4 – Change in Fuel Costs Used to Compute Sales Differences

$$\Delta FuelCosts_{t,a-0} = \left(\frac{FuelPrice_{t}}{NewVehFE_{t,a}} - \frac{FuelPrice_{t}}{NewVehFE_{t,0}}\right) * 35000$$

Where 35,000 miles is assumed to be equivalent to 2.5 years of vehicle usage.[1785] The agencies assume that consumers behave as if the fuel price faced at the time of purchase is the fuel price that they will face over the first 2.5 years of ownership and usage. Essentially, they behave as if fuel prices follow a random walk, where the best prediction of (near) future prices is the price today. Scrappage rates in the first few years of ownership are close to zero, so buyers can reasonably expect to travel the full annual mileage in each of the first three years of ownership. Total sales in each alternative (that is not the baseline) will equal $NominalSales_{y}$ + $\Delta Sales_{a,y}$ for alternative *a* in year *y*.

This implementation produces a range of differences in total sales, both between alternatives and over time. Table VI-189 shows the range of differences in the final rule at the industry level for CO_2, and Table VI-190 shows the sales changes under CAFE. While cost decreases between the baseline and alternatives differ by program, one can see that removing the value of fuel savings from the price limits the sales increases in the alternatives to under 300,000 units in a single year under the preferred alternative, and about one percent of total sales between 2017 and 2050.

Table VI-189 – Sales Changes Under CO_2 Program

Model Year	**Sales and Differences (millions)**			**Avg. Reg Cost and Differences (dollars)**		
	Baseline	0% increase	1.5% increase	Baseline	0% increase	1.5% increase
2017	17.010	0.000	0.000	554	-	-

[1785] Based on odometer data, 35,000 miles is a good representation of typical new vehicle usage in the first 2.5 years of ownership and use—though the distribution of usage is large.

Table VI-189 and Table VI-190 show sales under the baseline (augural standards), and differences under the proposal (0 percent increase in stringency) and final rule (1.5 percent increase in stringency) of MYs 2017-2050.

(c) Dynamic Fleet Share (DFS)

The first module described above (the forecast function and applied elasticity) determine the total industry sales in each model year from 2018 (in this analysis, 2017 is based on certified compliance data) to 2050. A second module, the dynamic fleet share, acts to distribute the total industry sales across two different body-types: "cars" and "light trucks." While there are specific definitions of "passenger cars" and "light trucks" that determine a vehicle's regulatory class, the distinction used in this phase of the analysis is more simplistic. All body-styles that are obviously cars—sedans, coupes, convertibles, hatchbacks, and station wagons—are defined as "cars" for the purpose of determining fleet share. Everything else—SUVs, smaller SUVs (crossovers), vans, and pickup trucks—are defined as "light trucks"—even though they may not be treated as such for compliance purposes. In the case of SUVs, in particular, many models may have sales volumes that reside in both the passenger car and light fleets for regulatory purposes, but the dynamic fleet share does not make this distinction. The fleet share model was applied at the same level in the NPRM—namely, at the level of body-style rather than regulatory class. EDF expressed concern that any simulated increase in the light truck share represented consumers shifting from sedans to either 4WD drive crossovers, SUVs or pickup trucks.[1786] However, this was not the case. All crossovers are considered light trucks for the purposes of fleet share, even though they may be 2WD crossovers treated as passenger cars for compliance purposes. So, while the number may increase overall for a given scenario, the proportion of crossovers sold as 4WD, rather than 2WD, does not.

EDF was also concerned that the sales implementation in the NPRM, which relied on the absolute average price to determine differences between alternatives, was unduly influenced by fleet share—as differences in the share of light-trucks had the potential to skew differences in average price because light-trucks are generally more expensive than sedans and hatchbacks. The final rule implementation, which starts from an observed average transaction price and evolves the average price in the alternatives based on average regulatory cost, is less vulnerable to this potential distortion. Even if the fleet share model (described in greater detail below) increases the share of light trucks (for example), the inherent price difference between passenger cars and light trucks does not pass through to the average price—only the relative difference in compliance costs associated with the vehicle types. Despite the fact that light trucks have generally higher transaction prices than passenger cars, there is no guarantee that regulatory costs will be higher for light-trucks than for cars (which depend upon the mix of footprints, their distance from the relevant curve, and the technology cost needed to bring each fleet into compliance). Thus, the average price differences used in the sales calculations are relatively unaffected by the fleet share model.

As in the NPRM, the dynamic fleet share represents two difference equations that independently estimate the share of passenger cars and light trucks, respectively, given average new market attributes (fuel economy, horsepower, and curb weight) for each group and current fuel prices, as well as the prior year's market share and prior year's attributes. The two independently estimated shares are then normalized to ensure that they sum to one. As with the Sales Response model, the DFS utilizes values from one and two years preceding the analysis year when estimating the share of the fleet during the model year being evaluated. For the horsepower, curb weight, and fuel economy values occurring in the model years before the start of analysis, the DFS model uses the observed values from prior model years. After the first

---

[1786] EDF, Appendix B, NHTSA-2018-0067-12108, at 40-41 .

model year is evaluated, the DFS model relies on values calculated during analysis by the CAFE model. The DFS model begins by calculating the natural log of the new shares during each model year, independently for each vehicle class, as specified by the following equation:

Equation 5 – Dynamic Fleet Share Equation

$$\ln\left(Share_{VC,MY}\right) = \begin{pmatrix} \beta_C \times (1-\beta_{Rho}) + \beta_{Rho} \times \ln\left(Share_{VC,MY-1}\right) \\ +\beta_{FP} \times \left(\ln\left(Price_{Gas,MY}\right) - \beta_{Rho} \times \ln\left(Price_{Gas,MY-1}\right)\right) \\ +\beta_{HP} \times \left(\ln\left(HP_{VC,MY-1}\right) - \beta_{Rho} \times \ln\left(HP_{VC,MY-2}\right)\right) \\ +\beta_{CW} \times \left(\ln\left(CW_{VC,MY-1}\right) - \beta_{Rho} \times \ln\left(CW_{VC,MY-2}\right)\right) \\ +\beta_{MPG} \times \left(\ln\left(FE_{VC,MY-1}\right) - \beta_{Rho} \times \ln\left(FE_{VC,MY-2}\right)\right) \\ +\beta_{Dummy} \times (\ln(0.423453) - \beta_{Rho} \times \ln(0.423453)) \end{pmatrix}$$

Where:

$\beta_C - \beta_{Dummy}$: set of beta coefficients, as defined by Table VI-191 below, used for tuning the Dynamic Fleet Share model,

$Share_{VC,MY-1}$: the share of the total industry new sales classified as vehicle class *VC*, in the year immediately preceding model year *MY*,

$Price_{Gas,MY}$: the fuel price of gasoline fuel, in cents per gallon, in model year *MY*,[1787],

$Price_{Gas,MY-1}$: the fuel price of gasoline fuel, in cents per gallon, in the year immediately preceding model year *MY*,

$HP_{VC,MY-1}$: the average horsepower of all vehicle models belonging to vehicle class *VC*, in the year immediately preceding model year *MY*,

$HP_{VC,MY-2}$: the average horsepower of all vehicle models belonging to vehicle class *VC*, in the year preceding model year *MY* by two years,

$CW_{VC,MY-1}$: the average curb weight of all vehicle models belonging to vehicle class *VC*, in the year immediately preceding model year *MY*,

$CW_{VC,MY-2}$: the average curb weight of all vehicle models belonging to vehicle class *VC*, in the year preceding model year *MY* by two years,

---

[1787] As discussed elsewhere in this final rule, model year and calendar year are assumed to be equivalent in the simulation—as they always have been in all prior rulemaking analyses.

$FE_{VC,MY-1}$: the average on-road fuel economy rating of all vehicle models (excluding credits, adjustments, and petroleum equivalency factors) belonging to vehicle class *VC*, in the year immediately preceding model year *MY*,

$FE_{VC,MY-2}$: the average on-road fuel economy rating of all vehicle models (excluding credits, adjustments, and petroleum equivalency factors) belonging to vehicle class *VC*, in the year preceding model year *MY* by two years,

0.423453 : a dummy coefficient, and

$\ln(Share_{VC,MY})$: the natural log of the calculated share of the total industry fleet classified as vehicle class *VC*, in model year *MY*.

In the equation above, the beta coefficients, β_C through β_{Dummy}, are provided in the following table. The beta coefficients differ depending on the vehicle class for which the fleet share is being calculated.

Table VI-191 – DFS Coefficients

Coefficient	Car Value	Light Truck Value
βC	3.4468	7.8932
βRho	0.8903	0.3482
BFP	0.1441	0.4690
BHW	-0.4436	1.3607
BCW	-0.0994	1.5664
BMPG	-0.5452	0.0813
BDummy	-0.1174	0.6192

Once the initial car and light truck fleet shares are calculated (as a natural log), obtaining the final shares for a specific vehicle class is simply a matter of taking the exponent of the initial value, and normalizing the result at one (or 100%). This calculation is demonstrated by the following:

Equation 6 – Normalizing individual fleet shares

$$Share_{VC,MY} = \frac{e^{\ln(Share_{VC,MY})}}{e^{\ln(Share_{LDV,MY})} + e^{\ln(Share_{LDT1/2a,MY})}}$$

Where:

$\ln(Share_{VC,MY})$: the natural log of the calculated share of the total industry fleet classified as vehicle class *VC*, in model year *MY*,

$\ln(Share_{LDV,MY})$: the natural log of the calculated share of the total industry fleet classified as light duty passenger vehicles (LDV), in model year *MY*, ln($Share_{LDT1/2a,MY}$) : the natural log of the calculated share of the total industry fleet classified as class 1/2a light duty truck (LDT1/2a), in model year *MY*, and

$Share_{VC,MY}$: the calculated share of the total industry fleet classified as vehicle class *VC*, in model year *MY*.

These shares are applied to the total industry sales derived in the first stage of the sales response. This produces total industry volumes of car and light truck body styles. Individual model sales are then determined from there based on the following sequence: 1) individual manufacturer shares of each body style (either car or light truck) times the total industry sales of that body style, then 2) each vehicle within a manufacturer's volume of that body-style is given the same percentage of sales as appear in the 2017 fleet. This implicitly assumes that consumer preferences for particular styles of vehicles are determined in the aggregate (at the industry level), but that manufacturers' sales shares of those body styles are consistent with MY2017 sales. Within a given body style, a manufacturer's sales shares of individual models are also assumed to be constant over time. The agencies assume that manufacturers are currently pricing individual vehicle models within market segments in a way that maximizes their profit. Without more information about each OEM's true cost of production and operation, fixed and variables costs, and both desired and achievable profit margins on individual vehicle models, the agencies have no reason to assume that strategic shifts within a manufacturer's portfolio will occur in response to standards.

The Global Automakers noted in their comments that the market share of SUVs continues to grow, while conventional passenger car body-styles continue to lose market share.[1788] The agencies are aware of this, and include the DFS model in an attempt to address these market realities. In the 2012 final rule, the agencies projected fleet shares based on the continuation of the baseline standards (MY2012-2016) and a fuel price forecast that was much higher than the realized prices since that time. As a result, that analysis showed passenger car body-styles comprising about 70 percent of the new vehicle market by 2025. The reality, as Global Automakers note, has been quite different.

The coefficients of the DFS model show passenger car styles gaining share with higher fuel prices and losing them when prices are lower. Similarly, as fuel economy increases in light truck models, which offer consumers other desirable attributes beyond fuel economy (ride height or interior volume, for example) their relative share increases. NRDC, in particular, found this counterintuitive.[1789] However, this approach does not suggest that consumers *dislike* fuel economy in passenger cars, but merely recognizes the fact that fuel economy has diminishing returns. As the fuel economy of light trucks increases, the tradeoff between passenger car and light truck purchases increasingly involves a consideration of other attributes. Similarly, the coefficients show a relatively stronger preference for power improvements in cars than light

[1788] Global Automakers, Attachment A, NHTSA-2018-0067-12032, at 13.
[1789] NRDC, Attachment 3, NHTSA-2018-0067-11723, at 5.

trucks because that is an attribute where trucks have outperformed cars, like cars have outperformed trucks for fuel economy.

Rather than estimate new functions to determine relative market shares of cars and light trucks, the agencies applied existing functions from the transportation module of the National Energy Modeling System (NEMS) that was used to produce the 2017 Annual Energy Outlook. The functions above appear in the "tran.f" input file to that version of NEMS, and were embedded (in their entirety) in the CAFE model in the NPRM (and this final rule). NEMS uses the functions to estimate the percent of total light vehicles less 8,500 GVW that are cars/trucks. While NRDC asserted that the agencies must demonstrate the propriety of the fleet share model before relying on its estimates,[1790] they ignore the fact that, by using the AEO to develop a static fleet in prior rulemakings, the agencies have always relied on NEMS estimates. The primary difference between those analyses and the NPRM (and this final rule), is that prior analyses applied the fleet share that was simulated for the baseline to all regulatory scenarios considered. Based on the fleet share functions in NEMS, NPRM corrected this internal inconsistency found in previous analyses. This approach also enables consistent sensitivity cases—where higher fuel prices produce fleets with more transitional passenger car body styles, for example—and ensures that the starting point (MY 2017) evolves in response to both fuel economy improvements and fuel prices in a way that is internally consistent.

The agencies are making one change to the DFS function, which is the level of application. While NEMS intended the fleet shares to be defined by regulatory classes, vehicles are defined much more coarsely in NEMS than in the CAFE model, and manufacturers are not differentiated at all. In order to produce well-behaved fleet share projections with this model, the agencies applied the share functions to body-styles rather than regulatory classes. For many years, there was little overlap between nameplates in a manufacturer's passenger car regulatory class and its light truck regulatory class. However, with the recent emergence of smaller FWD SUVs and crossovers, it is increasingly common to have nameplates with model variants in both the passenger car and light truck regulatory classes, and it is also common for there to be only minor differences (like the presence of 4WD or AWD) between versions regulated as cars and versions regulated as light trucks. The agencies have modified the application of the fleet share equations to focus on body-style, rather than regulatory class, in recognition of the increased ambiguity between the regulatory class distinction for popular models like the Honda CR-V and Toyota RAV4, that sell more than 100K units in each regulatory class (typically using the same powertrain configuration). The Nissan Rogue sold more than 400K units in MY2017, and almost exactly half of them were in the light truck (LT) regulatory class. Applying the fleet share at the body-style level preserves the existing regulatory class splits for nameplates that straddle the class definitions. It also serves to minimize the deviation from the observed MY2017 regulatory class shares over time. Had the agencies applied the share equations at the regulatory class level, as some commenters incorrectly claimed the agencies were doing in the proposal, the passenger car regulatory class would have eroded much faster than we've seen in the real world and ceased to resemble the composition of the MY2017 fleet. Our implementation

[1790] *Id.*

allows the passenger car (PC) regulatory class to continue evolving toward crossover-type cars, if that is what economic and policy conditions favor.

Table VI-192 – Regulatory Class Shares Under CAFE[1791]

Model Year	Baseline		0% Increase		1.5% Increase	
	PC	LT	PC	LT	PC	LT
2017	0.53	0.47	0.53	0.47	0.53	0.47
2018	0.53	0.47	0.53	0.47	0.53	0.47
2019	0.53	0.47	0.54	0.46	0.54	0.46
2020	0.54	0.46	0.54	0.46	0.54	0.46
2021	0.54	0.46	0.54	0.46	0.54	0.46
2022	0.53	0.47	0.54	0.46	0.54	0.46
2023	0.53	0.47	0.54	0.46	0.54	0.46
2024	0.53	0.47	0.54	0.46	0.54	0.46
2025	0.53	0.47	0.55	0.45	0.55	0.45
2026	0.53	0.47	0.55	0.45	0.55	0.45
2027	0.53	0.47	0.55	0.45	0.55	0.45
2028	0.54	0.46	0.55	0.45	0.55	0.45
2029	0.54	0.46	0.56	0.44	0.55	0.45
2030	0.54	0.46	0.56	0.44	0.56	0.44

Table VI-192 shows the regulatory class shares under the baseline (augural standards), proposal (0 percent increase in stringency), and final rule (1.5 percent increase in stringency) between 2017 and 2030. The shares move relatively little between the classes in the baseline, with larger (but still small) deviations occurring in the least stringent alternative (0 percent increase) and the final rule. As the sensitivity cases show, the changes in shares (both over time and between regulatory classes) respond to the fuel price case, but remain internally consistent due to the inclusion of the DFS.

Some commenters encouraged the agencies to consider vehicle attributes beyond price and fuel economy when estimating a sales response to fuel economy/CO_2 standards, and suggested that a more detailed representation of the new vehicle market would allow the agencies to simulate strategic mix shifting responses from manufacturers and diverse attribute preferences among consumers. Doing so would have required a discrete choice model (at some level), and below the reasons why the agencies have not chosen to employ that approach in this final rule.

[1791] The "passenger car" fleet for CAFE represents the combination of both imported passenger cars (IC) and domestic cars (DC). While Table VI-192 illustrates shares for the CAFE program, resulting shares under the tailpipe CO_2 emissions standards are comparable.

(d) Using Vehicle Choice Models in Rulemaking Analysis

Some commenters argued that the NPRM's statistical model used to estimate changes in sales between alternatives was too highly aggregated and missed consumers' valuation of other vehicle attributes. CARB, Cities and States, and EDF all made some version of the argument that the sales model in the NPRM operated at too high a level of aggregation to estimate the real sales response, which primarily occurs at the model level where consumers are making decisions based on the comprehensive set of attributes and body styles available in the market. They also argued that a model must operate at the same level, such as a discrete choice model, in order to capture consumer response accurately. EPA's Science Advisory Board, Bento, Toyota, Automobile Alliance, RFF, and Bunch (writing on behalf of CARB) insisted that the best approach to estimating the change in sales across alternatives is to use a discrete choice model and embed it in the simulation.

Other commenters expressed different views on the importance of a consumer choice model. For example, while the Aluminum Association supported a consumer choice model, they suggested that total new vehicle sales may not change due to increases in price, but rather the attributes of new vehicles would shift, as consumers would likely shift their purchases toward lower content vehicles (in terms of safety, luxury, or other option content) when faced with generally higher prices. Other commenters, including UCS and CBD, strongly encouraged the agencies to avoid using consumer choice models; commenters asserted that consumer choice models have historically lacked reliability and predictive power.[1792]

In general, these various comments present the agencies with considerably different suggestions on how to address these issues, and certain suggestions are in direct opposition to each other. That is, while some commenters argue that only micro-level consumer responses are relevant to the analysis, and that a consumer choice model is required to estimate these responses, others argue that it is inappropriate to use a discrete choice model—the method by which those responses are econometrically estimated—in a regulatory analysis. Adding to the confusion, some of the same commenters who argued against a consumer choice model,[1793] also argued that it was necessary for the analysis to account for the influence of other vehicle attributes in purchasing decisions, which would require incorporating a discrete choice model.

CARB argued that "accurately capturing the relative impact of sales shifts versus no-buy decisions would require a more detailed consumer choice model, as recommended by the CAFE Model peer reviewers. The current new vehicle sales model has no way of capturing these types of effects."[1794]

David Bunch, writing for CARB, said, "In fact, in previous versions of the CAFE model there were no attempts to directly simulate consumer response from *within* the CAFE model at all. Instead, NHTSA relied on fixed projections of future vehicle market behavior from multiple

---

[1792] UCS, Technical Appendix, NHTSA-2018-0067-12039 at 50.
[1793] For example, *see* EDF, NRDC, RFF, NCAT, and CBD comments.
[1794] CARB, Detailed Comments, NHTSA-2018-0067-11873, at 192.

sources for the purpose of performing the required economic cost and benefit calculations. While this might possibly be less than ideal, this approach is only a problem if, in the real world, there [are] notable *differences* in future market behavior [that] occur under different regulation scenarios, and, moreover, that these differences would be large enough to compromise the validity of the net benefit comparisons." Bunch essentially argues that the old approach, asserting that standards can have no impact on sales, even at the individual model level, is more appropriate than trying to capture the general idea that when all new vehicles get more expensive, consumers are likely to buy fewer of them, all else being equal. The agencies disagree with that perspective.

There are a number of practical challenges to using estimates of consumer attribute preferences to simulate market responses. Discrete choice models typically rely on fixed effects (or alternative-specific constant terms) to account for the unobserved characteristics of a given model that influence purchasing decisions, such as styling,[1795] but are not captured by independent variables that represent specific vehicle attributes (horsepower, interior volume, or safety rating, for example). Ideally, these constant terms would contribute relatively little to the fit and performance of the model, assuming that the most salient characteristics are accounted for explicitly. In practice, this is seldom the case. While the fixed effects at the model level are statistically sound estimates of consumer preferences for the unobserved vehicle characteristics of the individual models, the estimates are inherently historical—based on observed versions of the specific vehicle models to which they belong. However, once the simulation starts, and new technologies are added to each manufacturer's product portfolio over successive generations, it is no longer obvious that those constant terms would still be valid in the context of those changes.

Another complication is that discrete choice models are highly dependent on their inputs and are unable to account for future market changes. For example, the Draft TAR relied on a MY 2014 market (for EPA's analysis) and a MY 2015 market (for NHTSA's analysis), while the NPRM used a MY 2016 fleet, and this final rule has updated the market characterization to a MY 2017 fleet. A discrete choice model estimated on any of those model years would probably produce different fixed effects estimates for each model variant in the fleet. Even assuming that no new variants of a given model are offered over time, new nameplates emerge as others are retired—and for those new nameplates and all of their model variants, no constant terms would exist. They would have to be imputed (either from comparable vehicles in the market, some combination of their attributes, or both). Some studies have attempted to estimate fixed effects for a single new entrant to the market,[1796] but none have attempted to do so at the scale required to migrate a discrete choice model fit on an earlier model year to a newer model year for simulation.

Figure VI-122 shows the cumulative percentage of nameplates in the 2017 new vehicle market by year of introduction. About ten percent of nameplates in 2017 have been around since the 1970s, but another ten percent have only existed since about 2010. This fact illustrates the

---

[1795] Aesthetics such as styling are difficult, if it not impossible, to define in a manner that allows meaningful comparison between choices.
[1796] Berry, Steven, James Levinsohn, and Ariel Pakes (2004). Differentiated products demand systems from a combination of micro and macro data: The new car market. Journal of Political Economy 112(1): 68-105.

likely necessity of constructing vehicle model fixed effects for the inevitable new entrants between the estimating fleet and the rulemaking fleet. But it also suggests another challenge. New model entrants are driven by the dynamics of the market, where some vehicle models succeed and others fail, but a simulated market with a discrete choice model can only simulate failure—where consumer demand for specific nameplates erode to the point that the nameplate volumes trend toward zero. It has no mechanism to generate new nameplates to replace those nameplates whose sales it estimates will erode beyond some minimal practical level of production.

Consumer choice models are typically fit on a single year of data (a cross-section of vehicles and buyers), but this approach misses relevant trends that build over time, such as rising GDP or shifting consumer sentiment toward emerging technologies. If such a model is used to estimate total sales, but lacks trends in GDP growth or employment, etc., it will have the wrong set (likely a smaller set) of new vehicle buyers and exaggerate price responses and attribute preferences. Consumer preferences change over time in response to any number of factors—given manufacturers' recent investments in electric powertrains, they are counting on this fact. But a choice model estimated on observed consumer preferences for EVs—or other vehicle attributes with comparatively little experience in the market—would necessarily disadvantage a technology that is currently (or only recently) unpopular, but gaining popularity. While these are problems that may not matter in the estimation process, where a researcher is attempting to measure revealed consumer preference for given attributes at a single point in time, they become material once that model is integrated into the simulation and dynamically carried forward for three decades. The agencies note that models that examine aggregate trends, such as the one utilized in this analysis, are able to side-step this issue by not placing a value on unique vehicle attributes.

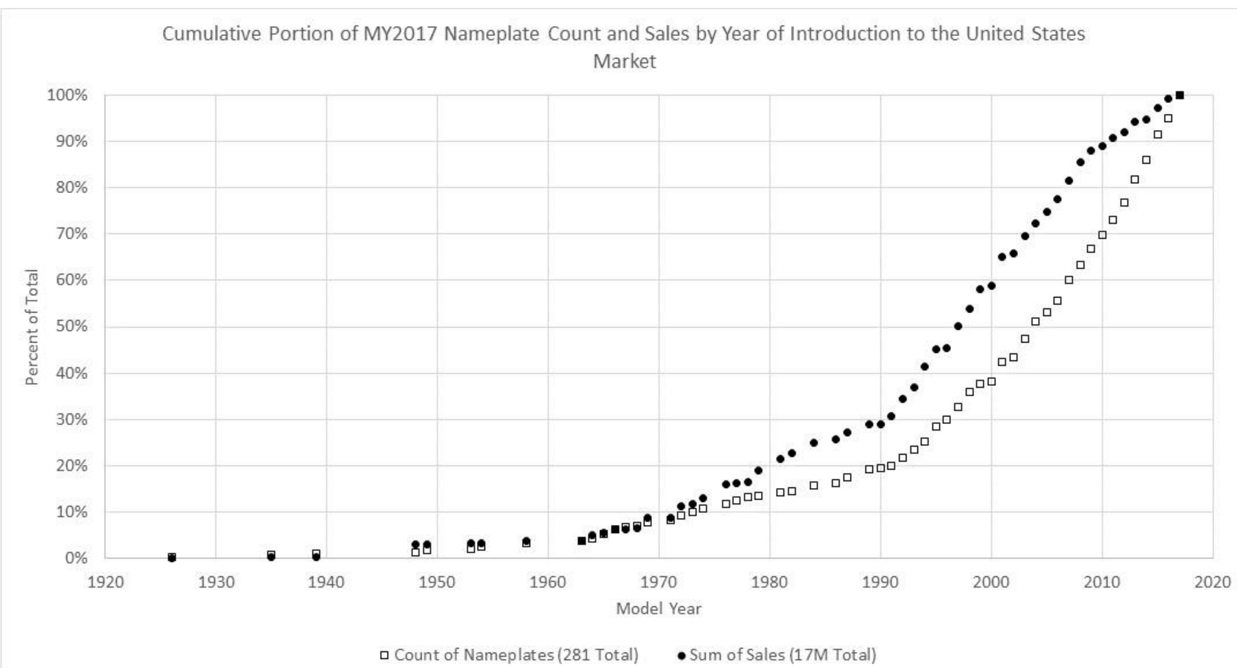

Figure VI-122 – Nameplate Introduction and Attrition

The agencies' compliance simulation model estimates the additional cost of technology required to achieve compliance, or to satisfy market demand for additional fuel economy. While it necessarily calculates these costs on a per-vehicle basis, estimating the cost of additional technologies as they are applied to each specific model in order to bring an entire fleet into compliance, it is agnostic about how these costs are distributed to buyers. Manufacturers have strategic, complex pricing models that rely on extensive market research and reflect each company's strategic interests in each segment. Automobile companies attempt to maximize profit from the sale of their vehicles, rather than solely focusing on minimizing the cost of compliance, as this rulemaking simulates. Lacking reliable data for each manufacturer on production costs and profit margins for each vehicle model in their portfolios, the most reasonable course of action is to simulate compliance as if OEMs are attempting to minimize costs, and, worth noting, this approach is also the one NHTSA takes in its rulemakings related to the FMVSS. However, it is obvious that some market segments and individual models are much less elastic than others.[1797] As reflected in the prices of those models, consumers are able to bear a greater share of the total cost of compliance before negatively affecting sales and manufacturer profits.

Several commenters (CARB, CBD, IPI, and Bento et al.) suggested that the agencies should employ a pricing model that allows manufacturers to vary prices in response to heterogeneous consumer preferences and different levels of willingness to pay for fuel economy, and other attributes, in the new vehicle market. Fundamentally, this would require the agencies to model strategic pricing for each manufacturer individually—no single pricing model would be appropriate for every manufacturer. Bento et al. stated that the agencies should simulate the market by allowing manufacturers to dynamically adjust vehicle prices to ensure compliance with the standards.[1798] There is no reasonable expectation that the agencies could embed and utilize each manufacturer's pricing strategy, as this is an essential feature of competitive corporate behavior and that automakers closely hold pricing strategy information and the agencies have insufficient information to model manufacturer pricing strategies. Furthermore, models in the academic literature that commenters have suggested are superior because they allow prices to adjust, merely demonstrate that the mechanics of those adjustments work; they do not imply that the resulting prices are reasonable or realistic. Given the burden to estimate each manufacturer's standard under the attribute-based system, where the mix of vehicles sold defines not only the achieved fuel economy of each fleet but also the standard to which it is compared, the agencies are understandably reluctant to implement models that might shift a manufacturer's mix of vehicles sold within a market segment.

Bunch suggested the agencies use a joint model of household vehicle holdings and sales that encompasses decisions to purchase new vehicles, retain existing ones, or reduce or augment current holdings of vehicles of all types and vintages in each period. Manufacturers would modify either new vehicle content, prices, or both to produce a supply of new vehicles that allowed them each to comply with standards. And, subsequently, households and manufacturers

[1797] *See*, for example, Kleit, A.N. (2004), Impacts of Long‐Range Increases in the Fuel Economy (CAFE) Standard. Economic Inquiry, 42: 279-294. doi:10.1093/ei/cbh060.
[1798] NHTSA-2018-0067-12326 at 10.

would iteratively interact until the market reached equilibrium. The model described by Bunch would face many of the same issues outlined above. There are significant econometric challenges associated with estimating a household's decision to buy a new vehicle instead of a used vehicle (of some vintage), or to maintain its current set. And integrating such a model would require the agencies to simulate the dynamics of the used vehicle market—hundreds of unique nameplates for each of dozens of vintages—in order to provide the correct choice set in each simulated year. Such a model is beyond the scope of the current analysis.

While the agencies believe that these challenges provide a reasonable basis for not employing a discrete choice model in today's final rule analysis, the agencies also believe they are not insurmountable, and that some suitable variant of such models may yet be developed for use in future fuel economy and CO_2 emissions rulemakings. The agencies have not abandoned the idea and plan to continue experimenting with econometric specifications that address heterogeneous consumer preferences in the new vehicle market as they further refine the analytical tools used for regulatory analysis.

Operating at the level of individual auto and light truck model variants—the same level at which compliance is, necessarily, simulated—may not be tractable for rulemaking analyses. However, market shares for brands and manufacturers within market segments are more stable over time—even if the volumes of segments across the industry fluctuate. In the 2012 final rule, the agencies' analysis showed a new vehicle market where the share of passenger car body styles—sedans, coupes, hatchbacks—reached almost 70 percent of the new vehicle market by 2025, while light trucks, including many crossovers, accounted for the remaining 30 percent. Those results were consistent with the assumptions made in 2012, but the combination of low fuel prices and decreasing differences in fuel consumption between body styles has instead reduced the market share of those body styles significantly (only 40% in the MY 2017 fleet), and, thus eroded the value of the 2012 analysis to inform current decisions. Including a choice model that operated on existing market shares, albeit at a higher level of aggregation than specific nameplates, such as brand/segment/powertrain, may be able to improve internal consistency with the interaction of assumptions about fuel prices and regulatory alternatives. The agencies will continue to engage with the academic community and other stakeholders to ensure that future work on this question improves our analysis of regulatory alternatives.

(3) Scrappage

(a) The Impacts of New Vehicle Fuel Economy Standards on Fleet Turnover

Economic literature and theory indicate that the retirement (or scrappage) rates of existing vehicles slows when new vehicle fuel economy standards increase and cause new vehicle price increases. Slower retirement rates result in an older distribution of the on-road fleet. Today's on-road fleet is the oldest it has ever been, approaching an average of 12 years old.[1799] Since older vehicles are, on average, less safe and less fuel efficient, modeling this

---

[1799] Bureau of Transportation Statistics (BTS). "Average Age of Automobiles and Trucks in Operation in the United States." Available at https://www.bts.gov/content/average-age-automobiles-and-trucks-operation-united-states.

reduction in the scrappage rates of existing vehicles has important implications. As mentioned in the sales section above, past quantitative analyses of CO_2 and CAFE standards excluded the scrappage effect (though the agencies discussed the scrappage effect qualitatively), which could have resulted in an overestimate of the benefits of increasing standards.

For the NPRM, the agencies chose for the first time to model the change in existing vehicle retirement rates across regulatory alternatives. The agencies used a logistic function to estimate the instantaneous scrappage rate for vehicles of different body styles and model year vintages using registration data from Polk, the estimated durability of specific model year vintages, the prices of new vehicles, a measure of the cost of travel for the model year cohort versus new vehicles in any given calendar year, and other cyclical macroeconomic indicators.[1800]

The agencies received many comments about the NPRM's scrappage model. While some commenters objected to the inclusion of a scrappage model, most commenters supported the inclusion of a dynamic scrappage model as an improvement in the agencies' analysis; these comments are discussed in Section VI.C.1.b)(3)(a)(ii). Other commenters raised concerns about the specific scrappage models used in the NPRM analysis; these are discussed in Section VI.C.1.b)(3)(b). Specifically, commenters raised concerns about overfitting in the models, the identification strategy, the modeling of new and used vehicle fuel economy in general, the exclusion of certain variables, about how the agencies captured macroeconomic effects, and about the lack of integration with the sales model.

The agencies contemplated all of the comments and suggestions made by commenters and, in response, have made several changes to final rule's model. First, the agencies changed the time-series strategy used in the model, as discussed in Section VI.C.1.b)(3)(c)(iii)(a). This change allows the agencies to simplify the models significantly, addressing commenters' concerns about potential overfitting of the model and difficulty of interpreting individual coefficient values (discussed in Section CI.C.1.b)(3)(b)(i)). Second, the agencies changed the modeling of the durability effect as discussed in Section VI.C.1.b)(3)(c)(iii)(c); this change reduces the reliance on the decay function and has the added benefit of addressing concerns about overfitting and out-of-sample projections discussed in Section VI.C.1.b)(3)(b)(i). Third, a portion of anticipated fuel savings from increased fuel economy are netted from new vehicle prices—meaning consumers are now assumed to value fuel economy at the time of purchase to a certain extent—as discussed in Section VI.C.1.b). This change is in response to comments discussed in Section VI.C.1.b)(3)(c)(iii)(d) and addresses inconsistent treatment of consumer valuation within the NPRM's analysis. Finally, the agencies consider the inclusion of additional or alternative variables in the scrappage model in response to comments discussed in Section VI.C.1.b)(3)(b)(ii). After extensive testing, the agencies concluded that these additional variables do not improve the model fits or would introduce autocorrelation in the error structures (see Sections VI.C.1.b)(3)(c)(iii)(e) and VI.C.1.b)(3)(c)(iii)(f) for further discussion). As such, the agencies rejected the additional terms suggested by commenters. Input from commenters was used to simplify the scrappage model, make it more consistent with modeling of new vehicle

[1800] For a more detailed explanation of the NPRM model, *see* PRIA Chapter 8.10.

prices elsewhere in the analysis, and improve its predictions for the instantaneous scrappage rates of vehicles beyond age 20.

(i) Basis for 'The Gruenspecht Effect'

Gruenspecht (1981) and (1982) recognized that since fuel economy standards affect only new vehicles, any increase in price (net of the portion of reduced fuel savings valued by consumers) will increase the expected life of used vehicles and reduce the number of new vehicles entering the fleet. The effects of differentiated regulation in the context of fuel economy is often deemed the *Gruenspecht Effect*.[1801] Jacobsen and van Bentham (2015) first quantified the Gruenspecht Effect, or the share of new vehicle fuel savings lost to the used vehicle fleet due to delayed scrappage, to be between 13 and 16 percent.[1802]

As discussed in the write up of the sales model, fuel economy standards increase the cost of acquiring new vehicles, but also improve the quality of those vehicles by increasing their fuel economy. The CAFE analysis assumes that consumers value 30 months of fuel savings, so that the quality-adjusted change in new vehicle prices is the increase in regulatory costs less 30 months of fuel savings. As long as the quality-adjusted price is positive,[1803] it becomes more expensive for manufacturers to produce vehicles and, as a result, prices of new vehicles increase. From a supply and demand perspective, this equates to the supply curve for new vehicles moving inwards or to the left and a corresponding increase in the equilibrium price and decrease in the equilibrium quantity of new vehicles purchased.

New and used vehicles are substitutes. When the price of a good's substitute increases, the demand curve for that good shifts upwards and the equilibrium price and quantity supplied also increases. Thus, increasing the quality-adjusted price of new vehicles will result in an increase in equilibrium price and quantity of used vehicles. Since, by definition, used vehicles are not being "produced" but rather "supplied" from the existing fleet, the increase in quantity must come via a reduction in their scrappage rates. Practically, when new vehicles become more expensive, demand for used vehicles increases (and they become more expensive). Because used vehicles are more valuable in such circumstances, they are scrapped at a lower rate, and just as rising new vehicle prices push marginal prospective buyers into the used vehicle market, rising used vehicle prices force marginal prospective buyers of used vehicles to acquire older vehicles or vehicles with fewer desired attributes.

[1803] The quality adjusted price is positive when regulatory compliance costs exceed 30 months of fuel savings.

(ii) Commenter Response to the Inclusion of the Gruenspecht Effect

(a) Many Commenters Support the Inclusion of the Effect

Academic researchers and automakers widely agree with the existence and direction of the Gruenspecht Effect. For example, RFF commented, "There's good evidence supporting the scrappage effect."[1804] The Auto Alliance stated that the agencies "made significant strides toward improving their modeling of consumer behavior by adding new modules to estimate new vehicle sales and in-use vehicle scrappage in response to changes to new vehicle prices."[1805] FCA agreed "that an outcome of the current augural stringency of the CAFE/[CO_2] emission regulations may be a decreasing trend in vehicle scrappage rates as consumers delay purchases […] forc[ing] consumers to hold their current vehicles for additional time."[1806]

Other commenters agreed with the existence of the effect, but took issue with the implications of the combination of the sales and scrappage models. Mark Jacobsen stated "while we agree that the scrappage effects we study will mitigate changes in the used fleet, we do not believe they could be strong enough to reverse completely the direction of change in the used fleet."[1807] Jacobsen's contention was echoed by many commenters; the main point was that they believed that the prices of both new *and* used vehicles should be less expensive in the NPRM's preferred alternative than the augural standards, and that this should, if anything, result in a larger fleet in the NPRM's preferred alternative. This issue is further discussed in Section (b)(iv) with other comments about integrating the sales and scrappage models and the incremental fleet size across alternatives. Here it is important to note that this concern does not suggest that *a* scrappage model *should not exist*, but takes issue with the *specific modeling* of scrappage and/or sales implemented in the NPRM analysis.

(b) Some Commenters Worry about the Shift in Agency Perspective

Some commenters argued that the agencies modeling of sales and scrappage in the NPRM analysis contradicted previous positions that these effects were too uncertain to model. For example, the Center for Biological Diversity (CBD) commented:

> In the 2012 rulemaking for fuel economy and [CO_2] standards, both NHTSA and EPA stated that analysis of the standards' impact on new vehicles sales and on the "scrappage"

[1804] RFF, Comments EPA NHTSA, NHTSA-2018-0067-11789, at 4.
[1805] Auto Alliance, Full Comment Set, NHTSA-2018-0067-12073, at 47.
[1806] FCA, Comments for CAFE-GHG NPRM Final Public Version, NHTSA-2018-0067-11943, at 22.
[1807] Mark Jacobsen and Arthur van Benthem, Letter Describing Scrappage Effects, NHTSA-2018-0067-7788, at 2.

of used vehicles was too uncertain to be used in the rulemaking. The agencies reiterated this position in their 2016 technical assessment of the standards. [1808]

They further stated:

> The agencies have not provided a meaningful rationale or justification for the change in position regarding their ability to present quantified estimates of the impact of the standards on new vehicle sales and the scrappage of used vehicles. [1809]

To respond to these comments, it is useful to look at the reasons the agencies gave for not considering fleet turnover effects on pages 845-46 of the 2012 rulemaking:

> If the value of fuel savings resulting from improved fuel efficiency to the typical potential buyer of a new vehicle outweighs the average increase in new models' prices, sales of new vehicles will rise, while scrappage rates of used vehicles will increase slightly. This will cause the "turnover" of the vehicle fleet—that is, the retirement of used vehicles and their replacement by new models—to accelerate slightly, thus accentuating the anticipated effect of the rule on fleet-wide fuel consumption and CO_2 emissions. However, if potential buyers value future fuel savings resulting from the increased fuel efficiency of new models at less than the increase in their average selling price, sales of new vehicles will decline, as will the rate at which used vehicles are retired from service. This effect will slow the replacement of used vehicles by new models, and thus partly offset the anticipated effects of the final rules on fuel use and emissions.
>
> *Because the agencies are uncertain about how the value of projected fuel savings from the final rules to potential buyers will compare to their estimates of increases in new vehicle prices, we have not attempted to estimate explicitly the effects of the rule on scrappage of older vehicles and the turnover of the vehicle fleet.* [1810]

The agencies' reason for not modeling the fleet turnover effects in prior rulemakings was not uncertainty about the direction or impact of vehicle prices on sales or scrappage rates, but rather uncertainty about how consumers value fuel savings. The agencies now have sufficient knowledge regarding the amount of fuel savings consumers are assumed to value at the time they purchase new vehicles and make these assumptions in the technology application simulation. With this assumption, it becomes possible to model the fleet turnover effects, including the scrappage effect.

[1810] 77 Fed. Reg. 62,623, 63,112-13 (emphasis added).

(c) Some Commenters Think the Effects Are Uncertain

Other commenters argue that the sales and scrappage effects are too uncertain to include in a rulemaking analysis. For example, CBD argued that "the models are attempting to evaluate the small and uncertain effects of changes in vehicle standards on certain dynamics—vehicle sales, scrappage rates, and vehicle usage—which are largely determined by much stronger forces, such as the state of the economy."[1811]

The agencies agree that there is uncertainty around the magnitude of the sales and scrappage response, but do not agree that sign of either effect is uncertain. Importantly, excluding modeling of the sales and scrappage effects would only make sense if there was a legitimate existential concern—the sales and scrappage effects are founded in very basic economic theory, as noted above, in Section VI.C.1.b)(3)(a)(i). Furthermore, the agencies believe that assessing the magnitudes of the sales and scrappage effects is a tractable task for researchers and sufficient data exists to quantify these effects. Thus, excluding these effects would be a serious omission that limits accurate accounting of the costs and benefits of fuel economy standards. Other stakeholders commented that the NPRM analysis did not thoroughly consider the uncertainty around the magnitudes of the sales and scrappage responses. These comments and the agencies response is discussed in Section VI.C.1.b)(3)(b)(i), below. The agencies believe it is better to consider a range of the scrappage and sales response to address concerns about uncertainty, and that excluding them would be inappropriate.[1812] The agencies did just that with the proposal through sensitivity analyses—including seeking comment and having the scrappage modeling peer reviewed—and continue to do so for the final rule.

(b) Summary of Notice, Request for Comments, and the Agencies' Response

The comments related to the scrappage model are summarized here into five major categories: overfitting and identification strategies, modeling fuel economy and new vehicle prices, consideration of other additional variables, integration with sales or VMT, and evaluations of associated costs and benefits due to changes in scrappage rates within the CAFE model. Specific modeling decisions the agencies have made or considered in response to the public comments summarized in this section are discussed in Sections VI.C.1.b)(3)(c)(ii)(d) and VI.C.1.b)(3)(c)(iii).

(i) Overfitting and Identification Strategy

Several commenters argued that the NPRM scrappage model did not have a clear identification strategy, or that the model *over-fit* the data. These commenters suggest that the

---

[1811] CBD, Appendix A, NHTSA-2018-0067-12000, at 177.

[1812] *See*, e.g. *Ctr. for Biological Diversity v. Nat'l Highway Traffic Safety Admin.*, 538 F.3d 1172, 1203 (9th Cir. 2008), (finding that NHTSA inappropriately assigned no value to reducing carbon emissions when the value for doing so was "certainly not zero.").

NPRM model may not capture a causal relationship, but picks up other correlation or noise within the data. This section outlines the specific claims made by commenters.

(a) Overfitting and the Use of Lagged and Interactions Terms

Several commenters argued that the results presented in the NPRM could be driven by the specific structure of the price effect used in the scrappage models that were implemented into the CAFE Model. IPI, California States et. al., CARB, and other commenters suggested that the NPRM model is over-fit. CARB outlined its argument that the agencies overfit the data in the following passage:

> [T]he model appears to be significantly overfit and to suffer from multicollinearity. An overfit model means that the model is able to precisely replicate past trends, but only through the use of too many variables. An overfit model fits the data too well, fitting the noise or errors in the data in addition to the underlying relationships between the variables of interest. Because an overfit model also fits the noise and errors of the data, the out-of-sample predictions are unreliable. Comments from Jeremy Michalek and Katie Whitefoot suggest that choice of specification of the scrappage model could result in substantially different predictions, and that the agencies should make only those claims that are robust to reasonable variations in the model specifications.[1813]

The agencies agree that it is important that the scrappage model results are robust across those specifications that meet a set of econometric criteria (these criteria are discussed further in Section VI.C.1.b)(3)(c)(iii)). However, the agencies acknowledge that the NPRM could have provided further evidence that the specification did not drive the results. In the analysis for the final rule the agencies have presented more than one specification of the price effect as evidence that the specification chosen here does not drive the results of the analysis. Further, claims that the specification of the scrappage response in the NPRM is inconsistent with economic theory are false.

Theoretically, changes in average new prices may have longer-term trends that can be picked up by including lagged terms, and/or be non-linear with age, so that vehicles of different ages have different elasticities of scrappage (relative to changes in average new vehicle prices). Further, sometimes the effect of one independent variable on the dependent variable depends on the magnitude of another independent variable—this is called an interaction effect. Regression analysis can capture these interaction effects by defining a new variable using some combination of independent variables.[1814] It is necessary to retain such interaction terms when doing so.[1815] For example, it is not obvious that the elasticities of scrappage rates to changes in new vehicle

---

[1813] CARB, Detailed Comments, NHTSA-2018-0067-11873, at 245.

[1814] Davis, J. B.,*Statistics using SAS enterprise guide*. Cary, NC: SAS Institute, pp. 411-415 (2012).

[1815] As explained in more detail in Section I.A.1.a)(1)(a)(ii)(a), below, the agencies perform several sensitivity analyses to ensure the model captures the correct impact of interactive effects.

prices should be constant for all vehicle ages, or put another way, the older a vehicle is, the higher likelihood the vehicle will be scrapped instead of being retained or resold.

Michalek and Whitefoot, Honda, and other commenters, argued that the fact that some of the interaction terms were not statistically significant was evidence that the response measured is uncertain. CBD in particular claimed that the "scrappage model is poorly constructed, and its results are not statistically significant."

In response to such comments, it is important to note that when interaction terms are included, the significance of the overall effect of a variable should be tested by performing a restricted F-test, which simultaneously tests that all coefficients of the variable of interest are jointly indistinguishable from zero. The insignificance of one term of the interaction does not imply that the effect is indistinguishable from zero.[1816]

Commenters also noted the lagged terms and age interactions make the new vehicle price effect difficult to interpret. IPI argued that "[t]he inclusion of interaction variables make it very difficult to evaluate the results of the regression for an individual variable of interest." Michalek and Whitefoot suggested "using a Monte Carlo analysis to understand the distribution of scrappage outcomes implied by uncertainty of the value of the coefficients in the model regression and reporting 95% confidence intervals."

We agree that the inclusion of lags and age interactions of new vehicle prices can make interpreting the sign and magnitude of the price effect difficult. It also makes it difficult to use the confidence intervals on the coefficients as a way to capture uncertainty, since the interaction variables are jointly estimated. Thus, for the NPRM analysis, the agencies could not independently sample each coefficient from the confidence intervals and perform a Monte Carlo analysis.

While the agencies think that the inclusion of lags and interaction terms is theoretically plausible, in response to commenter and peer reviewer concerns about overfitting and the difficulty of interpreting coefficients, the agencies reconsidered the time series approach. The agencies found that new vehicle prices are integrated to order one and that the dependent variable is stationary (as discussed in Section VI.C.1.b)(3)(c)(iii)(a)). It is therefore sufficient to fit the first difference of new vehicle prices within the models. Thus, the agencies have simplified the central model of the response of scrappage rates to changes in new vehicle prices to exclude lags of the effect. The agencies further simplified the central scrappage models to exclude interaction of new vehicle prices and vehicle age; this allows the agencies to take the 95 percent confidence intervals as a low and high range for the magnitude of the price effect for the sensitivity analysis. The agencies also include a sensitivity analysis which includes interaction terms between new vehicle price and vehicle age to allow the elasticity of scrappage to changes in new vehicle price to vary by vehicle age.

[1816] Davis, J. B., *Statistics using SAS enterprise guide*. Cary, NC: SAS Institute, pp. 411-415 (2012).

Commenters also noted that the model did not perform well for vehicles beyond age 20. The agencies noted in the PRIA that the Polk dataset for older vehicles was limited and likely led to the inability to estimate the scrappage rates for older ages.[1817]

The final rule dataset includes almost 30 percent more data for vehicles fifteen years or older than the NPRM, which improves estimates of the scrappage rate of vehicles aged 20 to 30 (see Table VI-193). The agencies are still unable to capture the scrappage trends for vehicles over 30, as the dataset is still limited for the oldest ages of vehicles, and still rely on the decay function used in the NPRM for vehicles over the age of 30. The limited data explains the inability to predict the scrappage rates for older vehicles. However, including model year fixed effects and including the share of the initial cohort remaining does improve predictions of the final share remaining in the final rule models. These changes are discussed in Section VI.D.1.b)(c)(i)(c).

(b) Reduced Form and Endogenous Prices

California States et. al., CARB, EDF, IPI and academic commenters expressed concerns that the NPRM analysis fit a reduced form of the scrappage model, rather than a structural model. In other words, instead of explicitly modeling new and used vehicle prices in equilibrium under different regulatory alternatives and applying a measurement of the elasticity of scrappage to the resulting *used* vehicle prices, the agencies modeled the elasticity of scrappage from changes to *new* vehicle prices. For example, California States et. al., argued that the model "does not link the new and used vehicle markets as required by economic theory, nor does it attempt to measure used vehicle prices, which form the basis of scrappage theory."

While the agencies recognize that there are certain advantages to a structural model, they disagree that the sales of new and used vehicles must be modeled simultaneously. The agencies do link the new and used car markets by including new vehicle prices as an independent variable in scrappage regression equation. However, it would be inappropriate to include used vehicle prices in this equation due to endogeneity concerns. A change in used vehicle prices may change scrappage rates, but also an exogenous shock to scrappage rates may cause used car prices to vary.

Furthermore, the agencies are unaware of a viable structural model for the scrappage effect. The agencies performed an extensive review of economic of literature, both before creating the scrappage model for the proposal and revising it for the final rule, but were unable to find such a model or any insights on how to construct one. The agencies note that commenters did not suggest a structural model that the agencies should use or give any indication of whether such a model exists.

In order to understand why such a model is difficult to construct, it is important to understand what a structural model of the sales and scrappage responses would entail. A

[1817] FR, Vol 83, No. 165, August 24, 2018, p.43097.

hypothetical structural model for the new vehicle market can be represented by the following simultaneous demand and supply equations:

$$D_{New} = \beta_0 + \beta_1 * P_{New} + \beta_2 * P_{Used} + \beta_3 * P_{Transit} + \beta_4 * Income + \beta_5 * Households$$

$$S_{New} = \beta_6 + \beta_7 * P_{New} + \beta_8 * Production\ Cost_{New}$$

The demand equation for new vehicles in a given year is determined by the annual price of owning and operating new vehicles, the annual price of owning and operating used vehicles, the annual price of other substitutes, average household income, and the number of households. The supply equation is made up of the average price of new vehicles and the average cost to produce them.

As noted in the sales model write up, reducing required fuel economy stringency reduces the cost of producing new vehicles, and shifts the supply curve to the right. This results in an increase in the quantity supplied of new vehicles.

The structural model for the used vehicle market can be represented by the following simultaneous demand and supply equations:

$$D_{Used} = \gamma_0 + \gamma_1 * P_{Used} + \gamma_2 * P_{New} + \gamma_3 * P_{Transit} + \gamma_4 * Income + \gamma_5 * Households$$

$$S_{Used} = \gamma_6 + \gamma_7 * P_{Used} + \gamma_8 * Maint\ Repair_{Used} + \gamma_9 * Scrap\ Value_{Used}$$

The aggregate demand equation for used vehicles is determined by the price of owning and operating used vehicles, the price of owning and operating new vehicles, the price of other transit substitutes, average income, and the number of households. The supply curve equation for used vehicles is determined by the price of used vehicles, the cost to repair and maintain them in service, and the opportunity cost of the scrappage value of doing so. Relaxing new vehicle standards reduces new vehicle prices and shifts the demand curve for used vehicles downward, which reduces demand for used vehicles and the equilibrium price and quantity of used vehicles, and increases the annual scrappage rate.

Modeling the structural equations would require that the agencies predict new and used vehicle prices in equilibrium, allowing prices of new and used vehicles be determined simultaneously from estimates of the supply and demand curves for each market. As CARB stated in the following comment, new and used vehicle prices are endogenous—the equilibrium prices of each good are simultaneous:

> Because both scrappage rates and new vehicle prices may influence one another, the Agencies would need to utilize different statistical techniques to credibly identify the impact of new vehicle prices on scrappage rates. For example, the Agencies would need to identify an instrumental variable that impacts new vehicle price but that does not impact the scrappage rate. Models that suffer from endogeneity problems will have biased estimates. In other words, the estimates from these models cannot be used to inform policy, because they do not actually tell us how new vehicle prices impact scrappage.

CARB suggested a way to correct for endogeneity: using an instrumental variable in a two-stage least squares methodology where the instrumental variable is correlated with new vehicle prices, but not scrappage rates.[1818] The agencies could also address the potential for endogeneity in two steps: first, they could model the impacts of exogenous changes in new vehicle prices on used vehicle prices, and second, they could model the impacts of exogenous changes in used prices on scrappage rates. Implementing the first step would require using an instrumental variable to isolate exogenous shifts to the new vehicle supply curve, and then using the predicted values of new vehicle prices to model changes in prices for used vehicles of all ages. Because prices and scrappage rates are jointly determined in the market for used vehicles, predicting the elasticity of scrappage with respect to price variation also requires isolating exogenous changes in used vehicle price via the use of an instrumental variable.

There is one literature example that approaches the structural model that some commenters would like the agencies to implement. Jacobsen and van Bentham[1819] developed a structural model that simultaneously solves for prices that clear new and used vehicle supplies, and then applies an elasticity of scrappage measure that corrects for potential endogeneity of used vehicle values and scrappage rates using an instrumental variable methodology. Specifically, they use changes in fuel prices as an instrumental variable; changes in fuel prices shift the demand for different vehicle models, but not the cost of supplying them. This should capture exogenous changes in value, so that an exogenous measure of the scrappage elasticity can be isolated in the second stage of the two-staged least squares method.

While Jacobsen and van Bentham are able to correct for potential endogeneity between used vehicle values and their scrappage rates, their structural model to set new and used vehicle values simultaneously makes some presumptions that the agencies are not comfortable making. First, they calibrate their constant elasticity of substitution (CES) utility function using 1999 data from GM's internal model. This type of model would estimate elasticities of specific vehicle models and require a pricing strategy other than allotting all additional technology costs to the vehicle models to which they are applied. The agencies have avoided a pricing strategy for the reasons cited in the sales model write up. Second, by relying on GM's internal model, Jacobsen and van Bentham used elasticities calculated using only 1999 data of the GM fleet. The agencies do not expect that elasticities estimated from 20-year old data from a single OEM's portfolio of vehicles would translate to the entirety of the current vehicle fleet.[1820] Finally, Jacobsen and van Bentham represent total vehicle demand of a representative consumer from a composite vehicle. This approach precludes the realistic consideration that a household may prefer two used vehicles over one new vehicle, which is accounted for in the agencies' functional equations.

[1818] CARB, Detailed Comments, NHTSA-2018-0067-11873, at 244.

[1820] Kleit, Andrew N., 2004. "Impacts of Long-Range Increases in the Corporate Average Fuel Economy (CAFE) Standard." Economic Inquiry 42:279-94.

Jacobsen's and A. van Benthem's model is not a household level choice model, and is not meant to determine fleet size, as noted in their comment:

> In summary, while the Jacobsen and van Benthem (2015) paper cannot inform by how much the total vehicle fleet would expand under a CAFE rollback (since we do not estimate by how much it shrinks under CAFE), all the evidence and economic logic points to a larger total vehicle fleet under a rollback, at odds with NHTSA's fleet turnover model. [1821]

The agencies agree that the long-term fleet should be smaller in the augural case, as fewer new vehicles flow into the used car market (because of lower sales), but do think it is plausible that in the short term the fleet size *could* increase under augural standards if in some cases consumers substitute two used vehicles for one new one or choose to retain an additional vehicle on the margin because the higher value makes doing so a more reasonable investment (at the annual level). This sort of outcome is not possible with the Jacobsen and van Bentham 2015 model, because the overall demand for vehicles is set by the annual rent prices of a composite vehicle. The updates to the scrappage model for the final rule are consistent with this view, but do show a smaller fleet size under the augural standards relative to the proposal. This is discussed further in Section VI.C.1.b)(3)(b)(iv)(b).

Fitting the reduced form equation requires that endogenous variables are excluded from the model to avoid biased coefficients. As a result, used vehicle prices were omitted by design, because used vehicle prices and scrappage rates are endogenous.[1822] Some commenters argue that new vehicle prices and scrappage rates are also endogenous; CARB argued that "the model tries to rely solely on new vehicle prices to predict scrappage rates without realizing or controlling for the fact that scrappage rates may also affect new vehicle prices."[1823]

Commenters provided neither evidence nor an explanation as to why there may be some degree of "reverse causality" or endogeneity between new vehicle prices and scrappage rates. Two potential econometric explanations for such endogeneity could be that: 1) these variables are jointly or simultaneously determined, so each one influences the other; or 2) the model omitted a variable that causes covariance between new vehicle prices and scrappage rates. The agencies believe the first source of potential endogeneity can be dismissed, as any causal relationship between scrappage rates and new vehicle prices would *necessarily* flow through the used car market, which are substitute products for new vehicles, and specifically through the mechanism of used car prices. For example, an exogenous shock to scrappage rates *might* cause the supply curve in the market for the lowest-price used vehicles to shift, and the resulting change in their price *might* cause price responses in higher-price segments of the used vehicle market, which in turn *might* eventually filter up to the new vehicle market and affect the prices

for new vehicles. This chain of events suggests omitted variable bias might be a concern, rather than simultaneity.

The agencies believe that supply and demand for used vehicles (or some measure of their interaction, such as used vehicle prices) are the most likely sources of any potential omitted variable bias. If an omitted variable is causing bias in the estimates, then the bias is observable. Whether endogeneity—through an omitted variable—is causing bias is an empirical question, which can be answered by conducting common empirical test—the Durbin-Wu-Hausman test. The Durbin-Wu-Hausman test requires identifying a suitable instrument(s)—a variable—that is correlated with new vehicle prices but not with scrappage rates, so any effect exerted on scrappage rates by the instrument will occur through their association with prices for new vehicles.[1824] The agencies tested a few alternative approaches, which included using the change in new vehicle prices during the preceding time period and the level of prices during the current period as instrumental variables for the change in prices during the current period, and another test using the current-period growth rate in GDP as an instrument for the change in new vehicle prices during the current period. Each of these tests fails to reject the null hypothesis that no endogeneity is present at the 0.05 level of significance.

For both theoretical and empirical reasons, the agencies are therefore skeptical about both the likelihood that scrappage rates will affect prices for new vehicles, and the extent to which they might do so. The agencies find the theoretical underpinnings for endogeneity to be tenuous, and believe the empirical evidence suggests such endogeneity is not an issue for today's analysis.

The agencies chose not to fit a model predicting used vehicle prices directly from new vehicle prices for the proposal because currently-available time-series data on the prices of used vehicles of a given vintage going back to 1975 is limited. EDF cited the lack of available data as the reason not to fit the structural model:

> In the absence of any data or analysis, NHTSA did not describe the extent to which changes in new vehicle prices affect used vehicle prices of varying age, condition, etc.[1825]

The agencies note that acquisition, assembly, and cleaning of a nationally representative database for calendar years 1974 to 2017 on used vehicle prices by vintage from Kelly Blue Book (or a similar source) would take months to years, and would push the final rule beyond the necessary April 2020 lead time requirement to set MY 2022 standards. Kelly Blue Book data is readily searchable for current prices, but without a time series of used vehicle prices the data cannot be used to answer the causal relationship of changes in used vehicle prices over time on vehicle retirement rates. Even assembling a nationally representative sample of used vehicle prices by vintage would be a major undertaking. This is not to suggest that doing so is out of scope for

[1825] EDF, Appendix B, NHTSA-2018-0067-12108, at 56.

future analyses; the agencies plan to consider further the possibility of conducting additional analysis on the relationship between new and used vehicle prices.

The agencies considered use of the Consumer Expenditure Survey (CEX), which has reported vehicle transaction data annually since 1984.[1826] However, the sample of used vehicle purchase prices aged twenty and older is severely limited. For vehicles purchased between 1996 and 2017, the average number of transaction prices reported for vehicles aged 20 is 58, and for vehicles aged 25 is 18. Any computation of average used vehicle prices from such a small sample would not be reliable, and in fact, would be quite noisy. The agencies do not think that estimates of a structural model based on such limited sampling would improve the prediction of the scrappage effects over use of the reduced form equation.

EDF argued that modeling the impact of changes in new vehicle prices directly on used vehicle scrappage may not capture the fact that changes in used vehicle prices impact vintages differently. Further, they argue that if new and used vehicle prices change by the same proportion, the effect will have a very small impact on the prices of the oldest used vehicles. They argue that these small changes are not enough to change the scrappage decisions:

> Given that vehicles can sell for as little as a couple of hundred dollars and new vehicle prices average over $30,000, used vehicle prices can be as little as 1% of that of a new vehicle. Given that the largest increase in new vehicle prices projected by NHTSA in the NPRM is less than $3000, and assuming that its effect on used vehicle prices is likely to be roughly proportional to current relative prices, this might mean that the value of a very old vehicle or one in poor condition might only increase by $30 (decline by $30 under the proposal). It is difficult to see how such a change in value would have a measurable impact on scrappage. Of course, the impact of an increase in new vehicle prices on used vehicle prices might be more or less than proportional to their current relative values. However, NHTSA has done nothing to show which might be the case. The probability of any realistic change in used vehicle prices to induce the scrappage of used vehicles is still a complete mystery.[1827]

However, the age interaction on the new vehicle price effect allows that the elasticity of scrappage to changes in new vehicle prices may not be constant for all ages. Allowing the scrappage elasticity to new vehicle prices to vary by age incorporates the fact that the elasticity of scrappage of used vehicles and the cross-price elasticity of used vehicle demand to new vehicle prices may not be constant with age. At some point, the thirty-dollar increase EDF cited could be the difference in keeping a marginally used vehicle on the road; it would be a 10 percent increase in the price of a used vehicle, and may cover State registration fees on a marginally scrapped vehicle.

(c) Time Series

The scrappage model utilizes panel data. Panel data observes multiple individuals or cohorts over time. The data employed by the scrappage model observes the scrappage rates of individual model year cohorts between successive calendar years. The model allows for the isolation of trends over time and across individuals.[1828] Since the scrappage model uses aggregate model year cohorts to estimate scrappage rates by age and time-dependent variables (new vehicle prices, fuel prices, GDP growth rate, etc.) panel data is necessary to estimate the model. A major challenge to using panel data is that the data structure requires consideration of potential violations of econometric assumptions necessary for consistent and unbiased estimates of coefficients both across the cross-section and along the time dimension. The cross-section of the scrappage data introduces potential heterogeneity bias—where model year cohorts may have cohort-specific scrappage patterns.[1829] Another way to put this is that each model year may have its own inherent durability. The NPRM captured this potential bias by including model year as a continuous variable, but the model amended for the final rule includes the more traditional individual fixed effects. This is discussed in Section VI.C.1.b)(3)(c)(iii)(a). The time dimension of a panel introduces a set of potential econometric concerns present in time series analysis. The agencies considered potential autocorrelation in the error structures and included lags of the dependent and specific independent variables to correct for it; this is not an uncommon practice in dynamic panel models.[1830] Some commenters argued that time series approaches were not appropriate in the scrappage model at all. CARB stated the following:

> Time-series analysis for modeling scrappage is also inappropriate for the same reasons as it was for the new vehicle sales model—particularly because time-series analysis does not capture structural changes, which the scrappage model seeks to illustrate.[1831]

The agencies disagree with CARB's assessment. The potential scrappage effect can only be measured with a time series dimension; the agencies are interested in how changes in new vehicle prices *over time* impact the retirement rate of the on-road fleet *over time*. In order to isolate this effect, the agencies need multi-period data on the scrappage rates of used vehicles and prices of new vehicles.

The literature on vehicle scrappage rates utilizes panel data, but most research has ignored potential autocorrelation issues caused by the structural properties of independent variables that vary along the time dimension. With the NPRM analysis, the agencies found evidence of auto-correlated errors, which were corrected by including three lagged terms of the dependent variable.[1832] While in a pure time series analysis, this can be an appropriate methodology to account for autocorrelation in the error structure; estimates of the coefficients of

[1832] FR, Vol 83, No. 165, August 24, 2018, p.43097.

the lagged dependent variable are biased downwards when applied in fixed or random effects panel models. The reason for this is that the constant individual specific terms are correlated with the lagged dependent variable (by definition, since the individual specific terms are constant for all time periods, including the previous period), creating a bias in the estimate of the coefficient on the lagged dependent variable, and potentially other measures.[1833] The eponymous bias was first discussed in a paper written by Nickell in 1982.[1834] There is an increasing body of work developing estimators built specifically for dynamic panel data (DPD), or panel data where there is an autoregressive component to the data-generating process. In other words, the previous value of the dependent variable impacts the current value.

Further research into this literature (discussed above), comments on the NPRM, and peer review comments prompted the agencies to reconsider the approach developed for the NPRM. The NPRM analysis did not use fixed effects for specific model years, but instead imposed a parametric logarithmic relationship of successive model years. This parametric model year term will still result in biased estimates of the lagged dependent variable because it also does not vary over time for the same model year, and is therefore correlated with the autoregressive term. Since the autoregressive term carries through effects from the previous period (the new vehicle price effect), this will also bias the predicted Gruenspecht effect in the NPRM model. Updates to the model used for the final rule correct this issue by more deliberately considering the time series properties of both the dependent and independent variables.

In reconsidering the appropriate way to address the time series properties of the scrappage model, the agencies first consider the stationarity of dependent and independent variables. This was suggested in James Sallee's peer review:

> In contrast to the new vehicle sales regression reported in the PRIA's section 8.6, the discussion of the scrappage regressions does not include any discussion of the time series properties of the estimators. It is important to test for non-stationarity, for example. [1835]

Importantly, the agencies find that the instantaneous scrappage rate is stationary, so that there is no longer term information in the scrappage rates to recover with an autoregressive term. This means that a DPD model is not necessary to correct for potential autocorrelation in the model. This also implies that the autocorrelation in the errors is a result of non-stationarity in some or all of the regressors, and not the independent variable. The solution to this problem is to identify the order of integration of each regressor and difference until each is non-stationary. Table VI-195 in Section VI.C.1.b)(3)(c)(iii)(a) shows the order of integration of variables considered in the scrappage modelling.

(ii) Modeling Fuel Economy

(a) Counterintuitive Signs

In the NPRM analysis, the agencies controlled for the changes in the relative fuel economy of new and used vehicles by including the cost per mile of travel in the current period and the previous period for both new vehicles and the model year cohort whose scrappage is being predicted. This allowed fuel prices to alter the scrappage rates of existing vehicles, meaning model year cohorts with lower-than-average fuel economies were impacted by increases to fuel prices to a greater extent than cohorts with higher-than-average average fuel economies. It also allowed increases in the fuel economy of new vehicles to impact the scrappage rates of existing vehicles; the idea is that when new vehicles have a higher average fuel economy, holding price constant, the demand for new vehicles should increase relative to used vehicles, and scrappage rates should increase. While this was a plausible way of controlling for changes in the relative fuel cost per mile of usage of new and used vehicles, the agencies noted in the NPRM that some of the signs on new vehicle cost per mile were counterintuitive, so that increases in the average new vehicle fuel economy of certain body styles actually increased the scrappage rates of existing vehicles.

IPI, CARB, CBD, Natural Resources Defense Council (NRDC), and other commenters argued that these results were driven more by modeling decisions than by actual relationships within the data. NRDC suggested that the conclusions from the NPRM model should be treated with suspicion until validated by further research:

> [A]n increase in fuel price for a given level of fuel economy results in longer vehicle retention even though operational costs per mile increase. While it is not possible to rationalize this response without significant additional research, it is indicative of the fact that the algorithm response functions may not be properly defined.[1836]

The agencies agree that the results were counter-intuitive—having identified this issue in the NPRM and specifically seeking comment on the matter—and considered multiple alternative methods of capturing the fuel economy improvements of new vehicles within the scrappage model in response to comments. Among the changes considered were alternate forms of modeling the form of new vehicle fuel economy, as suggested by IPI:

> A paper by Shanjun Li et al., provides a useful example of how the agencies could include fuel efficiency in their regression without raising the econometric concerns that may be leading to their nonsensical results. Li et al. include fuel price and vehicle fuel efficiency (gallons per mile) of used vehicles as well as a variable that captures the interaction of fuel efficiency of used vehicles and fuel price in their regression as explanatory variables. Unlike the agencies' model, the regression analysis used in the Li

---

[1836] NRDC, Attachment 3: CAFE Model Activity Review, NHTSA-2018-0067-11723, at 20.

et al. paper found results that are consistent with economic theory: a decrease in overall demand for vehicles and an increase in demand for more fuel-efficient cars.[1837]

The NPRM included changes in new vehicle cost-per-mile, but did not include separate variables for fuel prices or fuel economy. This could potentially have conflated changes in the cost-per-mile of new vehicles from changes in fuel prices and changes in new vehicle fuel economy. The agencies considered including changes in fuel prices and new vehicle fuel economy as separate measures, as suggested in IPI's comment above, but opted for a different method of addressing the concern of how to include changes to new vehicle fuel economy in the scrappage model. However, specifications considering this approach are shown in Section VI.C.1.b)(3)(c)(iii)(d).

(b) New Vehicle Prices Net of Fuel Savings

UCS, CBD, NRDF, EDF, and other commenters expressed concern that quality adjustments were not included in the price series used to fit the NPRM model. In particular, commenters suggested that the valuation of fuel savings at the time of purchase should be deducted from the new vehicle price increases. For example, CBD argued:

> . . . [T]he agencies rely heavily on work by Howard Gruenspecht regarding the scrappage effect, and the NPRM acknowledges that Gruenspecht considered the effect of an increase in price "net of the portion of reduced fuel savings valued by consumers." Yet consumer valuation of fuel savings is excluded from the scrappage model, as well.[1838]

The scrappage model cannot include both independent variables on the fuel economy and cost-per-mile of new vehicles, and adjust the new vehicle prices by the value of fuel savings considered at the time of purchase, which would account for the improvement of the fuel economy of new vehicles twice. Thus, the agencies must choose between these methods to capture the value improvement of new vehicles when their fuel economy increases. The agencies show both methods in Section VI.C.1.b)(3)(c)(iii)(d). However, additional comments give reason to prefer a methodology that does not model the fuel economy or cost per mile of new model year cohorts directly, but instead adjusts the new vehicle price series by the amount of fuel savings valued at the time of purchase.

IPI expressed concern that the cost-per-mile measure was included in the scrappage model, but not in the sales model:

> [T]he CPM results in the scrappage model are inconsistent with the agencies' sale model. In the sales module, the agencies have chosen to ignore consumer demand for fuel economy and significantly boosted the price impact of the baseline standards as a result.

[1837] IPI, Policy Integrity Comments: NHTSA Final- Appendix, NHTSA-2018-0067-12213, at 72.
[1838] CBD, Appendix A, NHTSA-2018-0067-12000, at 177.

> But in the scrappage model, the agencies have incongruously allowed consumer valuation of fuel economy to drive a significant portion of the estimated fatalities.[1839]

The agencies note that the fuel economy of new vehicles was not included in the sales model because the signs were statistically insignificant when it was included, and the fit of the overall model was not improved. It was not excluded because the agencies do not think that new vehicle fuel economy does not affect their sales. One way to consider the value of increased fuel economy in both the sales and the scrappage model (in the same way) is to adjust the price of new vehicles by the amount of fuel savings consumers value at the time of purchase in both models. This is also consistent with how the CAFE model applies technology in the absence of CAFE standards, or when a manufacturer is already in compliance with existing standards. In response to comments about the counterintuitive signs of the change in new vehicle cost per mile for some body styles, and about the disconnect in how the fuel economy of new vehicles is modelled in the sales and scrappage models, the agencies have adjusted the new vehicle price series in both models by the amount of fuel savings consumers are assumed to value at the time of purchase (30 months of fuel savings). As noted in Section VI.C.1.b)(3)(b)(ii)(a), alternatives to this solution are presented in Section VI.C.1.b)(3)(c)(iii)(d). The agencies also discuss consideration of other quality improvements over successive model years in Section VI.C.1.b)(3)(b)(iii)(d).

(iii) Consideration of Other Additional Variables

Some commenters expressed concern that the scrappage model implemented in the NPRM analysis omitted several theoretically important variables in predicting the scrappage rates of the existing vehicle fleet. To understand these comments more fully it is useful to recall that existing vehicle owners can be private households/individuals, businesses, or dealerships. They supply the used vehicle (in the sense of making it available for use) to the market either by reselling them, or continuing to own the vehicle for their own use. Theoretically an existing owner will supply a used vehicle for additional use if the value of the vehicle (net of the opportunity cost of its value as scrap metal and used parts) exceeds the cost of maintenance, repair, insurance, and registration fees for the vehicle. If a seller does not perform necessary repair or maintenance services on the vehicle prior to sale, the value of the vehicle should be offset by the cost of those services. Accordingly, the scrappage threshold for a vehicle should remain the same regardless of whether the seller or buyer pays for any necessary maintenance or repair services on the vehicle.

Under this framework, commenters have argued that the agencies should include maintenance and repair costs, the value of the used vehicle when scrapped, and other costs to purchase the vehicle, all of which were excluded in the NPRM version of the scrappage models. IPI stated the following:

[1839] IPI, Policy Integrity Comments: NHTSA Final- Appendix, NHTSA-2018-0067-12213, at 79.

> The agencies should include the variables that Gruenspecht and others have traditionally included in their scrappage analysis, including price of vehicles indexed by maintenance and repair costs, the price of scrap metal, and interest rates.[1840]

The agencies agree that these variables are relevant to determining the scrappage rates of existing vehicles, but have concerns that the level of aggregation of available series related to each of these factors may obscure the ability of a statistical model to capture their impact on vehicle scrappage rates. Below, the agencies discuss commenter concerns about the omission of maintenance and repair costs, scrap steel prices, and interest rates, in turn. This rulemaking then outline the agencies' further consideration of each factor in this final rule analysis, and why each chose whether to consider each factor in the analysis for the final rule. Empirical results of models considering these factors are shown in Sections VI.C.1.b)(3)(c)(iii)(e) and VI.C.1.b)(3)(c)(iii)(f); the decision to exclude them from the primary analysis is further explained in these sections.

(a) Maintenance and Repair Costs

EDF, IPI, California States et. Al., CARB, CBD, and other commenters suggest that the omission of maintenance and repair costs by the agencies was not justified, and that the measure should be included in future models. CARB claimed that:

> parameters for repair costs and used vehicle prices towards the end of life should likely be included in a scrappage model. However, neither of these variables appear in the Agencies' model.[1841]

The agencies agree that the theoretically ideal model of scrappage would include maintenance and repair costs. For this reason, the agencies explored several methods for explicitly incorporating maintenance and repair costs. Section VI.C.1.b)(3)(c)(iii)(f) reports model results both with and without a maintenance and repair variable. Since the variable is integrated of order one, (see Table VI-193), the models including it take the first difference; in this form, increases in maintenance and repair costs result in an increase in the scrappage rate of existing vehicles, as expected. The sign is also statistically significant. While the agencies would prefer a maintenance and repair price series that varies by calendar year and vintage, such a series is not currently available. The agencies hope to continue to improve this variable in future work on the scrappage model, but respond to comments by including the first difference of the maintenance and repair series in some of the models considered for the model used for the final rule.

Commenters were apparently confused about the agencies' discussion of the impact of fuel economy standards on durability. The agencies discussed a finding from the Greenspan and Cohen (1996) paper that suggested that higher EPA emission standards actually decreased the durability of certain model years. The discussion from the PRIA follows:

[1840] IPI, Policy Integrity Comments: NHTSA Final- Appendix, NHTSA-2018-0067-12213, at 91.
[1841] CARB, Detailed Comments, NHTSA-2018-0067-11873, at 244.

> In addition to allowing new vehicle prices to affect cyclical vehicle scrappage à la the Gruenspecht effect, Greenspan & Cohen also note that engineering scrappage seems to increase where EPA emission standards also increase; as more costs goes towards compliance technologies, it becomes more expensive to maintain and repair more complicated parts, and scrappage increases. In this way, Greenspan and Cohen identify two ways that fuel economy standards could affect vehicle scrappage - 1) through increasing new vehicle prices, thereby increasing used vehicle prices, and finally, reducing on-road vehicle scrappage, and 2) by shifting resources towards fuel-saving technologies—potentially reducing the durability of new vehicles by making them more complex.[1842]

EDF and IPI misinterpret the agencies' discussion of findings from Greenspan and Cohen's work to imply that the fuel efficiency variable is meant to control for changes in maintenance and repair costs. The following quote from IPI exemplifies their confusion:

> In addition, the agencies have explicitly excluded several theoretically important explanatory variables (e.g., the cost of maintenance and repair), which are potentially correlated with fuel efficiency. [Footnote 405: Id. at 1000 (indirectly making this point with respect to fuel efficiency and maintenance and repair costs when emphasizing that 'Greenspan & Cohen also note that engineering scrappage seems to increase where EPA emission standards also increase; as more costs goes towards compliance technologies, it becomes more expensive to maintain and repair more complicated parts, and scrappage increases'). In other words, maintenance and repair costs are correlated with respect to fuel efficiency and scrappage rates.][1843]

The agencies did not mean to imply that including some measure of the fuel economy of a model year cohort (cost per mile, in the NPRM model) would control for variation in maintenance and repair costs over time. The discussion of Greenspan and Cohen's results was intended only to demonstrate that durability and standards that increase technological complexity may be correlated, so that durability increases may not be independent of CAFE/CO_2 standards.

Maintenance and repair costs for a given model year cohort likely are correlated with the fuel saving technologies applied to that cohort, but there is also a dimension of maintenance and repair costs that are correlated with other macroeconomic factors (i.e., wages, materials, etc.). Controlling for fuel economy would not capture calendar-year-specific changes to maintenance and repair costs that are caused by factors other than fuel economy. It also does not seem likely that variation in maintenance and repair costs from different fuel savings technology would be linearly related to fuel consumption, so that even model year variation in maintenance and repair costs could not be captured by including some measure of fuel economy or fuel consumption. As noted above, the agencies agree that maintenance and repair prices exist in the theoretically ideal scrappage model, and consider the variable in some of the models presented in Section VI.C.1.b)(3)(c)(iii)(f).

[1842] PRIA at 1000.
[1843] IPI, Policy Integrity Comments: NHTSA Final- Appendix, NHTSA-2018-0067-12213, at 78.

(b) Scrap Values

In the NPRM model, the agencies considered inclusion of the BLS scrap steel CPI series. The agencies gave the following reasons for excluding the measure in the final NPRM models in the PRIA:

> As noted by Parks (1977), the value of a scrapped vehicle can be derived either from the value of recoverable scrap metal or from the value of sellable used parts. There are several issues with using the BLS scrap steel CPI. First, as in Park's work, the coefficient on scrap steel is statistically insignificant—model results including the CPI of scrap steel are not shown, as there were other theoretical problems with the measure. The material composition and mass of vehicles has changed over time so that the absolute amount of recoverable scrap steel is not constant over the series. The average weight of recoverable steel by vintage would have to be known, and this measure would still be missing any other recoverable metals and other materials. Further, projecting the future value of the recoverable scrap metal would involve computing the amount of recoverable steel under all scenarios of fuel economy standards, where mass and material composition are assumed to vary across all alternatives. This value is not calculated explicitly in the current model, which is another reason some estimate of the value of recoverable metal is not included in the preferred model specification. [1844]

The concerns the agencies raised in the NPRM continue to be present for the model used for the final rule. The BLS scrap steel CPI will not have the same effect on the opportunity cost (the scrap value) of keeping an existing vehicle on the road as opposed to scrapping it for successive model year cohorts. The average weight of vehicles has changed over successive model years, as has the average steel composition.

Even considering the limitation of using the BLS scrap steel price series, commenters expressed concern about the exclusion of a variable to capture changes in the value of a vehicle as scrapped metal and/or used vehicle parts. As noted in Section VI.C.1.b)(3)(b)(iii)(a), IPI suggested that "the price of scrap metal" should be included, while CARB suggested the model include "used vehicle prices towards the end of life." The agencies made several further attempts to capture this component of vehicle scrappage, and address commenters' concerns, in the scrappage models used in the final rule. The agencies continue to consider models which include the BLS iron and scrap steel CPI series; results of these considerations are shown in Section VI.C.1.b)(3)(c)(iii)(f).

(c) Interest Rates

IPI and EDF expressed concerns that changes in the real interest rates of vehicle loans had not been included in the final NPRM scrappage model. EDF commented the following:

> NHTSA's model also does not include interest rates or the cost of financing a vehicle, another variable which NHTSA acknowledges affects scrappage. NHTSA itself states

[1844] PRIA at 1012,

> that "[a]s the real interest rate increases so does the cost of borrowing and the opportunity cost of not investing. For this reason, it is expected that as real interest rates increase that vehicle scrappage should decline. Consumers delay purchasing new vehicles because the cost of financing increases. Conversely, as real interest rates decrease, vehicle scrappage should increase . . . . Yet, NHTSA chooses not to include interest rates in its model since inclusion of interest rates yields results that are opposite to what is expected—"as real interest rates increase, so does the scrappage rate" in NHTSA's model. As discussed above, this is yet another indication that the model is flawed and cannot be relied upon.[1845]

The agencies considered real interest rates in the NPRM analysis. Increasing the cost of purchasing a vehicle should increase the incentive for households to hold onto existing vehicles (as opposed to purchasing one) and scrappage rates should decline. The agencies excluded real interest rates from the final NPRM model for the reasons stated in the PRIA:

> Table 8-14, Table 8-15, and Table 8-16 include interest rates and maintenance and repair CPI for cars, vans/SUVs, and pickups, respectively. For cars, as shown in Table 8-8, real interest rate is of the opposite sign than expected; as real interest rates increase, so does the scrappage rate—this model is also a worse fit by measures of AIC and BIC relative to the preferred model.[1846]

In response to commenters' concerns, the agencies continue to consider interest rates in the model used for the final rule, as shown in Section VI.C.1.b)(3)(c)(iii)(e). However, interest rates only affect scrappage rates where a household might be unable to finance the purchase of a new or used vehicle and instead decides to maintain an existing vehicle that would have otherwise been scrapped. The most likely substitute for a marginal scrapped vehicle would not be a vehicle that could be financed. Accordingly, the relationship between interest rates and scrappage rates may be weaker than that between new vehicle prices and scrappage rates. The most likely substitutes for new vehicles are vehicles just off lease, and the resulting increase in residual values will affect slightly older vehicles. Eventually, the price of the most likely substitutes for marginally scrapped vehicles will also increase, so that scrappage rates will also be affected.

(d) Other Vehicle Quality Adjustments

CARB and other commenters expressed concerns that the NADA series used by the agencies in development of the NPRM scrappage model did not make quality adjustments. CARB made the following specific comment:

> By only including new vehicle prices and no other controls for vehicle quality, the Agencies' scrappage model omits variables that are important predictors of scrappage rates and of vehicle prices. Prior work that has relied on new vehicle prices to estimate

[1845] EDF, Appendix A, NHTSA-2018-0067-12108, at 41.
[1846] PRIA at 1028.

scrappage rates have also included some aspects of quality improvements, meaning considering that the vehicle is improving in some way. For example, Greenspan and Cohen (1996) include both the Bureau of Labor Statistics (BLS) new vehicle price index and the BLS cost of repair index.[1847]

The NADA average new vehicle transaction price does not control for other average characteristics that may change over successive model years. The agencies considered controlling for average body style and model year characteristics in the scrappage model as an alternative to including fixed effects in the model. The considered characteristics included: horsepower to weight, zero to sixty acceleration time, and average curb weight. However, performing the *pFtest* implementation of an F-test of goodness-of-fit, from the "plm" R package, suggested that fixed effects are necessary to control for heterogeneity across model years.[1848] For this reason, average characteristics that are constant over calendar years for a given model year cohort cannot be included in the model. The agencies do present specifications that include the ratio of new to used vehicle performance (since this has calendar year level variation and can be included with model year fixed effects) in Section VI.C.1.b)(3)(c)(iii)(f).

(iv) Integration of Sales and/or VMT, Total Fleet Size, and Total VMT

Some commenters believe the ideal model of how CAFE/CO_2 standards affect sales, scrappage, and usage would be a joint household choice model. RFF makes the following comment:

> The agencies can fix those problems by making two changes. First, they can jointly model VMT and vehicle holdings (i.e., scrappage and new-vehicle purchases). The literature provides many examples of such modeling for guidance (see citations above). Jointly modeling these choices will make the analysis internally consistent and will account for the fact that households do not make scrappage and vehicle use decisions in isolation. If the model predicts that weaker standards cause more scrappage, it will simultaneously estimate any increase in VMT for the remaining vehicles.[1849]

The advantage of such a model is that sales, scrappage, and usage would be jointly determined so that the impacts on scrappage is conditional on how increased new vehicle prices affect sales and vehicle prices, and usage is dependent on both effects. The agencies agree that this type of model would better capture the joint nature of the choices of which vehicles to buy, which to sell or scrap, and how much to use each than modelling each effect separately. However, the agencies are not aware of any national dataset that would allow sales, scrappage

and usage to be jointly predicted, nor are they confident of such a model's ability to predict better than carrying current market shares forward.

The papers cited in the RFF comment, Linn and X. Dou, 2018;[1850] Berry, Levinsohn, and Pakes, 1995;[1851] and Jacobsen and van Bentham, 2015,[1852] either use the CEX or the NADA transaction price series merged with the Polk registration counts. The CEX is a relatively small sample of households (about 160,000), their vehicle holdings, vehicle purchases, and usage. However, it does not report retirement rates, but only when a vehicle exits a household's fleet (most often it is sold or traded in). Thus, at best, the CEX could be used to build a household consumer vehicle holdings and usage model, but the vehicles that are scrapped would be implied; scrappage would not be modeled directly, nor would it be attached to the number of miles on a vehicle. The NADA and Polk datasets used by Jacobsen and van Bentham links vehicles prices and scrappage rates, but does not track individual household decisions. The Jacobsen and van Bentham paper relies instead on a model of the new and used vehicle market which takes cross-price elasticities as an assumption derived from the outputs of a 1997 GM consumer choice model.[1852, 1853] The agencies will continue investigating whether a consumer/household choice model can serve as an alternative to aggregate estimates of sales and scrappage, but are skeptical about the ability of such models to predict future model shares accurately.

As was the case with the 2012 final rule and the 2016 TAR, the agencies again note there is no credible consumer choice model which can be implemented in the CAFE model. Literature comparing the performance of consumer choice models to holding manufacturers constant suggest that the latter predicts future market shares better than the former. NCAT raises this point in their comment below:

> Academic and other researchers have developed a number of vehicle demand (consumer choice) models for the new and/or used vehicle markets to look at effects on sales and fleet mix. Rarely has there been any effort to validate these models, either for consistency across models, or for ability to predict out of sample. Recent academic research, as well as work by EPA, has found that these models commonly perform worse, especially in the short run, than simply holding market shares constant. [1854]

For these reasons, the agencies have not used a consumer choice model to capture the sales and/or scrappage impacts, but have built reduced form equations from aggregate data instead.

[1854] NCAT, NCAT Comments, NHTSA-2018-0067-11969, at 11.

NCAT and CBD also refer to EPA attempts to develop a consumer choice model in conjunction with Oak Ridge National Labs, and note that the agencies did not use this model for the NPRM analysis. This specific choice model, as referenced in the excerpted NCAT comment above, has not predicted future market shares as well as projecting current shares forward. For this reason the model was not deemed fit to include in the policy analysis. NHTSA also worked to develop a consumer choice model, but when implemented, the model predicted that some OEM's would have unrealistic declines in total sales. The limitations of the consumer choice models the agencies have considered is overlooked in the following comments from CBD:

> The sales model the agencies use is not the consumer-choice model that EPA has been developing and refining for almost a decade. Rather, both it and the scrappage model appear to have been developed by NHTSA in just the last two years. Neither model has been peer-reviewed, nor even released publicly until the publication of this NPRM.[1855]

The agencies did not use the consumer choice models either agency developed because the predictions are not reliable—which has disappointed not only the commenters mentioned above, but the agencies and researchers who have spent significant resources attempting to develop models for these purposes. Instead, the agencies have modelled the effects from reduced form equations from aggregate data.

(a) Integration with Sales Model

The NPRM models did not include any direct linkage between the sales, scrappage, and usage functions, as noted by the agencies. Here, the agencies consider comments from stakeholders about the lack of integration of the scrappage model with sales (and the effect on total fleet size), and the lack of integration with the vehicle usage schedules (and the effects on total VMT).

NCAT, EDF, CBD, CARB, and other commenters argued that the sales and scrappage models should be directly linked, and that their independence predicts the higher fleet size and total VMT under the augural standards. CBD makes the following statement:

> The agencies now, irrationally, decouple those two effects, such that the number of new vehicles sold (or left unsold) has no effect on the number of vehicles scrapped. Relying on the deeply flawed scrappage model, the agencies have predicted a massive ballooning of fleet size under the existing standards that leads, automatically under their model, to a massive increase in VMT. [1856]

The agencies note that the structural model presented in Section VI.C.1.b)(3)(b)(i)(b) demonstrates that both the equilibrium quantity and the price of new vehicles sold are changed when the production cost of new vehicles changes under different regulatory alternatives. Specifically, under relaxed standards, the equilibrium price is lower and equilibrium sales are higher than the counterfactual augural standards. Controlling for other variables that might shift

---

1855 CBD, Appendix A, NHTSA-2018-0067-12000, at 175.
1856 CBD, Appendix A, NHTSA-2018-0067-12000, at 185.

the new vehicle supply or demand curves, either new vehicle prices or sales could enter the used vehicle demand equation (as in the structural model, there is a functional relationship between the two, again, controlling for factors that shift the supply and demand curves for new vehicles). Thus, the agencies could use either new vehicle sales or prices to control for changes in the new vehicle equilibrium solution in the scrappage equation. It is important to control for factors that affect the demand for vehicles overall (business cycle conditions, etc.). The agencies present the preferred models using either new vehicle prices or new vehicles sales in Section VI.C.1.b)(3)(c)(iii)(d). Since there should be a collinearity between the two, it would be inappropriate to include both variables simultaneously.

(b) Total Fleet Size

NCAT, EDF, CBD, CARB, UCS, IPI, California et. al., academic commenters, and other stakeholders argue that the fleet size should not change much with new vehicle prices. Some commenters go further to argue that higher vehicle prices under the augural standards should result in a *smaller* fleet size in the augural case relative to the proposal. The agencies agree that the long-term impact of higher new vehicle prices should be a slight reduction in fleet size, but do not agree that the short-term impacts of the standards on fleet size are obvious.

Many examples from the literature make assumptions that ensure that the fleet size under different regulatory alternatives remain constant. UCS cites this assumption in the original Gruenspecht works (their emphasis):

> Though the agencies cite the Gruenspecht effect for its basis for the scrappage model, they ignore a central constraint of Gruenspecht's work—namely, his assumption that FLEET SIZE AND TOTAL VMT ARE INSENSITIVE TO PRICE. [1857]

Other works ensure the same conclusion with different assumptions. Within the Jacobsen and van Bentham, 2015 and Goulder et. al., 2012 framework, a household first chooses the number of vehicles to own based on the average price of all vehicles subject to a budget constraint. After choosing the number of vehicles to hold, the household chooses the specific type and age of vehicles to hold. However, for some households the choice of how many and which vehicles to hold is not disjoint, so that a household may choose to hold two used vehicles as a second choice to one new vehicle. When new vehicle prices increase, under the same budget constraint, they may choose to hold two vehicles instead of one. If enough households make this choice, the fleet size could slightly increase.

IPI gives a literature example of a model that does not ensure this outcome with initial assumptions. This model directly predicted fleet size, and not sales and scrappage. The fleet size in the CAFE model is the result of the sales and scrappage models, and not the result of a

[1857] UCS, UCS MY2021-2026 NPRM: Technical Appendix, NHTSA-2018-0067-12039, at 60.

single of the models. Small and Van Dender, 2007 finds that higher new vehicle prices are associated with lower total vehicle stock, as IPI states in the quote below:[1858]

> In their 2007 study estimating the rebound effect caused by changes in fuel efficiency, Kenneth Small and Kurt Van Dender derived estimates of the relationship between vehicle price and fleet size. By simultaneously estimating a system of equations for VMT per capita, fleet size, and fuel efficiency for the United States from 1966 to 2001, Small and Van Dender also found that an increase in new vehicle price has a negative, statistically significant effect on total vehicle stock. [1859]

However, it is worth noting that Hymel, Small, and Van Dender in 2010 published a study finding a statistically insignificant result of the opposite sign.[1860] The general framework of the two papers are very similar, so that the updated results show that the fleet size impact is ambiguous.

Toyota and the Automobile Alliance mentioned that NERA built sales and scrappage models, and requested that the agencies "review the NERA econometric study's methodologies for adoption or to refine their own models." The agencies considered the NERA scrappage model, but note that the model merges the data for all vehicle types, so that the scrappage relationship by age for pickups is adjusted by the same constant for all ages. However, the agencies note that each body style has a unique functional form with age—as evidenced in Section VI.C.1.b)(3)(c)(iii)(c))—so that it does not seem appropriate to merge them. Further, it does not seem likely that the elasticity of scrappage is the same for all vehicle types.

While the agencies think there are reasons not to adopt the NERA scrappage model as is, this suggested general approach does support simplifying the model as further suggested in Section VI.C.1.b)(3)(b)(i). Also, this research supports the notion that the relative fleet size of the proposed and augural standards is not a given. NERA's comments about their model provided:

> The separate changes in new vehicle sales and changes in scrappage rates would lead to differences in the overall fleet size for the CAFE standard alternatives. The net effects of these two changes did not have a substantial effect on the overall fleet population under any of the three CAFE alternatives (never more than 0.25% change in fleet size compared to the augural standards). [1861]

[1861] Auto Alliance, Attachment 1: NERA Evaluation, NHTSA-2018-0067-1207, at D-3.HONDA.

The NERA model shows the same directional fleet impacts as the NPRM sales and scrappage model. This lends some further support to the notion that the fleet impacts are not as certain as some commenters suggest.

Another empirical model predicts a larger total fleet size under the augural standards than under the proposed standards. Comments by David Bunch offer an extended comparison of the sales, fleet size, and retirement rate results of the Department of Energy's National Energy Modeling System (NEMS) model under the proposed and augural standards. NEMS predicts fleet size from input assumptions about the size of the on-road fleet, endogenous new vehicle sales estimates, and exogenous assumptions about scrappage.[1862] However, in his comments Bunch said:

> Scrappage is an implied behavior determined by projecting total fleet size and new vehicle sales. Through this mechanism, all else equal, an increase in new vehicle sales would yield an increase in scrappage. [1863]

NEMS does not project total fleet size endogenously in their model as Bunch assumes. Nor is scrappage an implied behavior determined by fleet size and new sales projections. Instead, total fleet size is implied from an endogenous sales model, and constant age- and body-style-specific scrappage rates. The difference between the CAFE Model and NEMS is that the CAFE model has both endogenous new vehicles sales *and* scrappage rates—scrappage rates are not assumed to be constant for all regulatory alternatives. Fleet size is the implied variable in *both* models.

Bunch finds that the NEMS model also predicts a larger fleet size under the augural standards than the proposed standards. Specifically, he finds the following:

> The differences are initially about 100K, increasing linearly from 2031 from 200K to 1.8M in 2050. Because even the Existing standards remain at the same level after 2025, this would seem to represent a very different effect from what might be going on in the CAFE model results. [1864]

Bunch goes on to discuss the relationship between sales, scrappage and fleet size in NEMS in the following passage:

> New vehicle sales generally are growing in both scenarios, so economic theory suggests that fleet sizes should also be growing (they are). Specifically, although the Gruenspecht effect logic suggests that increasing new vehicle sales should lead to increased used vehicle scrap rates, the total "value" of the fleet is increasing, so this would suggest an

---

[1862] From page 109 of 2016 NEMS documentation "*exogenously* estimated vehicle scrappage and fleet transfer rates." https://www.eia.gov/outlooks/aeo/nems/documentation/archive/pdf/m070(2016).pdf.
[1863] David Bunch, Bunch-UC Davis: Consumer Behavior Modeling, at 77.
[1864] David Bunch, Bunch-UC Davis: Consumer Behavior Modeling, at 69.

increase in the fleet size. Moreover, new vehicle sales are higher under Existing, so the fleet size should be also. [1865]

Bunch makes several claims that are not consistent with available data and the agencies' understanding of how the NEMS model. First, he states that because sales are growing fleet size should also be growing. However, change in fleet size is the result of new vehicle sales less the number of existing vehicles scrapped; if new vehicle sales and used vehicle scrappage rates both increase, the fleet size is not necessarily increasing. Second, he states that the 'Gruenspecht effect logic' suggests that increasing new vehicle sales results in increasing scrappage rates. However the NEMS model does not change vintage-specific scrappage rates endogenously, but takes them as an exogenous input. Thus, the NEMS model does not capture the Gruenspecht effect, and its fleet size projections can only vary from changes in new vehicle sales. Any differences in the projected total fleet scrappage rates Bunch considers later are due to different initial sales of each body style, and therefore a different weighting of the constant body-style- and vintage-specific scrappage rates. This makes the comparison of the fleet size and scrappage rates of the two models not particularly meaningful. However, the difference in the projected sales impacts are worth a second glance. NEMS predicts prices that are at most about $1,000 higher in the Augural than the proposed standards, while the CAFE model predicts prices that are up to approximately $2,500 higher. The difference in the projected costs to meet the CAFE standards is likely the main reason for the difference in the sales outcomes—if the average fuel savings exceed the average incremental cost of the augural standards (relative to the proposal) in the NEMS model, the expected outcome is that sales should be higher in the augural case, as shown.

It is also worth noting Bunch's discussion of the empirical results of the CAFE scrappage model. Bunch purports to calculate the scrappage elasticity relative to new vehicle price increases, but his point of comparison does not hold constant other factors that might impact used vehicle scrappage rates. Instead, Bunch calculates the inter-annual percentage change in the scrappage rates for each regulatory alternative, then calculates the inter-annual change in new vehicle prices for each regulatory alternative, and finally takes the quotient. However, for inter-annual changes in scrappage rates, different projected GDP growth rates and fuel prices will have also played a critical role in the scrappage rates. The better point of comparison would be the incremental percentage decrease in scrappage rates for the augural standard relative to the proposal, over the incremental percentage increase in new vehicle price in the augural standard relative to the proposal for each calendar year. This ensures that the point of comparison holds constant all other factors that determine scrappage, as the regulatory alternatives use the same GDP growth rate and fuel price projections. When computing the implied scrappage elasticity in this way, the implied elasticities vary between approximates -0.1 and -1.1, with the average being approximately -0.5—which is *more* in line with what Bunch determines reasonable for his incorrect calculations of the NEMS model scrappage elasticities, as cited below:

[1865] David Bunch, Bunch-UC Davis: Consumer Behavior Modeling, at 71.

> Finally, the average values are -0.90 and -0.88 for the Existing and Rollback scenarios, respectively. On one hand, these are reasonably close to the Jacobsen and van Benthem (2015) estimate for scrap elasticity with respect to used vehicle prices. On the other hand, the Bento et al. (2018) estimate was -0.4, and one might expect the elasticity with respect to new vehicle price to be smaller. In any case, these results are not unreasonable. [1866]

The implied elasticities from the NEMS model are approximately zero, which is not a surprise since these are merely the result of different new vehicle sales affecting the relative weighting of NEMS' *constant* age-specific scrappage rates. Figure VI-123, below, shows a comparison of fleet sizes under the baseline, preferred alternative, and AEO 2019. The agencies see that, as commenters believed likely, the fleet size under the preferred alternative (where sales are larger in many years and scrappage rates higher) is eventually larger than in the baseline. However, those differences are minimal in the early years of the simulation where policy differences produce only small differences in sales and scrappage. Furthermore, the agencies see that the magnitudes of the fleet sizes in today's rule are generally similar to those produced by the AEO 2019 model. NEMS tends to produce growth that is more linear, leading to slightly smaller fleet sizes than those simulated by the CAFE Model through the 2030's and slightly larger fleet sizes through the 2040's. However, these differences are at most three percent of fleet size, and typically closer to one or two percent.

[1866] David Bunch, Bunch-UC Davis: Consumer Behavior Modeling, at 79.

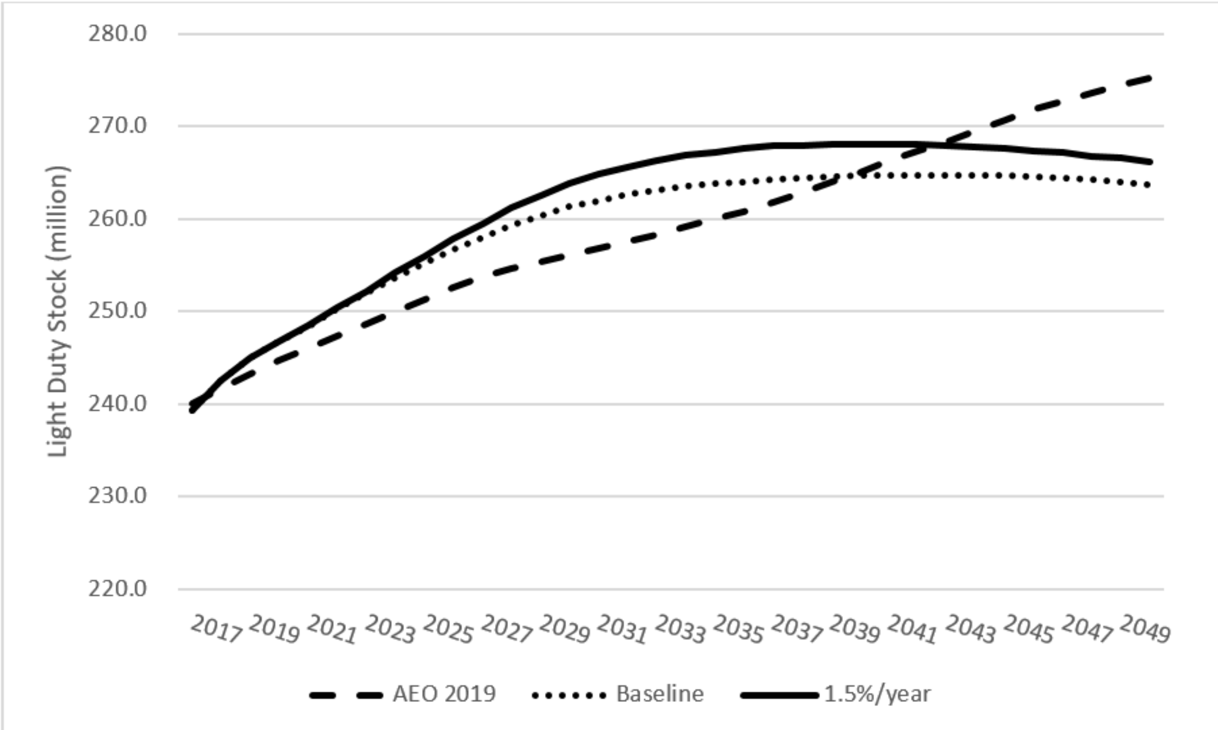

Figure VI-123 – Fleet Size Comparisons

As discussed above, commenters offered NERA's model and NEMS as points of comparison for NHTSA's sales and scrappage models and their combined implied fleet size. However, since NEMS does not model the scrappage effect, but takes static scrappage rates, it is not a fair point of comparison. NERA's model shows a larger fleet under the Augural standards, providing evidence that the impacts of the sales and scrappage models are ambiguous.

(c) Integration with VMT

In the NPRM the agencies noted that the average VMT by age is constant regardless of instantaneous or cumulative scrappage rates. The agencies noted that this was a limitation of the model, and sought comment on ways to integrate the two effects:

> [O]ur scrappage model assumes that the average VMT for a vehicle of a particular vintage is fixed—that is, aside from rebound effects, vehicles of a particular vintage drive the same amount annually, regardless of changes to the average expected lifetimes. The agencies seek comment on ways to further integrate the survival and mileage accumulation schedules.[1867]

Several commenters suggest that the lack of integration between VMT and scrappage rates is not justified. Some commenters suggested that the VMT should be determined from a household

[1867] EDF, Appendix B, NHTSA-2018-0067-12108, at 51.

holdings model, while others suggested merely that delayed scrappage under higher standards should increase average mileage accumulation, which will have some feedback for the next year's scrappage rates.

Joshua Linn and other commenters suggest that VMT is determined at the household level and should thus be modelled as such. EDF makes the following comment, which seems to reflect a fundamental misunderstanding of the type of model used to predict the scrappage effect:

> When describing the process whereby a potential new vehicle purchaser chooses to forego buying a new vehicle and continues to drive their existing vehicle, NHTSA's scrappage model ignores the fact that this action shifts VMT from a new vehicle with a higher average mileage per year to a used vehicle with a lower average mileage. Either the driver of this vehicle will drive their older vehicle less, causing overall VMT to decline, or the average mileage of the used vehicle will increase without any need to affect scrappage. By focusing solely on scrappage, and focusing the change in scrappage on those vehicles with the worst fuel economy (i.e., the oldest vehicles), NHTSA essentially shifts new vehicle VMT to the oldest vehicles. According to NHTSA's own rationale, much of the lost VMT from new vehicles will be replaced by vehicles only a few years old. The VMT of these relatively new used vehicles which is then replaced by VMT from older used vehicles, and so on.[1868]

The agencies' scrappage model does not capture household choices, but uses aggregate data to predict new vehicle sales and age-specific scrappage rates in response to changes in new vehicle prices. In addition, the scrappage rates of all ages change in response to increases in new vehicle prices, not just the oldest vehicles. Further, the household that does not buy a new vehicle but holds onto an existing vehicle instead, in EDF's example, results in one fewer used vehicle supplied to the used market—this will result in an increased price for used vehicles and potentially lead to some used vehicles not being scrapped. Because the VMT schedules the agencies use in modelling show usage declining with age, the agencies' model does assume that younger vehicles that are not scrapped are driven more than older vehicles that are not scrapped.

EDF, IPI, and Honda further argue that mileage accumulation should not be constant under all scrappage rates. Specifically, they suggest that the assumption that average VMT accumulation by age is constant even when scrappage rates decline, results in an *over*estimate of VMT. IPI suggests that the marginally unscrapped vehicles should drag down the average VMT accumulation under higher standards in the following comment:

> Because those schedules assume each vehicle of a certain age and type in the fleet drives a set amount of miles without any adjustment for the increase in total fleet size or vehicle quality (i.e., wear and tear and durability), the finding that the standards cause the fleet size to increase results in a significant increase in total VMT.[1869]

[1868] EDF, Appendix B, NHTSA-2018-0067-12108, at 51.
[1869] IPI, Policy Integrity Comments: NHTSA Final- Appendix, NHTSA-2018-0067-12213, at 61.

The agencies note that mileage accumulation and scrappage are not disjoint. A vehicle that is driven more miles is more likely to be scrapped. However, since the National Vehicle Population Profile (NVPP) data does not track individual vehicles, there is no obvious way to merge individual vehicle odometer readings with those that are scrapped. The agencies explored different data sources that could be used to capture the joint relationship of the two effects, but unfortunately were unable to identify a workable dataset. Furthermore, the agencies note that while commenters could be correct about the relationship between mileage accumulation and scrappage, they did not provide the agencies with any empirical evidence supporting their assertions.[1870] In the meantime, the agencies have adjusted the final rule analysis to conservatively assume that total demand for VMT, not including the rebound effect, should be constant for all regulatory alternatives, as discussed in Section VI.C.1.b)(3)(b)(iv)(d), below. This requires that the VMT schedules are no longer constant for all fleet sizes.

(d) Total VMT

Many commenters think that total VMT, not considering rebound miles, should be constant, regardless of the number of new vehicles sold and used vehicles scrapped. NCAT, Global, Auto Alliance, CBD, EDF, IPI, CARB, and Honda all make this argument. CARB makes the following statement suggesting that even a larger fleet size should not increase aggregate demand for VMT (again, not including rebound miles):

> A change in the overall fleet size due to the Augural standards might not in and of itself be problematic, as long as the VMT schedules are adjusted to account for overall travel activity that is distributed over a larger number of vehicles. However, the As-Received version of the [scrappage] model does not adjust VMT schedules, with the result that the additional unscrapped vehicles inflate total VMT proportionally.[1871]

The agencies agree that the aggregate demand for VMT should be roughly constant across alternatives, and stated this in the NPRM, where the differences in non-rebound VMT were on the order of 0.4%.

NERA's modelling efforts found similar small decreases in VMT in regulatory alternatives where the standards are relaxed. The Alliance stated:

> Under all three scenarios, vehicle miles traveled ("VMT") decreases relative to the augural standards. This is due primarily to rebound effects. Because NERA was only examining vehicles through MY 2029, the difference in VMT between the alternatives and the augural standards decreases over time, since fewer of the MY 2029 and earlier vehicles are on the road in those later years.[1872]

NERA's model used similar assumptions as the NPRM analysis and, like the NPRM results, the NERA model results suggest that it is plausible that total VMT could decline under

[1870] EDF, Appendix B, NHTSA-2018-0067-12108, at 54.
[1871] CARB, Detailed Comments, NHTSA-2018-0067-11873, at 238.
[1872] Auto Alliance, Full Comment Set, NHTSA-2018-0067-12073, at 11.

less stringent standards. A key assumption common to NERA's model and the NPRM analysis is that the VMT schedules are constant under all scrappage rates. However, as discussed in Section VI.C.1.b)(3)(b)(iv)(c), this can potentially overestimate total VMT in the augural case, where vehicles that were marginally scrapped in the proposal are kept on the road.

Presumably, vehicles that are scrapped in the proposal, but not in the augural, are in more disrepair than others in the same age cohort. As a result, these vehicles would on average be driven less, bringing down the average usage of the entire age cohort. This effect could alter the relative size of total VMT under the regulatory alternatives, as Honda notes in the following comment:

> According to our calculations, if the impact of lowering the average cohort's utility is even 0.2% the augural standards would become *safer* than the preferred alternative. We believe that the agencies should consider VMT behavior change as part of an effort to mature and refine the scrappage model.[1873]

As Honda suggests, a relatively small reduction in the average VMT schedules for the more stringent regulatory alternatives could result in a change in the direction of the safety impact. This shows the importance of investigating the linkage between usage and scrappage rates, but also shows that small changes to the total VMT assumptions can have meaningful impacts on the predicted effects of the analysis. Other commenters make similar points.

As noted above, the difference in total non-rebound VMT in the NPRM analysis was only 0.4%. However, CBD notes that this relatively small change in VMT across the alternatives in a single year can result in a large number of cumulative additional miles in more stringent regulatory alternatives:

> While 0.4% sounds small, when the scrappage model's effect it is multiplied by all the VMT that NHTSA includes in its analysis, spanning decades, it becomes highly significant—at least 692 billion additional VMT under the CAFE standards and 894 billion under the CO_2 program, both relative to the preferred alternative.[1874]

Since VMT is related to many of the costs and benefits of the program, differences in cumulative VMT of this magnitude can have meaningful impacts on the incremental net benefit analysis. This point was implied by comments from CBD, EDF, NCAT, EAO, and in a paper published by academics after the issuance of the NPRM.[1875] For this reason, the agencies have opted to constrain total non-rebound VMT across regulatory alternatives.

[1873] Honda, Honda Comment, NHTSA-2018-0067-11818, at 18.
[1874] CBD, Appendix A, NHTSA-2018-0067-12000, at 180.
[1875] Bento, Antonio M., et al. "Flawed Analyses of U.S. Auto Fuel Economy Standards." Science, vol. 362, no. 6419, 2018, pp. 1119–21., doi:10.1126/science.aav1458.

Such a constraint was suggested by EDF, IPI and other commenters. EDF states the following:

> A sophisticated model is not needed to correct this problem. One only needs to adjust the VMT added by the "scrappage model" so that it matches the VMT lost by the sales response model. Put another way, used vehicles would be used to the same extent as new vehicles since they meet the identical demand (possibly minus a rebound effect). [1876]

EDF goes on to suggest some potential issues with implementing this constraint:

> Even this adjustment would still be in favor of the proposal, as it assumes that all the VMT lost from fewer new vehicle sales would be replaced by used vehicle VMT. This assumes that travel is inelastic. This is clearly not the case given NHTSA's position on the rebound effect. NHTSA must first justify the used vehicle response to any change in new vehicle sales. Then, in the unlikely event that this can be done, NHTSA must link the scrappage model to the sales response model to ensure that the combination of the two models does not increase VMT in any calendar year (and probably show a decrease, as the overall cost of driving will have increased).[1877]

The agencies disagree that lost new vehicle sales would impact the VMT of the new vehicles that are sold. The agencies do, however, as EDF notes, adjust the VMT of new vehicles to consider changes in the cost per mile of travel. In fact, when fuel prices increase, the agencies assume that owners of all existing vehicles drive less; the reduction will be greater when the vehicles on the road are less efficient, which seems consistent with what EDF suggests in the last sentence above. The agencies have justified the scrappage effect throughout this discussion, above.

EDF identifies another reason the agencies think a constraint on total VMT is reasonable for purpose of the final rule analysis. The scrappage, sales, and VMT models each have a certain amount of uncertainty associated with it (the uncertainty of the scrappage model is discussed in Section VI.C.1.b)(3)(b)(i)(a)), so that when the three models are combined, the uncertainty is compounded. EDF characterizes these results as being inconsistent with economic theory in the comment below:

> We are not aware of any economic arguments which would support such an increase. All that can be said is that NHTSA put data from a variety of sources through a statistical regression and never bothered to see if the results were reasonable or consistent with its own economic theory. [1878]

The NPRM analysis discussed total fleet size and VMT at length; the agencies noted that the fleet was 1.5% bigger for the augural standard than the proposal, resulting in 0.4% additional non-rebound VMT in CY2050.[1879] However, given the amount of uncertainty around each of the

1879 FR, Vol 83, No. 165, August 24, 2018, p.43099.

models, and considering that differences in total VMT can have meaningful impacts on the cost benefit analysis, the agencies are conservatively assuming for the final rule analysis that non-rebound VMT is constant, to constrain the outputs derived from the combination of the three models.

(v) Comments on the Evaluation of Associated Costs and Benefits

(a) Presentation and Valuation of Non-Rebound Miles

IPI and EDF argued that it was inconsistent to exclude the costs and benefits of additional rebound driving but include them for the sales and scrappage effect. For example, EDF stated:

> [W]henever a vehicle is driven an additional mile, there is value associated with that travel. NHTSA completely ignores the value of any additional travel which occurs due to reduced scrappage. Including this value would not be an adequate surrogate for the additional repair costs required to keep older vehicles on the road. Just as NHTSA is now recognizing that rebound VMT is due to drivers' express decision to drive more, any driving of older vehicles in lieu of new vehicles is due to the same choice. To treat these identical choices in 180 degree different manners is of course manifestly arbitrary. [1880]

The agencies agree that there is value associated with additional miles driven. The NPRM did not directly attribute costs for the loss of additional miles in the scrappage analysis when the fleet size shrank. The final rule analysis addresses this issue by holding non-rebound total VMT constant across regulatory alternatives. However, contrary to what EDF suggests above, the cost of additional maintenance and repair for otherwise-scrapped vehicles are not directly related to the additional miles. The cost of additional maintenance and repair is incurred because the value of used vehicles has increased. The increase in value of the used vehicles should at least offset the maintenance and repair costs.

Holding aggregate non-rebound VMT constant across alternatives addresses IPI's and EDF's concerns that additional miles due to a larger fleet size were not adequately valued. However, on average newer vehicles tend to be safer, more efficient, more powerful, and more spacious than used vehicles. Because of this, driving a newer vehicle will be more enjoyable, and provide more utility per mile, than driving a used vehicle. Even disregarding trends in vehicle quality, the utility of a mile driven in a newer vehicle is on average higher than that driven in an older vehicle because the average newer vehicles in better condition. The regulation is responsible for the shift in the distribution of miles driven at each vehicle age. Including the additional safety risks and fuel costs accrued from more miles being driven by older vehicles accounts for part of the reduction in the utility of the average mile under more stringent standards. Quantifying the remaining change in utility of more miles being driven by older vehicles is currently beyond the scope of this rulemaking analysis and will require extensive

[1880] EDF, Appendix B, NHTSA-2018-0067-12108, at 58.

future research. The agencies do not think excluding other sources of changes in the utility of driving (performance, comfort, etc.) will significant change the outcome of the analysis.

(b) Increase in Maintenance and Repair Costs and Used Vehicle Values

EDF and others also commented that the agencies should include the value of additional maintenance and repair costs and the increase in value for used vehicles explicitly in the cost and benefit analysis. They state the following:

> "It is important to note that NHTSA fails to account for three large economic impacts occurring during this process.
>
> 1. The increase in value of the entire used vehicle fleet from 2017-2050. This is a windfall gain for all current vehicle owners that is completely ignored;
> 2. The cost of repairing and maintaining the older vehicles which are no longer scrapped,
> 3. The value of the additional driving that these vehicles provide.
>
> NHTSA only counts the costs related to the additional driving performed by the non-scrapped vehicles. Again, NHTSA's decision to only include this cost maximizes monetary costs related to the current standards and minimizes those related to the proposal." [1881]

As discussed above, in Section VI.D.1.b)(3)(a)(a), the agencies hold the non-rebound fleetwide VMT constant to an exogenous projection of aggregate VMT. This addresses EDF's third concern, above. Without a model of the used vehicle market it is impossible for the agencies to estimate the value increase of used vehicles due to a substitution towards used vehicles when new vehicle prices increase. However, the maintenance and repair costs should be less than or equal to the increase in vehicle value (or the current owner would not pay to maintain the vehicle). Not including the additional maintenance and repair costs should at least partially offset not including the increase in the value of used vehicles. The remaining increase in vehicle value should be a transfer between the seller and buyer of a used vehicle so that it should be both a cost and benefit exactly offsetting. Thus, the total costs and benefits are understated by the same amount, and including them should not affect the reported net benefits of the rule.

(c) Scrappage Effects from MY2030 and Beyond

The NPRM analysis considered cost per mile as a continuous variable, and new vehicle prices in discrete levels. This means that persistently higher new vehicle prices in more stringent standards would continue to suppress the scrappage rate of existing vehicles. It also means that higher fuel economies in more stringent scenarios would continue to affect the scrappage rates as well. EDF noted that the cost and benefit accounting that considered the costs and benefits

---

[1881] EDF, Appendix B, NHTSA-2018-0067-12108, at 50.

accruing to the remaining lifetimes of MYs 1977-2029 included some of the costs of the scrappage effect due to the higher prices of MYs beyond 2030, but did not include the benefits of the reduced fuel economy for these MYs. EDF proposed that the agencies consider a CY analysis instead of the model year presented in the NPRM:

> [A] 2017-50 CY analysis would include the operation of 2017-2029 MY vehicles through CY 2050. This would include the any scrappage effects on these vehicles through 2050, consistent with the inclusion of new 2050 MY vehicles in the analysis. Some of the operation of all the 2017-2029 MY vehicles would be excluded from the analysis, as these vehicles are not assumed to be scrapped in the Volpe Model until CY 2052-2068. Such an analysis would include the benefits over the clear majority of the operation of 2017-2029 MY vehicles compared to both the shorter calendar year analysis and NHTSA's 1977-2029 MY analysis. It would also include the scrappage effects caused by 2017-2050 MY vehicles through CY 2050. Any scrappage effects would be applied to 2030-2050 MY vehicles, as well as 2017-2029 MY vehicles. [1882]

However, as the commenter also notes, a CY analysis would exclude some of the lifetime costs and benefits of improving the fuel economy of MYs impacted by the rule (MYs 2017-2029). For this reason, the agencies do not think that a CY analysis should supplant the MY perspective shown in the NPRM.

EDF presents an alternative to switching to a CY analysis which would exclude the scrappage effects due to differences in the prices and fuel efficiencies of MYs not included in the cost benefit analysis (MY 2030 and beyond):

> An alternative that keeps the model year structure of NHTSA's 1977-2029 MY analysis would be to modify it by removing any scrappage effects occurring in 2030 CY and beyond. This analysis would still have the disadvantage of barely including any vehicles which reflect full compliance with the current and proposed standards in 2025. However, it would at least remove the primary problem with NHTSA's current MY analysis. The impact of including the scrappage effects caused by 2030 and later MY vehicles simply and straightforwardly increases the VMT of used vehicles under the current standards.[1883]

The agencies note that previous analyses have not considered the costs and benefits of MYs beyond those which could be a response to the change in the considered set of standards. Part of the reason for this was that future standards are unknown, and without existing standards in place, manufacturers may choose to shift application of fuel saving technologies to increases in vehicle performance or safety. The CAFE model does not currently simulate such actions, so that including MYs too far into the future may overstate the costs and benefits of the rule.

While the agencies disagree that excluding cost and benefits of MYs beyond 2030 is an issue for the cost benefit analysis, the agencies agree that allowing persistently higher prices and fuel economies of future MYs to impact the scrappage of the on-road fleet but not considering

[1882] EDF, Appendix B, NHTSA-2018-0067-12108, at 22.
[1883] EDF, Appendix B, NHTSA-2018-0067-12108, at 23.

the costs and benefits of those MYs is inconsistent. However, changes to the scrappage model mitigate this issue. As noted in Section VI.C.1.b)(3)(b)(i)(c) and VI.C.1.b)(3)(b)(ii), updates to the time series strategy and the way that new vehicle fuel economy is modelled in the FRM scrappage model change the form of how new vehicle prices and fuel economy enter the equation. First, addressing the autocorrelation by taking the first difference of variables with first order integration instead of including lags of the dependent variables means that cost per mile variables and new vehicle prices are captured as changes rather than in levels. This means that constant, but higher, new vehicle prices in the augural standards will not continue to impact the scrappage rates of existing vehicles. More specifically, higher prices of MYs 2030 and beyond in the augural case will no longer result in lower scrappage rates for prior MYs. Further, since new vehicle cost per mile is no longer explicitly included, but rather the amount of fuel savings consumers of new vehicles value at the time of purchase is excluded from the new vehicle prices series, differences in new vehicle fuel economies for MYs beyond 2029 will no longer impact the scrappage rates of earlier MYs. This naturally takes care of the concern raised by several commenters that the accounting for costs and benefits due to changes in MYs 2030 and beyond was inconsistent due to the scrappage model.

(c) Estimation of the FRM Scrappage Models

(i) Framing Dynamic Scrappage Models in the Literature

(a) How Fuel Economy Standards Impact Vehicle Scrappage

As noted above, any increase in price (net of the portion of reduced fuel savings valued by consumers) will increase the expected life of used vehicles and reduce the number of new vehicles entering the fleet (the Gruenspecht effect). In this way, increased fuel economy standards slow the turnover of the fleet and the entrance of any regulated attributes tied only to new vehicles. Gruenspecht tested his hypothesis in his 1981 dissertation using new vehicle price and other determinants of used car prices as a reduced form to approximate used car scrappage in response to increasing fuel economy standards.

Greenspan and Cohen (1996) offer additional foundations from which to think about vehicle stock and scrappage. Their work identifies two types of scrappage: engineering scrappage and cyclical scrappage. Engineering scrappage represents the physical wear on vehicles which results in their being scrapped. Cyclical scrappage represents the effects of macroeconomic conditions on the relative value of new and used vehicles—under economic growth the demand for new vehicles increases and the value of used vehicles declines, resulting in increased scrappage. In addition to allowing new vehicle prices to affect cyclical vehicle scrappage à la the Gruenspecht effect, Greenspan and Cohen also note that engineering scrappage seemed to increase where EPA vehicular-criteria pollutant emissions standards also increased; as more costs went towards compliance technologies, scrappage increased. In this way, Greenspan and Cohen identify two ways that fuel economy standards could affect vehicle scrappage: 1) through increasing new vehicle prices, thereby increasing used vehicle prices, and finally, reducing on-road vehicle scrappage, and 2) by shifting resources towards fuel-saving technologies—potentially reducing the durability of new vehicles.

(b) Aggregate vs. Atomic Data Sources in the Literature

One important distinction in literature on vehicle scrappage is between those that use atomic vehicle data (data following specific individual vehicles), and those that use some level of aggregated data (data that counts the total number of vehicles of a given type). The decision to scrap a vehicle is made on an individual vehicle basis, and relates to the cost of maintaining a vehicle, and the value of the vehicle both on the used car market, and as scrap metal. Generally, a used car owner will decide to scrap a vehicle when the value of the vehicle is less than the value of the vehicle as scrap metal, plus the cost to maintain or repair the vehicle. In other words, the owner gets more value from scrapping the vehicle than continuing to drive it, or from selling it.

Recent work is able to model scrappage as an atomic decision due to the availability of a large database of used vehicle transactions. Work by authors including Busse, Knittel, and Zettelmeyer (2013), Sallee, West, and Fan (2010), Alcott and Wozny (2013), and Li, Timmins, and von Haefen (2009) consider the impact of changes in gasoline prices on used vehicle values and scrappage rates. In turn, they consider the impact of an increase in used vehicle values on the scrappage rate of those vehicles. They find that increases in gasoline prices result in a reduction in the scrappage rate of the most fuel efficient vehicles and an increase in the scrappage rate of the least fuel efficient vehicles. This has important implications for the validity of the average fuel economy values linked to model years, and assumed to be constant over the life of that model year fleet within this study. Future iterations of such studies could further investigate the relationship between fuel economy, vehicle usage, and scrappage, as noted in other places in this discussion.

While the decision to scrap a vehicle is made atomically, the data available to NHTSA on scrappage rates and variables that influence these scrappage rates are aggregate measures. This influences the best available methods to measure the impacts of new vehicle prices on existing vehicle scrappage. The result is that this study models aggregate trends in vehicle scrappage, and not the atomic decisions that make up these trends. Many other works within the literature use the same data source and general scrappage construct, including those by Walker (1968), Park (1977), Greene and Chen (1981), Gruenspecht (1981), Gruenspecht (1982), Feeney and Cardebring (1988), Greenspan and Cohen (1996), Jacobsen and van Bentham (2015), and Bento, Roth, and Zhuo (2016.). These works all use aggregate vehicle registration data as the source to compute vehicle scrappage.

Walker (1968) and Bento, Roth and Zhuo (2016) use aggregate data directly to compute the elasticity of scrappage from measures of used vehicle prices. Walker (1968) uses the ratio of used vehicle Consumer Price Index (CPI) to repair and maintenance CPI. Bento, Roth, and Zhuo (2016) use used vehicle prices directly. While the direct measurement of the elasticity of scrappage is preferable in a theoretical sense, the CAFE model does not predict future values of used vehicles, only future prices of new vehicles. For this reason, any model compatible with the current CAFE model must estimate a reduced form similar to Park (1977), Gruenspecht (1981), and Greenspan and Cohen (1996), who use some form of new vehicle prices or the ratio of new vehicle prices to maintenance and repair prices to impute some measure of the effect of new vehicle prices on vehicle scrappage.

(c) Historical Trends in Vehicle Durability

Waker (1968), Park (1977), Feeney and Cardebring (1988), Hamilton and Macauley (1999), and Bento, Ruth, and Zhuo (2016) all note that vehicles change in durability over time. Walker (1968) simply notes a significant distinction in expected vehicle lifetimes pre- and post-World War I. Park (1977) discusses a 'durability factor' set by the producer for each year, so that different vintages and makes will have varying expected lifecycles. Feeney and Cardebring (1988) show that durability of vehicles appears to have generally increased over time both in the U.S. and Swedish fleets using registration data from each country. They also note that the changes in median lifetime between the Swedish and U.S. fleet track well, with a 1.5-year lag in the U.S. fleet. This lag is likely due to variation in how the data is collected—the Swedish vehicle registration requires a title to unregister a vehicle, and therefore gets immediate responses, where the U.S. vehicle registration requires re-registration which creates a lag in reporting further discussed in Section VI.C.1.b)(3)(c)(ii)(b).

Hamilton and Macauley (1999) argue for a clear distinction between embodied versus disembodied impacts on vehicle longevity. They define embodied impacts as inherent durability similar to Park's producer supplied 'durability factor' and Greenspan's 'engineering scrappage' and disembodied effects as those which are environmental, not unlike Greenspan and Cohen's 'cyclical scrappage.' They use calendar year and vintage dummy variables to isolate the effects—concluding that the environmental factors are greater than any pre-defined 'durability factor.' Some of their results could be due to some inflexibility of assuming model year coefficients are constant over the life of a vehicle, and also some correlation between the observed life of the later model years of their sample and the 'stagflation'[1884] of the 1970's. Bento, Ruth, and Zhuo (2016) find that the average vehicle lifetime has increased 27 percent from 1969 to 2014 by sub-setting their data into three model year cohorts. To implement these findings in the scrappage model incorporated into the CAFE model, this study takes pains to estimate the effect of durability changes in such a way that the historical durability trend can be projected into the future; for this reason, the agencies include a continuous 'durability' factor as a function of model year vintage.

(ii) Polk/IHS Registration Data

As in the NPRM, NHTSA uses proprietary data on the registered vehicle population from IHS/Polk for the scrappage models. IHS/Polk has annual snapshots of registered vehicles counts beginning in calendar year (CY) 1975 and continuing until CY2017. Notably, the data collection procedure changed in CY2002, which requires some special consideration (discussed below). The data includes the following regulatory classes as defined by NHTSA: passenger cars, light trucks (classes 1 and 2a), and medium and heavy-duty trucks (classes 2b and 3). Polk separates these vehicles into another classification scheme: cars and trucks. Under their schema, pickups, vans, and SUVs are treated as trucks, and all other body styles are included as cars. In order to build scrappage models to support the model year (MY) 2021-2026 light duty vehicle (LDV)

[1884] Continued high inflation combined with high unemployment and slow economic growth.

standards, it was important to separate these vehicle types in a way compatible with the existing CAFE model.

(a) Choice of Aggregation Level: Body style

Two compatible methods existed by which the agencies could aggregate scrappage rates: by regulatory class or by body style. Since, for CAFE purposes, vans/SUVs are sometimes classified as passenger cars and sometimes as light trucks (depending upon vehicle-specific attributes) and there was no simple way to reclassify some SUVs as passenger cars within the Polk dataset, the agencies chose to aggregate survival schedules by body style. This approach is also preferable because it is consistent with the level of aggregation of the VMT schedules. Since usage and scrappage rates are not independent of each other, if average usage rates are meaningfully different at the level of body style, it is likely that scrappage rates are as well.

Once stratified into body style level buckets, the data can be aggregated into population counts by vintage and age. These counts represent the population of vehicles of a given body style and vintage in each calendar year. The difference between the counts of a given vintage and vehicle type from one calendar year to the next is assumed to represent the number of vehicles of that vintage and type scrapped in each year.

(b) Greenspan and Cohen Correction

One issue with using snapshots of registration databases as the basis for computing scrappage rates is that vehicles are not removed from registration databases until the last valid registration expires—for example, if registrations are valid for a year, vehicles will still appear to be registered in the calendar year in which they are scrapped. To correct for the scrappage that occurs during a calendar year, a similar correction as that in Greenspan and Cohen (1996) is applied to the Polk dataset. It is assumed that the real on-road count of vehicles of a given MY registered in a given CY is best represented by the Polk count of the vehicles of that model year in the succeeding calendar year ($Polk_{CY+1}$). For example, the vehicles scrapped between CY2000 and CY2001 will still remain in the Polk snapshot from CY2000 ($Polk_{CY2000}$), as they will have been registered at some point in that calendar year, and therefore exist in the database. Using a simplifying assumption that all States have annual registration requirements,[1885] vehicles scrapped between July 1st, 1999 and July 1st, 2000 will not have renewed registration between July 1st, 2000 and July 1st, 2001, and will not show up in $Polk_{CY2001}$. The vehicles scrapped during CY2000 are therefore represented by the difference in count from the CY2000 and CY2001 Polk datasets: $Polk_{CY2001}$ - $Polk_{CY2000}$.

[1885] In future analysis, it may be possible to work with State-level information and incorporate State-specific registration requirements in the calculation of scrappage, but this correction is beyond the initial scope of this rulemaking analysis. Such an approach would be extraordinarily complicated as States can have very different registration schemes, and, further, the approach would also require estimates of the interstate and international migration of registered vehicles.

For new vehicles (vehicles where MY is greater than or equal to CY), the count of vehicles will be smaller than the count in the following year—not all of the model year cohort will have been sold and registered. For these new model years, Greenspan and Cohen assume that the Polk counts will capture all vehicles which were present in the given calendar year and that approximately one percent of those vehicles will be scrapped during the year. Importantly, this analysis begins modeling the scrappage of a given model year cohort in: $CY = MY + 2$,[1886] so that the adjustment to new vehicles is not relevant in the modeling because it only considers scrappage after the point where the on-road count of a given MY vintage has reached its maximum.

(c) Polk Data Collection Changes

Prior to calendar year 2002, Polk vehicle registration data was collected as a single snapshot on July 1st of every calendar year. All vehicles that are in the registration database at that date are included in the dataset. For calendar years 2002 and later, Polk changed the timing of the data collection process to December 31st of the calendar year. In addition to changing the timing of the data collection, Polk updated the process to a rolling sample. That is, they consider information from other data sources to remove vehicles from the database that have been totaled in crashes before December 31st, but may still be active in State registration records.

The switch to a partially rolling dataset will mean that some of the vehicles scrapped in a calendar year will not appear in the dataset and their scrappage will wrongly be attributed to the year prior to when the vehicle is scrapped. While this is less than ideal, these records represent only some of the vehicles scrapped during crashes and scrappage rates due to crashes should be relatively constant over the 2001 to 2002-time period. For these reasons, the agencies expect the potential bias from the switch to a partially rolling dataset to be limited. Thus, the Greenspan and Cohen adjustment applied does not change for the dataset complied from Polk's new collection procedures. As indicated in Figure VI-124, the scrappage counts computed from the old Polk snapshot series represent vehicles scrapped between July 1st of a given calendar year and the succeeding July 1st, and is computed for CY1976-2000. The new Polk snapshot series represents vehicles scrapped between December 31st of a given calendar year and the succeeding calendar year, and is computed for CY2002-2016.

[1886] Calculating scrappage could begin at CY=MY+1, as for most model year the vast majority of the fleet will have been sold by July 1st of the succeeding CY, but for some exceptional model years, the maximum count of vehicles for a vintage in the Polk data set occurs at age 2.

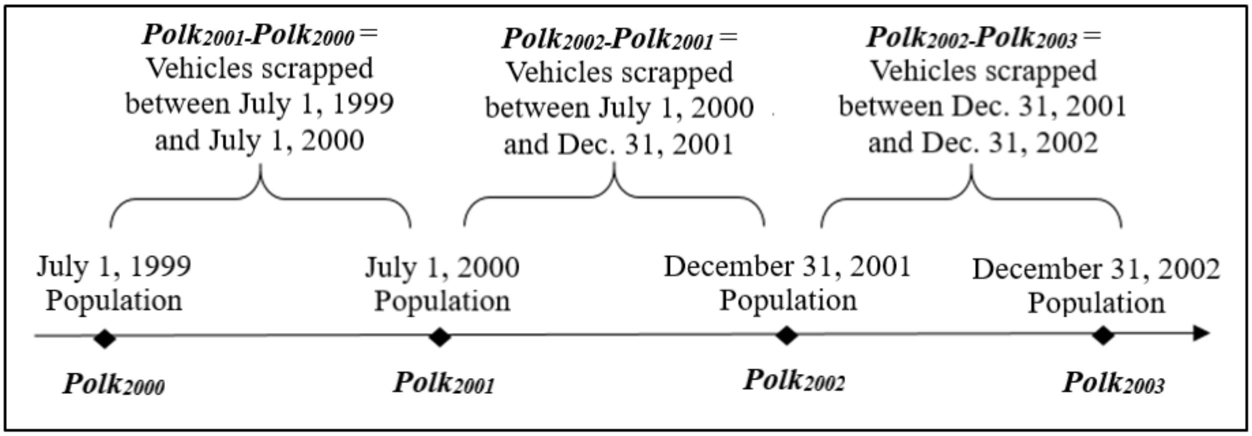

Figure VI-124 – Visualization of Greenspan-Cohen Adjustment and Polk Data Collection Change

There is a discontinuity between the old and new methods so that the computed scrappage for calendar year 2001 represents the difference between the vehicle count reported in $Polk_{CY2002}$ and $Polk_{CY2001}$. $Polk_{CY2001}$ represents all vehicles on the road as of July 1st, 2000, and $Polk_{CY2002}$ represents all vehicles on the road as of December 31, 2001. For this one timespan, the scrappage will represent vehicles scrapped over a 17-month time period, rather than a year. For this reason, the CY2001 scrappage data point is dropped, and because of the difference in the time period of vehicles scrapped under the old and new collection schemes, an indicator for scrappage measured before and after CY2001 was considered; however, this indicator is not statistically significant, and is dropped from the preferred model.

(d) Updated FRM Dataset

As noted in section II.A.1, some commenters expressed concern about the inability of the scrappage model to predict the scrappage rates of vehicles over age 20. The inability was in large part due to the limited data on the scrappage rates of older vehicles. NHTSA has worked with Polk/IHS to construct some of the historical registration databases using the new methodology for the purposes of other research. As a result, the agency has registration data using *both* Polk collection methods for CY's 2001-2012. Importantly, the old Polk dataset censored data on older vehicles, with CY's 1975-1993 including vehicles ages 0-15 and each successive CY past 1993 adding one additional age to the dataset—so that by 2000 ages 0-22 are included. The new datasets do not censor data on older vehicles, giving these datasets an advantage over the old datasets—for this reason, NHTSA uses as many years of the new data as is available.

The NPRM analysis also used all of the available data using the new methodology at the time of publication (CY's 2005-2015). Since the NPRM was published, NHTSA has gained access to registration data using Polk's new methodology for CY's 2002-2005 and CY's 2016-2017. Table VI-193 shows the calendars years of data in the NPRM and the final rule datasets by age, as well as the total number of data points for each age. There are a total of 330 and 420 data points for ages over 15 in the NPRM and final rule datasets, respectively. That represents almost a 30 percent increase in the number of data points for vehicles over 15, and a 50 percent increase in the number of data points for the oldest vehicles considered in the dataset (ages 27-39). This additional data on older vehicles allows the new scrappage models to better predict the survival rates of older vehicles than the NPRM models.

Table VI-193 – Summary of NPRM vs. Final Rule Datasets by Vehicle Age

Ages	NPRM CYs	Count	Final Rule CYs	Count
0-15	1975-2015	41	1975-2017	43
16	1994-2015	22	1994-2017	24
17	1995-2015	21	1995-2017	23

(e) Models of the Gruenspecht Effect Used in Other Policy Considerations

This is not the first estimation of the 'Gruenspecht Effect' for rulemaking policy considerations. In their Technical Support Document (TSD) for its 2004 proposal to reduce emissions from motor vehicles, CARB outlined how they utilized the CARBITS vehicle transaction choice model in an attempt to capture the effect of increasing new vehicle prices on vehicle replacement rates. They considered data from the National Personal Transportation Survey (NPTS) as a source of revealed preferences and a University of California (UC) study as a source of stated preferences for the purchase and sale of household fleets under different prices and attributes (including fuel economy) of new vehicles.

The transaction choice model represents the addition and deletion of a vehicle from a household fleet within a short period of time as a "replacement" of a vehicle, rather than as two separate actions. CARB's final data set consists of 790 vehicle replacements, 292 additions, and 213 deletions; they do not include the deletions, but assume any vehicle over 19 years old that is sold is scrapped. This allowed CARB to capture a slowing of vehicle replacement under higher new vehicle prices. That said, because their model does not include deletions, it does not explicitly model vehicle scrappage, but assumes all vehicles aged 20 and older are scrapped rather than resold. CARB calibrated the model so that the overall fleet size is benchmarked to Emissions FACtors (EMFAC) fleet predictions for the starting year; the simulation then produced estimates that match the EMFAC predictions without further calibration.

The CARB study captures the effect on new vehicle prices on the fleet replacement rates, and offers some precedence for including an estimate of the Gruenspecht Effect. However, because vehicles that exited the fleet without replacement were excluded, the agencies do not learn the effect of new vehicle prices on scrappage rates where the scrapped vehicle is not replaced. New and used vehicles are substitutes, and therefore the agencies expect used vehicle prices to increase with new vehicle prices. And because higher used vehicle prices will lower the number of vehicles whose cost of maintenance is higher than their value, the agencies expect the replacements of used vehicles to slow, but the agencies also expect that some vehicles that would have been scrapped without replacement under lower new vehicle prices will now remain on the road because their value will have increased. The agencies' aggregate measures of the Gruenspecht effect includes changes to scrappage rates both from slower replacement rates, and from slower non-replacement scrappage rates.

(f) Car Allowance Rebate System ('Cash for Clunkers')

On June 14, 2009, the Car Allowance Rebate System (CARS) became law, with the intent to stimulate the economy through automobile sales and accelerate the retirement of older, less fuel efficient and less safe vehicles. The program offered a $3,500 to $4,500 rebate for vehicles traded-in for the purchase of a new vehicle. Vehicles were subject to several program eligibility criteria: first, the vehicle had to be drivable and continuously registered and insured by the same owner for at least one year; second, the vehicle had to be less than 25 years old; third, the MSRP had to be less than $45,000; and finally, the new vehicle purchased had to be more efficient than the trade-in vehicle by a specified margin. The fuel economy improvement requirements by body style for specific rebates are presented in Table VI-194.

Table VI-194 – CARS Fuel Economy Improvement Required for Rebates by Regulatory Class

	$3,500 Rebate Eligibility	**$4,500 Rebate Eligibility**
Passenger Car	4-9 MPG Improvement	10+ MPG Improvement
Light Truck	2-5 MPG Improvement	5+ MPG Improvement

The program was originally budgeted for $1 billion dollars and to end on November 1, 2009, but that amount was spent far more quickly than expected and the program received an additional $1.85 billion in funding. Even with that additional funding, the program only lasted through August 25, 2009, expending $2.85 billion on 678,359 eligible transactions. To ensure that the replaced vehicles did not remain on the road, the vehicles were scrapped at the point of trade-in by destroying the engine. While the program resulted in the replacement of more vehicles and at a faster rate than expected, critics have argued that many of the trade-ins would have happened even if the program had not been in place, so that any economic stimulus to the automobile industry during the crisis cannot be attributable to the CARS program. Further, others have argued that forcing the scrappage of vehicles that could still remain on the road has negative environmental impacts that could outweigh any environmental benefits of the reduced fuel consumption from the accelerated retirement of these less efficient vehicles.

Li, Linn, and Spiller (2010) use Canada as a counterfactual example to identify the portion of CARS trade-ins attributable to the policy, i.e., trade-ins that would not have happened anywhere if the program were not in place. They argue that the Canadian market is largely similar to the U.S. market, in part based upon the fact that 13 to 14 percent of households purchased new vehicles one year pre-recession in both countries. They also argue that the economic crisis affected the Canadian economy in a similar manner as it affected the U.S. economy. While they note that Canada offered a small rebate of $300 to vehicles traded in during January, 2009, hey further note that only 60,000 vehicles were traded in under that program. Using those assumptions, Li, et al., applied a difference-in-difference methodology to isolate the effect of the CARS program on the scrappage of eligible vehicles. Li, et al., found a significant increase in the scrappage only for eligible U.S. vehicles, suggesting they isolated the effect of the policy. They conclude that of the 678,359 trade-ins made under the program, 370,000 of those would not have happened during July and August 2009. They conclude that the CARS program reduced gasoline consumption by 0.9-2.9 billion gallons, at $0.89-$2.80 per gallon saved.

The agencies find the evidence from Li, et al., persuasive toward the inclusion of a control for the CARS program during calendar year 2009. The importance is discussed further both in the data section, Section VI.C.1.b)(3)(c)(ii), which provides more evidence for the effect of the CARS program, and in the model specifications Section VI.C.1.b)(3)(c)(iii), which describes the control used for the effect of the program. This ensures that the measurements of other determining factors are not biased by the exceptional scrappage observed in calendar year 2009.

(iii) Updated Final Rule Modeling

The agencies contemplated all of the comments and suggestions made by commenters and, in response, have made several changes to final rule's model. First, the agencies changed the time-series strategy used in the model, as discussed in Section VI.C.1.b)(3)(c)(iii)(a). This change allows the agencies to simplify the models significantly, addressing commenters' concerns about potential overfitting of the model and difficulty of interpreting individual coefficient values (discussed in Section VI.C.1.b)(3)(b)(i)). Second, the agencies changed the modeling of the durability effect as discussed in Section VI.C.1.b)(3)(c)(iii)(c); this change reduces the reliance on the decay function and has the added benefit of addressing concerns about overfitting and out-of-sample projections discussed in Section VI.C.1.b)(3)(b)(i). Third, a portion of anticipated fuel savings from increased fuel economy are netted from new vehicle prices—meaning consumers are now assumed to value fuel economy at the time of purchase to a certain extent—as discussed in Section VI.C.1.b)(3)(c)(iii)(d). This change is in response to comments discussed in Section VI.C.1.b)(3)(b)(ii) and addresses inconsistent treatment of consumer valuation within the NPRM's analysis. Finally, the agencies consider the inclusion of additional or alternative variables in the scrappage model in response to comments discussed in Section VI.C.1.b)(3)(b)(iii). After extensive testing, the agencies concluded that these additional variables do not improve the model fits or would introduce autocorrelation in the error structures (see Sections VI.C.1.b)(3)(c)(iii)(e) and VI.C.1.b)(3)(c)(iii)(f) for further discussion). As such, the agencies rejected the additional terms suggested by commenters. Input from commenters was used to simplify the scrappage model, make it more consistent with modeling of new vehicle prices elsewhere in the analysis, and improve its predictions for the instantaneous scrappage rates of vehicles beyond age 20.

(a) Changes to the Time Series Strategy

As discussed in Section VI.D.1.b)(3)(b)(i)(c), the agencies reconsidered the time series strategy for the final rule in response to comments. The first step in doing so is to test the time series properties of the dependent and independent variables. The agencies use the Augmented Dickey-Fuller (ADF) unit root test implemented in the 'CADFtest' R package to test for stationarity.[1887] The agencies find that the logistic scrappage rate is I(0), or stationary in levels. Since the dependent variable is stationary, there is no long-term trend in scrappage rates to capture. Lags of dependent variables need not be included, but their stationary forms should be used in the regressions. The following table summarizes the order of integration of each of the considered regressions; the regression forms represent the form of the variable that is included in the considered models.[1888] All the variables considered are either I(0) or I(1), meaning that they should be run in either levels or first differences, respectively. This significantly simplifies the regressions. Two unintended, positive outcomes of this change in time series strategy are that the coefficients on variables are easier to interpret and the models are less likely to be overfit. In this way, the shift to address concerns about the time series strategy (discussed in Section VI.D.1.b)(3)(b)(i)(c)) also addresses commenter concerns outlined in Section VI.D.1.b)(3)(b)(i)(a).

Table VI-195 – Summary of Order of Integration of Considered Scrappage Variables

Scrappage Factor	**Considered Measure**	**Source**	**Integration Order**	**Regression Form**	**Expected Sign**
Scrappage Rate	Logistic of inter-annual scrappage rate for a model year/body style cohort	NVPP (IHS/Polk)	I(0)	Levels	N/A
Age	Age defined by the Greenspan and Cohen adjustment	NVPP (IHS/Polk)	N/A	Levels	Polynomial1
Usage (VMT)	Average VMT from previous year/Average cumulative lifetime VMT	No source2	N/A	N/A	(+)
Model year	Model year as defined from dataset	NVPP (IHS/Polk)	N/A	Levels	See MY Projections3
Business cycle indicator	Growth in GDP from previous year (annual, %)	BEA	I(0)	Levels	(+)
Business cycle indicator	Civilian unemployment rate (annual, %)	BEA	I(1)	Difference	(-)

[1887] Lupi, Claudio (2019, September 7). Package 'CAFtest.' Retrieved from https://cran.r-project.org/web/packages/CADFtest/CADFtest.pdf.
[48] Note: some of these variables were considered or added in response to comments presented in Sections I.A.1.a)(1)(b)(ii), I.A.1.a)(1)(b)(iii), and I.A.1.a)(1)(b)(iv), and may not be present in the NPRM.

Scrappage Factor	Considered Measure	Source	Integration Order	Regression Form	Expected Sign
Business cycle indicator	Per-capita personal income ($2018)	BEA	I(1)	Difference	(+)
Business cycle indicator	Real discount US interest rate (annual, %)	BEA	I(1)	Difference	(-)
Prices of purchase	Average used vehicle prices by age in current year	No source; endogenous4	N/A	N/A	(-)
Maintenance/repair costs	Maintenance/repair CPI (fixed to 2016)	BLS	I(1)	Difference	(+)
Value as scrap	Iron/steel scrap CPI (fixed to 2016)	BLS	I(1)	Difference	(+)
Prices supply of substitutes	Average new vehicle prices in current year ($2018)	NADA	I(1)	Difference	(-)
Prices supply of substitutes	Average new vehicle prices less 30 months fuel savings in current year ($2018)	NADA, EIA, EPA trends	I(1)	Difference	(-)
Quantity supply of substitutes	New light weight vehicle sales (million units)	BEA	I(1)	Difference	(+)
Prices of usage	Fuel share weighted fuel prices for model year/body style cohort in current year ($2018)	EIA, EPA trends	I(1)	Difference	(-)5
Prices of usage	Cost-per-mile of model year/body style cohort in current year ($2018/100 mile)	EIA, EPA trends	I(1)	Difference	(+)
Control for quality	Average fuel consumption of model year/body style cohort (gal/100 miles)	EPA trends	I(1)	Difference	(+)
Control for quality	Ratio of average horsepower of model year cohort to new vehicle cohort by body style	EPA trends	I(0)	Levels	(-)6

[1]The effect of age on scrappage is an ‘inverted-U’ shape; the scrappage rate increases with age up to some age, after which the scrappage rate declines with age.
[2]There was not enough reliable data on usage rates for specific model years/ages over time, and using static estimates would have failed to capture the time series variation we are after.
[3]See the section on modeling durability tends over time. Generally, scrappage rates will decrease with successive model years, but this is no longer modelled parametrically, as it was in the NPRM and PRIA.
[4]As noted in the response to comments section, we considered the consumer expenditure survey (CEX) as a potential source, but data was limited. We also note that this variable is purposefully excluded from the reduced form model because it is endogenous with scrappage rates.
[5]Since we include the cost-per-mile and fuel consumption as separate variables, we would expect that the change in fuel prices should capture only a capital constraint where increasing fuel prices will result in less capital to scrap a used vehicle and replace it.

[6]As the average horsepower of used vehicles converges to the average horsepower of new vehicles, the ratio will increase. This makes used and new vehicles closer substitutes and should decrease the scrappage rate of used vehicles.

(b) Final Rule Preferred and Sensitivity Specifications

After consideration of comments on, and subsequent peer review of, the NPRM analysis, the agencies updated the scrappage model specifications for the final rule. Section VI.C.1.b)(3)(c)(iii)(a) through VI.C.1.b)(3)(c)(iii)(f) discuss other considered specifications and variables. The equation below represents the final form of the scrappage equation included in the central and sensitivity analysis:

$$\ln\left(\frac{S_{MY,CY}}{1-S_{MY,CY}}\right) = \beta_0 * Age_{MY,CY} + \beta_1 * Age^2{}_{MY,CY} + \beta_2 * Age^3{}_{MY,CY} +$$

$$Share\ Remaining_{MY,CY} * (\beta_3 + \beta_4 * Age_{MY,CY}) +$$

$$Diff(New\ Price - FS)_{CY} * (\beta_5 + \beta_6 * Age_{MY.CY} + \beta_7 * Age^2{}_{MY.CY} + \beta_8 * Age^3{}_{MY,CY}) +$$

$$\beta_9 * Diff(Fuel\ Price)_{CY} + \beta_{10} * Diff(CP100M_{MY})_{CY} + \beta_{11} * GDP\ Growth_{CY} +$$

$$(\beta_{12} + \beta_{13} * [Age \geq 25]) * CY2009 + (\beta_{14} + \beta_{15} * [Age \geq 25]) * CY2010 + FE_{MY}$$

Here, "S" represents the instantaneous scrappage rate in a period, so that the dependent variable is the logit form of the scrappage rates. Logit models ensure that predicted values are bounded—in this case between zero and one. It is not possible to scrap more than all the remaining vehicles, nor fewer than zero percent of them, which is illustrated in the graph below:

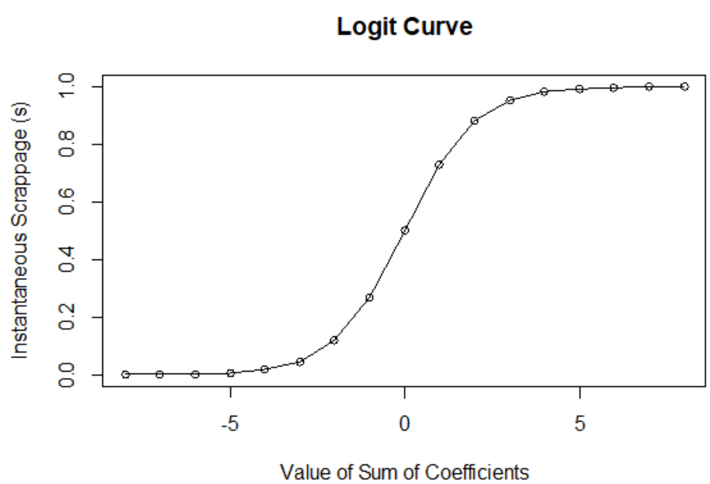

Figure VI-125 – Example Logit Curve

Solving for instantaneous scrappage yields the following:

$$S = \frac{e^{\sum \beta_i X_i)}}{1+e^{\sum \beta_i X_i)}}.$$

In the equation above, $\sum \beta_i X_i$ represents the right-hand side of the above model specification. Within the right-hand side of the equation, *Age* represents the age of the model year cohort in a specific calendar year, defined by the Greenspan and Cohen adjustment discussed in Section VI.C.1.b)(3)(c)(ii)(b). The coefficient on the cubic age term is assumed to be zero for the van/SUV and pickup specifications as this term is not necessary to capture the general scrappage trend for these body styles. *Share Remaining* represents the share of the original cohort remaining at the start of the period. These two components represent the engineering portion of scrappage—the inherent durability of a model year and the natural life cycle of how vehicles scrap out of a model year cohort as the cohort increases with age. The determination of these specific forms is discussed in detail in Section VI.C.1.b)(3)(c)(iii)(g).

New Price - FS represents the average price of new vehicles minus 30 months of fuel savings for all body styles. The central analysis assumes the coefficient on the age interactions for this term are zero for all body styles, but a sensitivity case allows the elasticity of scrappage to vary with age. *Fuel Price* represents the real fuel prices, weighted by fuel share of the model year cohort being scrapped. *CP100M* represents the cost per 100 miles of travel for the specific body style of the model year cohort being scrapped under the current period fuel prices and using fuel shares for that model year cohort. These measures capture the response of scrappage rates to new vehicle prices, fuel savings, and to changes in fuel prices that make the used model year cohort more or less expensive to operate. Because these measures are all I(1), as discussed above in 0, the first difference of all of these variables is used in modelling. The other specific modelling considerations that resulted in this form of modelling the new and used vehicles markets are discussed in Section VI.C.1.b)(3)(c)(iii)(d).

GDP Growth represents the GDP growth rate for the current period. This captures the cyclical components of the macro-economy. Section VI.C.1.b)(3)(c)(iii)(e) discusses how this specific measure was chosen, and what other measures were considered as alternative or additional independent variables.

CY2009 and *CY2010* represent calendar year dummies for 2009 and 2010 when the CARS program was in effect; this controls for the impact of the program. *[Age ≥ 25]* represents an indicator for vehicles 25 years and older. The interaction of the calendar year dummies with this indicator allows for the effect of the CARS program to be different for vehicles under 25 versus vehicles 25 and older. Since only vehicles under 25 were eligible for the program (see the discussion of the program in Section VI.C.1.b)(3)(c)(ii)(f)), this flexibility is important to correctly control for the program.

Finally, FE represents a set of model year fixed effects used to control for heterogeneity across different model years. This is related to the durability and engineering scrappage. The NPRM model did not include fixed effects because it fit a parametric relationship to model year as a continuous variable as a way to capture durability. This change in how the durability effect is modelled is discussed further in Section. Further, Section VI.C.1.b)(3)(c)(iii)(g) discusses trends in the fixed effects and how these are projected forward within the CAFE model.

(c) Modeling Durability Trends over Time

As noted in the NPRM, the durability of successive model years generally increases over time. However, this trend is not constant with vehicle age—the instantaneous scrappage rate of vehicles is generally lower for later vintages up to a certain age, but increases thereafter so that the final share of vehicles remaining converges to a similar share remaining for historically observed vintages. The NPRM parameterized this trend by using the natural log of the model year as a continuous variable interacted with a polynomial form of the age variable—this predicted an increasing but diminishing trend in vehicle durability for younger ages. The analysis for the final rule makes a change that allows more flexibility in durability trends. Below, the agencies consider the survival and scrappage patterns by body style.

Figure VI-126 to Figure VI-128 shows the survival and scrappage patterns of different vintages with vehicle age for cars, SUVs/vans and pickups, respectively. Cars have the most pronounced durability pattern. Figure VI-126 shows that newer vintages scrap slower at first, but that scrap more heavily so that the final share remaining of cars is more or less constant by age 25 for all vintages.

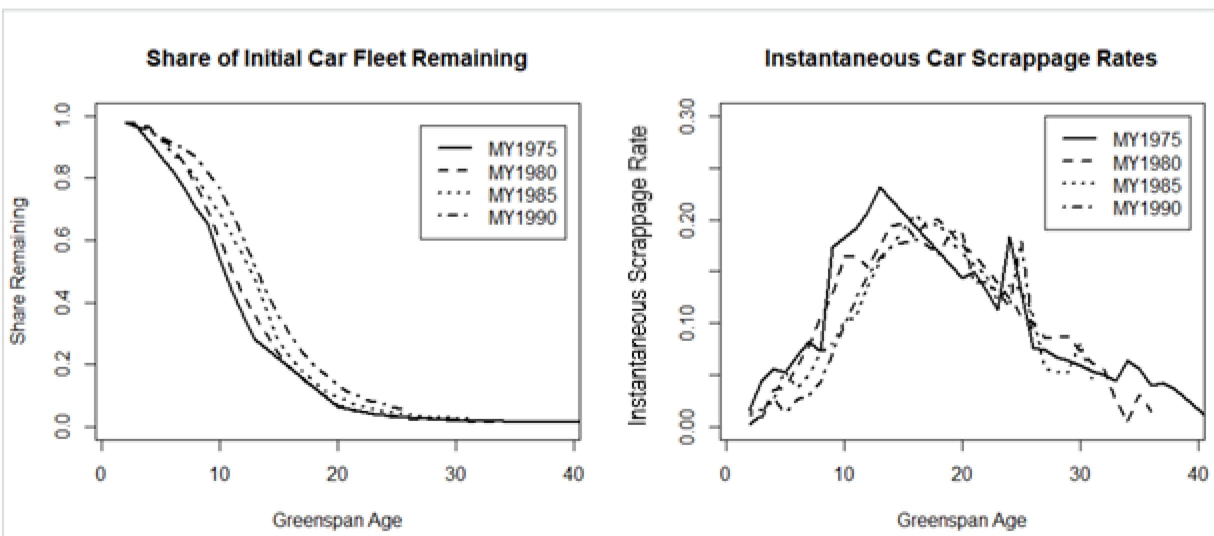

Figure VI-126 – Survival and Scrappage Patterns of Cars by Greenspan Age

SUVs/vans have a less pronounced durability pattern. Model year 1980 actually lives longer than model years 1985 and 1990. This is likely due to a switch of SUVs/vans to be based on car chassis rather than pickup chasses over time. However, through the later model years, the durability trend is more like that of cars. The lack of a continuous trend in durability of SUVs/vans make how this trend is captured particularly important. Below the agencies discuss a change in how the durability trend is modelled for the final rule, which is more flexible than the NPRM model.

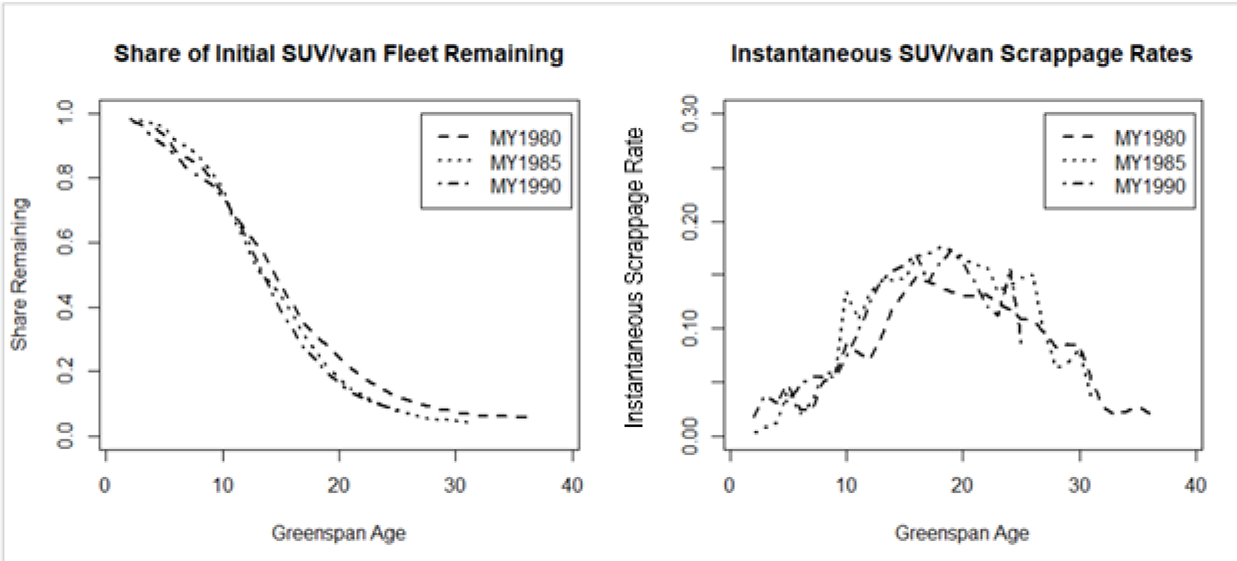

Figure VI-127 – Survival of Scrappage Patterns of SUVs/Vans by Greenspan Age

There is no clear trend in durability for pickups. Like SUVs/vans, this makes parameterizing by using a form of vintage as a continuous variable problematic. Such a parametric form does not allow for each model year to have its own durability pattern.

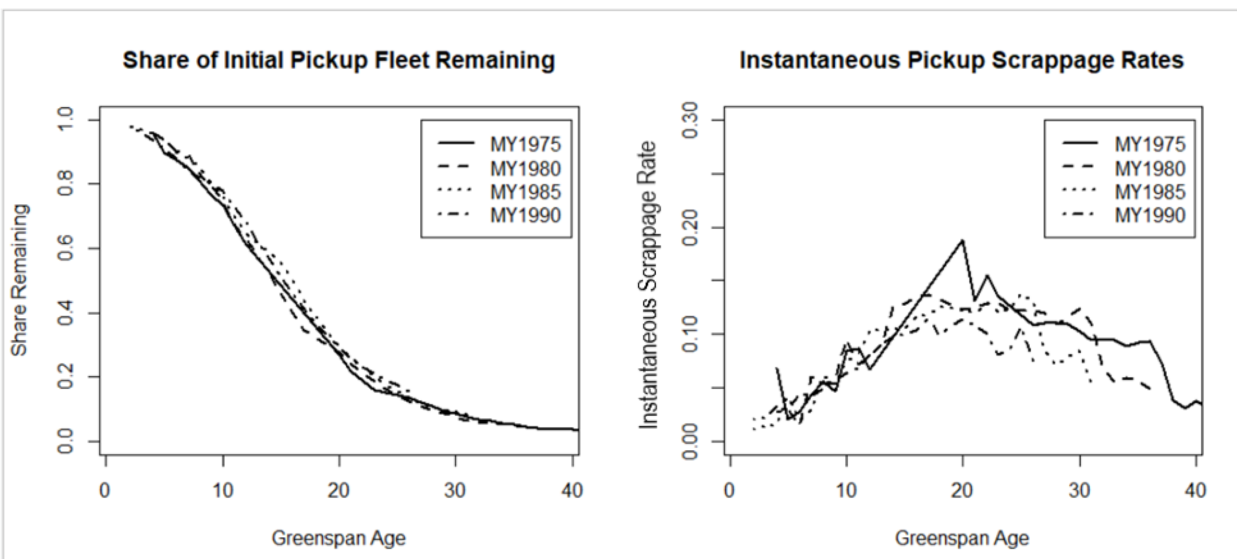

Figure VI-128 – Survival and Scrappage Patterns of Pickups by Greenspan Age

As noted above, the NPRM model used the natural log of model year as a continuous variable interacted with age to capture an increasing but diminishing trend of vehicle durability for the younger ages. However, enforcing a parametric form on a continuous model year excluded the possibility of including model year specific fixed effects and required that durability have a parametric trend with successive vintages. As seen above, SUVs/vans and pickups certainly do not follow such a trend, so that this constraint was too restrictive, at least for these body styles. The final rule analysis makes an adjustment that allows for an initial increase in the durability of a model year to persist, while including fixed effects and relaxing the parametric assumption.

Instead of regressing the natural log of the vintage share in the remaining models, shown in Table VI-196 through Table VI-198, the agencies use the share remaining in the previous period as an independent variable. Since the logistic instantaneous scrappage rate is stationary (it is independent of the previous periods' logistic instantaneous scrappage rate), the share remaining should not be endogenous. The share remaining models for the final rule include model year specific fixed effects and project a linear trend in durability by fitting a regression through the fixed effects. This latter part still requires a parametric assumption about durability (discussed in Section VI.C.1.b)(3)(c)(iii)(g)), but not while jointly estimating other coefficients. In this way, the other coefficients should not be biased by projecting the durability trend forwards in the implementation of the scrappage regressions within the CAFE model.

As Table VI-196 shows, the NPRM specification and both the constant and the quadratic forms of the age interaction with the share remaining variable to capture the durability effect show evidence of autocorrelation. The linear form of the interaction of age and share remaining does not show evidence of autocorrelation and also has the lowest AIC and highest adjusted R-squared. For these reasons, this is the preferred specification of the durability effect. Since the share remaining coefficient is negative and larger than the positive coefficient on the share remaining interacted with age, a cohort that has a higher share remaining at an early age will have a lower instantaneous scrappage rate in this period until a certain age and then a higher scrappage rate after that age. To find the age where the sign of the share remaining coefficient will switch from predicting a lower instantaneous scrappage rate to a higher one, the agencies must take the ratio of the coefficient on the share remaining variable to the share remaining interacted with age—this suggests that at age 19, the sign of the share remaining variable flips. That is, the instantaneous scrappage rate of cars is predicted to be lower if the share remaining is higher until age 18, after which a higher share remaining predicts a higher instantaneous scrappage rate.

As Table VI-197 shows, the linear interaction of age and share remaining is the only specification of the durability effect for SUVs/vans that do not show autocorrelation in the error structure. The linear interaction of age and share remaining has the lowest AIC and highest R-squared; for this reason, this is the preferred specification of the durability effect for SUVs/vans. The signs for share remaining and share remaining interacted with age show a similar trend as that to cars. Taking the ratio again of the share remaining to the share remaining interacted with age, for ages 0 to 18 a higher share remaining predicts lower instantaneous scrappage, and for ages beyond 18 it predicts a higher instantaneous scrappage rate.

As Table VI-198 shows, all but the NPRM specification of the durability effect for pickups do not show autocorrelation in the error structures. However, similar to cars and SUVs/vans, the linear interaction of age and share remaining has the lowest AIC and highest adjusted R-squared. For this reason, this is the preferred specification for all body styles. Taking the ratio of the coefficient on share remaining to share remaining interacted with age shows that a higher share remaining will predict a lower instantaneous scrappage rate in the next period for ages 0 through 14, but a higher instantaneous scrappage rate for ages 15 and older.

Using the preferred forms of the engineering scrappage rates for each body style as the reference point, Section VI.C.1.b)(3)(c)(iii)(d) considers different forms to predict the Gruenspecht effect for each body style. Section VI.C.1.b)(3)(c)(iii)(e) uses the preferred engineering and Gruenspecht forms to consider alternative macroeconomic variables to predict the effects of the business cycle. Finally, Section VI.C.1.b)(3)(c)(iii)(f) uses the preferred engineering, Gruenspecht and business cycle forms to consider the inclusion of other additional independent variables.

(d) Modeling Impacts of New Vehicle Market on Used Scrappage Rates

Table VI-199 through Table VI-201 show the relationship between car, SUV/van, and pickup scrappage rates and changes in new vehicle price and fuel economies. The agencies consider two methods in response to comments outlined in Section VI.C.1.b)(3)(b)(ii). 1) changes in average new vehicle prices net of 30 months of fuel savings (consistent with the technology selection and sales model) and 2) change in average new vehicle prices, change in average fuel prices, changes in new vehicle cost per mile and changes in new vehicle fuel consumption. The agencies allow the elasticity of average new vehicle prices net of 30 months of fuel savings to vary by age by including interaction terms.

[1] Note: Wooldridge Test For AR(1) Errors In FE Panel Models implemented as 'pwartest' from the R Package 'plm'. The null hypothesis is that there is serial correlation in the errors, so that a p-value<0.05 suggests that the errors are not serially correlated.

For all body styles, the specification of the Gruenspecht effect as the change in new vehicle prices net of fuel savings does not show signs of auto-correlated errors. However, for cars and vans/SUVs, the specification which separates the effect of new vehicle prices and fuel economy does show evidence of autocorrelation. For this reason, the changes in new vehicle fuel prices net of fuel savings is the preferred specification of the Gruenspecht effect.

The agencies consider the interaction of the change in average new vehicle prices with vehicle age. This relaxes an assumption that the elasticity of scrappage rates to change in new vehicle prices is constant. For cars and vans/SUVs the linear interaction of change to new vehicle prices net of fuel savings show evidence of autocorrelation. The quadratic interaction of age with change in new vehicle prices shows autocorrelation with cars. For this reason, the agencies consider the constant elasticity of scrappage rates to changes in new vehicle prices to be the preferred specification (as the only specification that does not show evidence of autocorrelation for all body styles). However, the agencies do consider the quadratic form of the elasticity with age as a sensitivity case (even though there is evidence of autocorrelation (but only in the car specification)). This allows the agencies to test the impact of relaxing the assumption around constant elasticity on CAFE model outcomes.

(e) Considering Alternative/Additional Macroeconomic Indicators

Table VI-202 through Table VI-204 show alternative macroeconomic indicators for cars, vans/SUVs and pickups, respectively. The agencies consider unemployment rate and per capita personal disposable income as alternatives to GDP growth rate to capture the cyclical component of the macro economy. The unemployment rate and the per capita personal disposable income are both I(1), so that the first difference of each is the form included. For the car and van/SUV specifications, the specifications replacing GDP growth rate show evidence of autocorrelation in the error structures. For this reason, the GDP growth rate is the preferred specification for the cyclical components of instantaneous scrappage rates, as in the NPRM models.

As discussed in Section VI.D.1.b)(3)(b)(iii)(c), some commenters were concerned with the exclusion of interest rates. In response, the agencies considered including the change in interest rates for the otherwise preferred specification. For vans/SUVs the model has a higher AIC and shows evidence of autocorrelation in the error structures. For pickups, the sign changes on the change in cost per mile when the interest rate is included, which would be an implausible result. Finally, the AIC for cars is nearly identical regardless as to whether the interest rate is included. For these reasons, the agencies continue to exclude the interest rate from the preferred specification.

(f) Considering Other Additional Variables

Table VI-205 through Table VI-207 show specifications that consider additional variables not included in the preferred specifications. As discussed in Section VI.D.1.b)(3)(b)(iii)(a), some commenters criticized the fact that maintenance and repair costs were excluded from the scrappage models. In response to comments, and since the maintenance and repair costs are I(1), the agencies considered including the difference in maintenance and repair costs. When included, changes in maintenance and repair costs show the expected sign—when maintenance and repair costs are higher, instantaneous scrappage rates are predicted to be higher (as used vehicles are more expensive to maintain). When included, the AIC is higher for the car and van/SUV specifications. That is, including the change in maintenance and repair costs does not improve the fit of the models. Because of this, and because there is no obvious way to predict future change to maintenance and repair costs (as discussed in the NPRM), the preferred specification continues to exclude maintenance and repair costs.

As discussed in Section VI.D.1.b)(3)(b)(iii)(b), some commenters criticized the exclusion of steel and iron scrap prices from the scrappage models. In response to comments, and since this variable is also I(1), the agencies considered including the change in steel and iron scrap prices. When included, the AIC of cars and vans/SUVs is higher. Further, the car specification includes evidence of autocorrelation in the error structures. In addition, there is no known projection of steel and iron scrappage prices, so that the agencies would have to make projections to include this variable in the scrappage models. Accordingly, the central case continues to exclude steel and iron scrap prices.

As discussed in Section VI.D.1.b)(3)(b)(iii)(d), some commenters and peer reviewers suggested that controlling for aggregate measures of model year cohorts, such as performance, might correct some unexpected signs. The preferred specification already addresses these concerns. Further, because fixed effects are included for model years, the agencies cannot include aggregate model year specific attributes that are constant over the lifetime of the cohort. The agencies do consider the ratio of the average horsepower to weight of a model year cohort to the new vehicle cohort, as this will change along with changes to the horsepower to weight ratio over successive calendar years. Including this variable results in a higher AIC for cars and vans/SUVs and shows evidence of autocorrelation in the errors for these two body styles. For this reason, the preferred specification excludes this metric.

The agencies also considered including new vehicles sales directly as a predictor of instantaneous scrappage rates. Since new vehicle sales are I(1), the difference in new vehicle sales is the included form. Including the change in new vehicle sales results in a higher AIC for cars and vans/SUVs. It also introduces evidence of autocorrelation in the error structure for the car model, and reduces the effect of the change in fuel prices by two orders of magnitude for vans/SUVs. It seems unlikely that the magnitude of the effect of fuel prices would so drastically vary between body styles. For these reasons, the preferred specifications exclude the change in new vehicles sales. The agencies also considered including changes in vehicle stock, but this similarly did not improve the fit of the scrappage models—and doing so limited the ability to link the sales and scrappage models as some commenters suggested (see Sections (b)(iv)(a) and (b)(iv)(b)).

(g) Projecting durability in the CAFE model

The left graphs in Figure VI-129 through Figure VI-131 show the fixed effects for the preferred scrappage specifications for cars, vans/SUVs, and pickups, respectively. For all body styles there is a general downward trend in the fixed effects. This suggests an increase in the durability of successive model years. However, since the panel datasets are not balanced, there is likely potential bias for the fixed effects that include only certain ages. This makes projecting the durability increase from the fixed effects a little more complicated than merely fitting to all fixed effects. First, the agencies must determine what part of this trend is likely due to increases in vehicle durability (and should be projected forward) and which part of the trend may conflate other factors.

The right graphs in Figure VI-129 through Figure VI-131 show the average observed logistic scrappage rates by model year for all ages where data exists. As can be seen, the average observed scrappage rates decline dramatically for model years after 1996 for all body styles. There are two reasons this trend exists. First, as Figure VI-129 through Figure VI-131 show, the instantaneous scrappage rate generally follows an inverted u-shape with respect to vehicle age. The instantaneous scrappage rates generally peak between ages 15 and 20 for all body styles. Model year 1996 is the first model year which will be at least age 20 at the last date of available data (calendar year 2016). This means that all model years newer than 1996 have likely not yet reached the age where the instantaneous scrappage rate will be the highest for the cohort. Accordingly, the fixed effects could be biased downwards (consistent with the sharper downward slope in the fixed effects for most body styles for model years beyond 1996) because of the unbalanced nature of the panel, and not because of an actual increase in inherent vehicle durability for those model years.

The second reason the average logistic scrappage rates for model years before 1996 is more stable is because each data point in the average has increasingly less effect on the average as more data exists. For model years 1996 and older there are at least 18 data points (we start the scrappage at age 2, by which point effectively all of a model year has been sold), and each will have a smaller effect on the average than for newer model years with fewer observations. For these reasons, the average observed logistic scrappage rate is more constant for model years before 1996. As a result, the agencies do not consider the trend in fixed effects after model year 1996 to rely on enough historical data to represent a trend in vehicle durability, as opposed to a trend in the scrappage rate with vehicle age.

In considering which model year fixed effects should be considered in projecting durability trends forward, another important factor is whether there are discrete shifts in the types of vehicles that are in the market or category of each body style over time. For cars, an increasing market share of Japanese automakers which tend to be more durable over time might result in fixed effects for earlier model years being higher. This trend is shown in the fixed effects in Figure VI-129, which follow a steeper trend before model year 1980.

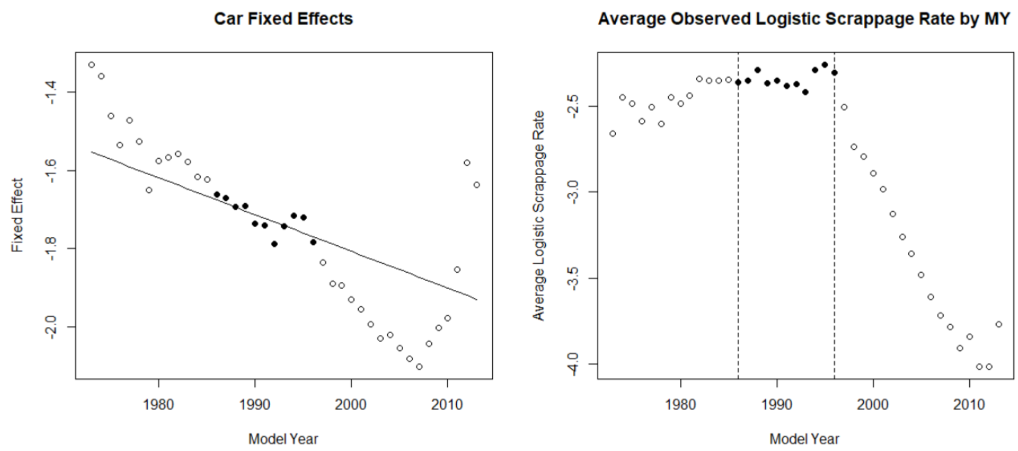

Figure VI-129 – Trends in fixed effects for preferred car specification

For vans/SUVs, earlier model years are more likely to be built on truck chassis (body-on-frame construction) instead of car chassis (unibody construction). Since pickups tend to be more durable, the earlier fixed effects are likely to be lower for vans/SUVs for earlier model years. The 1984 Jeep Cherokee was the first unibody construction SUV.[1889] As Figure VI-130 shows, the fixed effects before 1986 show inconsistent trends; these are likely due to changes in what was considered a van/SUV over time. For this reason, the agencies build the trend of fixed effects from model years 1986 to 1996.

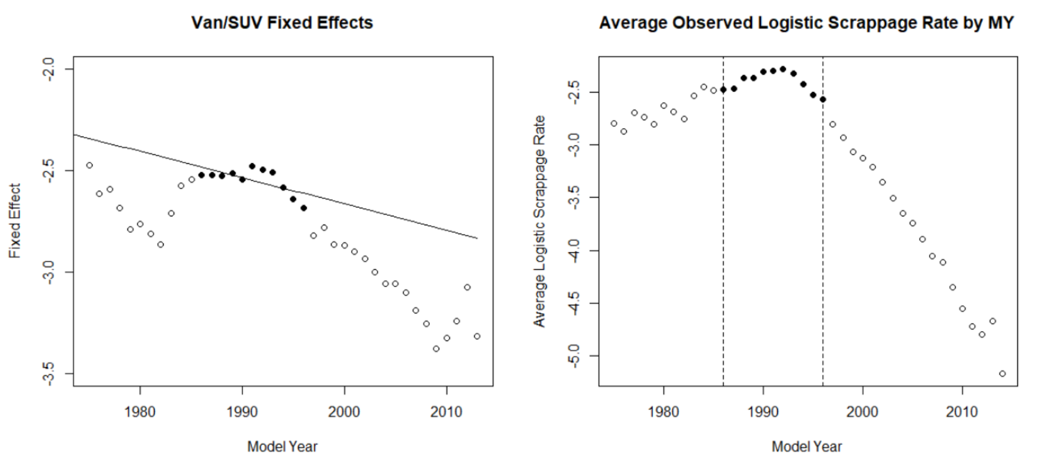

Figure VI-130 – Trends in Fixed Effects for Preferred Van/SUV Specification

[1889] https://www.autoguide.com/auto-news/2018/01/10-interesting-facts-from-the-history-of-the-jeep-cherokee.html

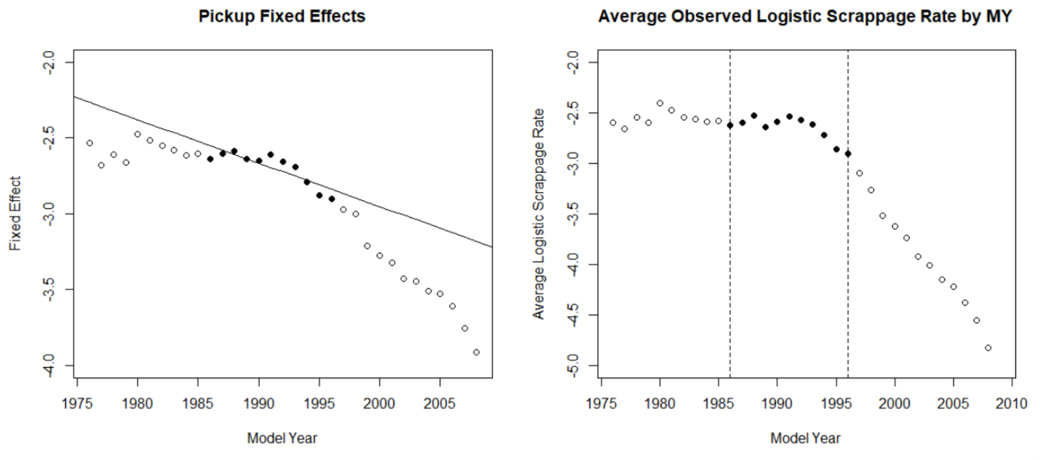

Figure VI-131 – Trends in Fixed Effects for Preferred Pickup Specification

While the trend for pickups and cars could be extrapolated before 1986, the agencies opt to keep the fixed effects included constant for all body styles. Thus, the projections are built from model year 1986 to model year 1996 fixed effects. Table VI-208 below, shows the linear regressions shown as the line on the left side of Figure VI-127 through Figure VI-129. The durability cap represents the last model year where the durability trend is assumed to persist. The agencies cap the durability impacts at model year 2000, as data beyond this point does not exist for enough ages to determine if durability has continued to increase since this point. The implication of this cap, is that model years after 2000 are assumed to have the same initial durability as model year 2000 vehicles. Since there is a limit to the potential durability of vehicles, this acts as a bound on this portion of the scrappage model.

Table VI-208 – Durability Inputs in the CAFE Model

Beta Coefficients	**Inputs**	**Cars**	**Vans/SUVs**	**Pickups**
β_{12}	Intercept	21.13195	25.488	54.52891
β_{13}	MY	-0.01141	-0.01364	-0.02879
β_{14}	MY Durability Cap	2000	2000	2000

The durability projections enter the scrappage equation in the CAFE modelling in accordance to the following equation:

$$\ln\left(\frac{S_{MY,CY}}{1-S_{MY,CY}}\right) = \beta_0 * Age_{MY,CY} + \beta_1 * Age^2{}_{MY,CY} + \beta_2 * Age^3{}_{MY,CY} +$$

$$Share\ Remaining_{MY,CY} * (\beta_3 + \beta_4 * Age_{MY,CY})+$$

$$Diff(New\ Price - FS)_{CY} * (\beta_5 + \beta_6 * Age_{MY.CY} + \beta_7 * Age^2{}_{MY.CY} + \beta_8 * Age^3{}_{MY,CY})+$$

$$\beta_9 * Diff(Fuel\ Price)_{CY} + \beta_{10} * Diff(CP100M_{MY})_{CY} +$$

$\beta_{11} * GDP\ Growth_{CY} + \beta_{12} + \beta_{13} * MY_{MY}$ - ifelse($MY_{MY} > \beta_{14}, \beta_{13} * (MY_{MY} - \beta_{14}), 0$)

The intercept enters as a constant added to the predicted logistic of the instantaneous scrappage rate. The model year slope enters as the model year for all model years older than 2000 and enters as 2000 for all model years 2000 and newer.

Once the predicted logistic scrappage rate is calculated in the CAFE model (including the projections of the fixed effect portion of the equation), the future population of model year cohorts can be predicted. The instantaneous scrappage can be calculated directly from S. It identifies the share of remaining vehicles in each calendar year that are scrapped in the next year. The population of vehicles in the next calendar year can be calculated as follows:

$$Population_{MY,CY+1} = Population_{MY,CY} * (1 - s_{MY,CY}).$$

This process is iteratively calculated at the end of the CAFE model simulation to determine the projected population of each model year in each future calendar year. This allows the calculation of vehicle miles travelled, fuel usage, pollutant and CO_2 emissions, and associated costs and benefits. The CAFE model documentation released with this final rule further details how the scrappage model is projected within the simulations.

(d) Updates to the Decay Function

The scrappage models described above fit the historical data of car and truck scrappage well, but when used to project the scrappage of future model years they over-predict the remaining cars and trucks for ages greater than 30 in an unrealistic manner. Nearly six percent of the MY2015 van/SUV fleet and eight percent of the pickup fleet is projected to persist until age 40. This is unrealistic, and likely due to the fact that the agencies do not observe enough model years for those ages and over-predict the impact of durability increases for those ages. For this reason, the agencies are using the curves with an accelerated decay function to predict instantaneous scrappage beyond age 30 for pickups and SUVs/vans. The implementation and parameter stricture of the decay function have not changed since the NPRM model. Table VI-209, below, shows the inputs used for the final rule analysis.

Table VI-209 – Decay Function Inputs

Beta Coefficients	**Inputs**	**Cars**	**Vans/SUVs**	**Pickups**
β_{15}	Decay Age	30	30	30
β_{16}	Final Survival Rate	0.01	0.025	0.025

The final survival rate has not changed since the NPRM, but the input *Decay age* has changed. In the NPRM, the decay function was specified to begin after age 20, while the decay function begins after age 30 in the final rule analysis. This input change was possible because the scrappage model for the final rule predicts shares remaining in line with observed historical trends through age 30, rather than through age 20. This improvement in the model fits for older ages is driven both by the shift of the modelling of the durability effect discussed in Section VI.D.1.b)(3)(a)(g) and the increase in available data on the scrappage rates of older vehicles discussed in Section VI.C.1.b)(3)(c)(ii)(d). Overall, this outcome suggests that the final rule model predicts the scrappage rates of older vehicle better than the NPRM model.

As in the NPRM, the decay function is implemented in the model using the following conditions:

If (age<β_{15}),

$$S = \frac{e^{\sum \beta_i X_i)}}{1 + e^{\sum \beta_i X_i)}}$$

And:

$$Population_{MY,CY+1} = Population_{MY,CY} * (1 - S_{MY,CY}).$$

If (age>=β_{15}),

$$Population_{MY,CY+1} = Population_{MY,CY=\beta_{15}} * exp^{rate*t}$$

Where:

$$t = (age + 1 - \beta_{15})$$

And:

$$rate = \frac{ln\left(\frac{(\beta_{16})}{Population_{MY,CY=\beta_{15}}}\right)}{40 - \beta_{15}}$$

Here, the population for ages beyond the start age of the decay function depends on the population of the cohort at that start age and the final share expected for that body style at age 40. The rate of decay necessary to make the final population count equal that observed in the historical data is applied.

(4) The Rebound Effect in the NPRM

The fuel economy rebound effect—a specific example of the well-documented energy efficiency rebound effect for energy-consuming capital goods—refers to the tendency of motor vehicles' use (as measured by vehicle-miles traveled, or VMT) to increase when their fuel economy is improved and, as a result, the cost per mile (CPM) of driving declines. Amending and establishing CAFE and CO_2 standards at a lower degree of stringency than the baseline level will lead to comparatively lower fuel economy for new cars and light trucks, thus increasing the amount of fuel consumed to travel each mile. The resulting increase in CPM will lead to a reduction in VMT over the lifetime of new vehicles, an example of the rebound effect working in reverse. In the NPRM, the agencies assumed a fuel rebound effect of 20 percent, meaning that a 5 percent decrease in fuel economy would result in a one percent decrease in the annual number of miles driven at each age over a vehicle's lifetime.

Many of the comments received on different components of the CAFE model can be traced back to the agencies' rebound selection. The agencies recognize that the value selected for the rebound effect influences overall costs and benefits associated with the regulatory alternatives under consideration as well as the estimates of lives saved under various regulatory alternatives, and that the rebound estimate, along with fuel prices, technology costs, and other analytical inputs, is part of the body of information that agency decision-makers have considered in determining the final levels of the CAFE and CO_2 standards. The agencies also note that the rebound effect diminishes the economic and environmental benefits associated with increased fuel efficiency.

For the analysis supporting the NPRM, the agencies conducted a thorough re-examination of the basis for the estimate of the fuel economy rebound effect used to analyze the impacts of CAFE and CO_2 emission standards for model years 2012-16 and 2017-21. This was prompted by three developments. First, more recent updates of the 2007 study by Small and Van Dender that had provided the basis for assuming the 10 percent rebound effect used in those previous analyses reported larger values. Second, projected growth in the income measure used in those authors' 2007 study, which was anticipated to reduce the magnitude of the rebound effect over the future period spanned by those analyses, did not occur during the decade following the 2007 study's publication. Finally, extensive new research on the rebound effect had become available since those previous analyses were conducted, and while its findings were mixed, many of those more recent studies reported values significantly above the agencies' previous 10 percent estimate.

In the NPRM, the agencies first summarized estimates of the fuel economy rebound effect for light-duty vehicles in the U.S. from studies conducted through 2011, when the agencies originally surveyed research on this subject. As the accompanying discussion in the proposal indicated, the research available through 2011 collectively suggested that the rebound effect was likely to fall in the range from 20 percent to 25 percent, although the then-recent study by Small and Van Dender (2007) pointed to smaller values, particularly for future years. The agencies then identified 16 additional studies of the rebound effect that had been conducted since their original survey, and the NPRM discussed the various approaches they used to measure the magnitude of the rebound effect, their data sources and estimation procedures, reported findings, and strengths and weaknesses of each study.

Based on this re-examination, the agencies concluded that currently available evidence did not appear to support the 10 percent estimate relied upon in previous rules, and identified a value of 20 percent as more representative of the totality of evidence, including both the research covered by the earlier and more recent studies examined in the NPRM. While acknowledging the wide range of estimates reported in more recent research—which extended from zero to more than 80 percent—the agencies noted that the central tendency of recent estimates appeared to lie in the same 20-25 percent range suggested by their extensive review of earlier research. The agencies also recognized that a 20 percent estimate differed markedly from the 10 percent estimate used in the regulatory analyses for the 2010 and 2012 final rules, but noted that it represented a return to the value NHTSA originally used to analyze the impacts of CAFE standards for model years prior to 2011.

(a) Comments on the Rebound Effect Used in the NPRM

The agencies received numerous comments on the decision to revise their previous estimate of the rebound effect, virtually all of which echoed a few common arguments. First, commenters generally agreed that the most appropriate measure for the agencies to rely on is the current long-run fuel economy rebound effect for U.S., although a few suggested that using an estimate of its short-run value might be preferable.[1890] However, many commenters argued that some of the more recent studies the agencies relied upon to support the revised 20 percent estimate may have limited relevance to the appropriate measure for analyzing the current rule, and that the agencies should place more emphasis on those that commenters asserted were more appropriate to rely upon.

To identify the most relevant research, some commenters proposed applying various selection criteria to choose which studies were most appropriate to rely on when estimating the value of the rebound effect to use in this analysis. While commenters proposed using certain criteria as "filters"—that is, to eliminate any studies that did not meet those criteria—they also suggested applying other criteria to emphasize studies with particular features they argued made them more relevant to identifying the current value of the rebound effect for the U.S.[1891] Among these suggested criteria were the following:

- Exclude estimates based upon data from outside the U.S.;
- Include only estimates based upon "more recent" data, usually taken to mean those published within approximately the last decade;
- View estimates based on the U.S. 2009 National Household Travel Survey skeptically, or exclude them from consideration completely;
- Emphasize estimates derived from vehicle use and fuel economy data spanning multiple years (such as aggregate time-series or panel data), while according less weight to those based on a single-year cross section (such as most household survey data);
- Emphasize estimates of the rebound effect that measure the response of vehicle use to variations in fuel efficiency, rather than in fuel cost per mile driven or fuel price per gallon;

[1890] *See, e.g.,* RFF, Comments, NHTSA-2018-0067-11789, at 30. For an thorough example of the arguments made for a short- to medium-term rebound effect, *see generally* IPI, Appendix, NHTSA-2018-0067-12213, at 61.
[1891] *See, e.g.,* IPI, Appendix, NHTSA-2018-0067-12213, at 58-64; EDF, Analysis of the Value and Application of the Rebound Effect, NHTSA-2017-0069-0574, at 16-19; California Office of the Attorney General et al., Attachment1, NHTSA-2017-0069-0625, at 8; States and Cities, Attachment 1, Docket No. NHTSA-2018-0067-11735, at 78; RFF, Comment, NHTSA-2018-0067-11789, at 3; CARB, Detailed Comments, NHTSA-2018-0067-11873, at 120; Aluminum Association, Comments, NHTSA-2018-0067-11952, at 5; NCAT, Appendix A, NHTSA-2018-0067-11969, at 34; and North Carolina Department of Environmental Quality, Comments, NHTSA-2018-0067-12025, at 12; among others. EPA's Science Advisory Board shared similar policy opinions.SAB at 26-27.

- Emphasize estimates that rely on identification strategies that account for potential endogeneity in fuel economy (as would result, for example, if households with high levels of demand for travel purchase vehicles with higher fuel economy);

- Emphasize estimates based on measures of vehicle use obtained from odometer readings; and

- Emphasize estimates that explicitly control for purchase prices of new vehicles in order to account for changes in new vehicle prices due to CAFE standards.

A few commenters illustrated how applying these criteria could reduce the large number of published studies of the rebound effect to a limited subset that suggested a smaller value than 20 percent.[1892] Using multiple criteria to exclude or de-emphasize studies that did not meet all of those applied, these commenters argued that the most appropriate value for this analysis was closer to (or possibly even below) the 10-percent estimate the agencies used for the previous rulemaking.[1893] However, one commenter noted that applying these criteria individually to exclude any estimates not meeting them had almost no effect on formal measures of the central tendency (the mean and median values) of the remaining estimates.[1894] This commenter suggested that only by applying two or more of these criteria jointly and excluding any studies that did not meet all of those applied could the universe of research on the rebound effect be reduced to a subset supporting a lower value than the 20 percent figure the agencies used to analyze the NPRM.

Commenters also identified several additional recent studies that were not included in the agencies' review of recent evidence for the NPRM, and suggested revised interpretations of the empirical estimates reported in two studies that had been included (the agencies also clarified a third). Commenters represented these additional studies as generally supporting lower values than the agencies' revised 20 percent estimate, although this appeared to be a selective interpretation of some of the results they reported.[1895] Other commenters asserted that the two most commonly-demonstrated features of the rebound effect are that it varies directly with fuel prices and declines in response to rising income over time, and argued that the latter suggests that a declining value is likely to be more appropriate for analyzing the longer-term impacts of this final rule.[1896]

[1892] *See, e.g.*, Gillingham, Nera-Trinity Responses, NHTSA-2018-0067-12403, at 16-30.
[1893] *See supra* note 1891.
[1894] Alliance of Automobile Manufacturers, Attachment 3, NHTSA-2018-0067-12386, at 15-17.
[1895] For example, some commenters (*e.g.*, Gillingham, Nera-Trinity Responses, NHTSA-2018-0067-12403, Table 2, at 24) represented the recent analysis of vehicle use data from Texas by Wenzel and Fujita as reporting a rebound effect of 8-15 percent, which appears to be based on those authors' estimates of the response of vehicle use to changes over time in fuel prices alone. This range appears to ignore those same authors' estimates of the sensitivity of vehicle use to variation in fuel costs per mile, which provides a more direct measure of the fuel economy rebound effect because it incorporates fuel economy as well as fuel prices. Those estimates range from 7-40 percent, with most falling in the interval from 15-25 percent; *see generally,* Wenzel and Fujita (2018), Table 4-12, at 38.
[1896] *See* particularly Small, NHTSA-2018-0067-7789, at 3.

Some commenters suggested that the rebound effect is asymmetrical, meaning that drivers are more responsive to price increases than price decreases. These commenters asserted that the asymmetrical nature of the rebound effect favors a lower estimate.[1897] Similarly, other commenters suggested that the rebound effect had to be lower than 20 percent because congestion would limit additional driving.[1898]

(b) Agencies' Response to Comments on the NPRM

In response to commenters who argued that the agencies' estimate of the rebound effect should be reduced, because research that incorporates the effects of congestion or allows asymmetrical responses to price changes suggests lower values, the agencies note that, for the final rule's analysis, those factors would be difficult and perhaps even inappropriate to incorporate in their analysis. In the case of congestion, the agencies note that their estimate of the rebound effect—like research on the rebound effect in general—represents a change in aggregate VMT, and has no clear implication about how that change in travel is likely to be distributed over times of the day or geographic locations.[1899]

As for possible asymmetry in the response of vehicle use to changes in driving costs, the CAFE model applies a single estimate of the rebound effect for all changes in cost-per-mile, and cannot accommodate a rebound effect that varies with the magnitude or direction of changes in driving costs, which would be necessary to capture asymmetrical or non-linear responses to cost changes. The agencies also remind commenters that this rule will result in an increase in driving costs, for which the research they cite generally suggests a *larger* value of the rebound effect is appropriate. In any case, using a different estimate of the rebound effect to analyze impacts of raising and lowering standards would not promote consistency or replicability, both desirable characteristics of regulatory analysis.

The agencies decided to include the previously omitted studies raised by commenters in their rebound analysis supporting the final rule, but do not feel that they suggest a value different from that used to analyze the proposal. Adding these studies to the list of recent research discussed in the NPRM, deleting one unpublished analysis, and revising the entries for selected studies to reflect more accurately the values reported by their authors produces a more extensive catalog of recent research, which is summarized in Table VI-210 below.

[1897] EDF, Analysis of the Value and Application of the Rebound Effect, NHTSA-2017-0069-0574, Comment, 37-38.
[1898] For example, the South Coast Air Quality Management District argued that, logistically, rebound cannot exist in Southern California because "any rebound effect will only worsen congestion in Southern California, such a result cannot be predicted." NHTSA-2018-0067-11813 at 45.
[1899] The agencies' estimate of increased congestion costs associated with additional driving due to the rebound effect implicitly assumes that increased driving will be distributed according to current travel patterns, producing similar proportional increases at various hours of the day and geographic locations. Such an assumption is made out of necessity to model congestion and noise; the agencies acknowledge that the rebound effect is unlikely to affect vehicle use in such a uniform fashion.

Table VI-210 – Recent Estimates of the Rebound Effect for Light-Duty Vehicles

Authors (Date)	Nation	Time Period	Data	Range of Estimates
Barla *et al.* (2009)	Canada	1990-2004	10 Canadian provinces	8-20%
Bento (2009)	U.S.	2001	150,000 household vehicles	21-38%
Waddud (2009)	U.S.	1984-2003	U.S income quintiles	1-25%
Hymel et al. (2010)	U.S.	1966-2004	50 U.S. states	16-24%
Gillingham (2011)	California	2001-09	1 million vehicles	1%
Anjovic and Haas (2012)	E.U.	1970-2007	6 E.U. nations	44%
Greene (2012)	U.S.	1966-2007	annual aggregate values	8-12%
Su (2012)	U.S.	2009	45,000 households	11-19%
Wang *et al.* (2012)	Hong Kong	1993-2009	annual aggregate values	45%
Linn (2013)	U.S.	2009	230,000 household vehicles	20-40%
Frondel and Vance (2013)	Germany	1997-2009	2,165 households	46-70%
Liu (2014)	U.S.	2009	1,420 households	39-40%
Gillingham (2014)	California	2001-09	5 million vehicles	22-23%
Weber and Farsi (2014)	Switzerland	2010	8,000 household vehicles	19-81%
Gillingham et al. (2015)	Pennsylvania	2000-2010	7 million vehicles	8-22%
Hymel & Small (2015)	U.S.	2003-09	50 U.S. states	4-18%
West *et al.* (2015)	U.S.	2009	166,000 new vehicles	0%
DeBorger et al. (2016)	Denmark	2001-11	23,000 households	8-10%
Stapleton et al. (2016)	Great Britain	1970-2011	annual aggregate values	13-23%
Langer et al. (2017)	Ohio	2009-13	229,000 driver-months	12%
Stapleton et al. (2017)	Great Britain	1970-2012	annual aggregate values	22-30%
Wenzel and Fujita (2018)	Texas	2005-2010	32 million vehicles	7-40%
Knittel and Sandler (2018)	California	1996-2010	36 million vehicles	5-27%

As evidenced in Table VI-210, studies continue to have a wide range of estimates, but collectively the research looks remarkably similar to the historical estimates. The newer studies suggest that a plausible range for the rebound effect is 10-50 percent. The central tendency of this range appears to be roughly 30 percent.

In response to comments proposing the application of specific criteria to eliminate or reduce the consideration accorded to studies without certain features thought to increase the relevance of their findings, the agencies note that measuring the rebound effect is both conceptually and technically challenging, and that analysts have used many different approaches in an attempt to surmount these challenges. The agencies' view is that each of the studies included in its previous survey and in Table VI-210 above provides some useful evidence on the likely value of the rebound effect, and while all have some conceptual or theoretical weaknesses, each nevertheless provides some useful insights into the appropriate magnitude of the rebound effect for the current analysis.

As a general approach to estimating parameters that are uncertain, the agencies prefer to rely on the totality of empirical evidence, rather than restricting the available evidence by categorically excluding or according less weight to that do not meet selection criteria that may not be widely agreed upon. From this perspective, analyses that rely on different measurement approaches, data sources, and estimation procedures all have the potential to provide valuable information for choosing the most representative value. The agencies also view sound measurement strategies and careful empirical analysis using reliable data as equally important features when compared to a study's vintage or geographic scope. Examining the widest possible range of research also enables useful comparisons and "cross-checks" on the estimates that individual studies report.

Notwithstanding this more inclusive perspective, the agencies endorse certain of the characteristics preferred by commenters, although the agencies view them as indicators of a strong study, rather than a bright-line test of whether to accord it any weight rather than discarding it from consideration. Specifically, the agencies agree with many commenters that both the extended time span encompassed by their analysis of the impacts of CAFE and CO_2 standards and the long expected lifetimes of vehicles subject to this final rule means that estimates of the long-run rebound effect are most relevant for purposes of the final rule analysis.[1900] The agencies also agree with commenters that estimates based upon more recent data are generally preferable, but nevertheless note that older studies that combine careful analysis with unusually reliable or novel data can offer evidence that remains useful.[1901] The agencies also concur with some commenters' argument that estimates of the rebound effect that are derived from the relationship of vehicle use to fuel efficiency, rather than to fuel cost per mile or gasoline prices, are likely to provide more direct measures of the fuel economy rebound effect itself, which is the desired parameter for the purposes of this analysis. Finally, the agencies generally view identification strategies and econometric methods that account or control for potential endogeneity in fuel economy as likely to provide more reliable estimates.

In contrast, the agencies view other criteria proposed by commenters as unnecessarily restrictive, particularly when they are used to disqualify otherwise informative research from consideration. For instance, categorically excluding from consideration non-U.S. studies—which the agencies agree should be treated cautiously—seems likely to exclude useful evidence, particularly recognizing some of those studies' access to unusually reliable data on vehicle use and fuel economy and use of sophisticated econometric analysis. In addition, many foreign studies have been conducted in nations with income levels comparable to the U.S., and in some

---

[1900] Most of the vehicles affected by today's standards will remain on the roads for at least a decade, with a significant fraction surviving considerably longer. As such, long-run estimates are more likely to reflect the lifetime mileage accumulation of the new fleet than either short-run or medium-run estimates. Furthermore, a long-run rebound estimate better reflects the cumulative impact of successive CAFE and CO_2 standards such as those adopted by the agencies beginning as early as 2010.

[1901] One example is the study by Greene et al. (1999), which used advanced econometric analysis of unusually detailed and reliable data on household demographic and economic characteristics, household members' use of individual vehicles, and fuel purchases to estimate the response of households' use of individual vehicles to their actual on-road fuel economy, and its implications for total household driving.

cases levels of auto ownership that are beginning to approach U.S. levels. Furthermore, driving habits throughout the U.S. are not homogenous. In fact, some regions in the U.S. may exhibit driving habits that more closely resemble those in some foreign nations than driving patterns in other regions of the U.S.[1902]

In response to some commenters' recommendation that the agencies more heavily weigh studies using data spanning multiple years than those relying on data for a single year, the agencies note that household surveys, the most common form of data for a single year, provide cross-sectional variation in vehicle use and other characteristics that is helpful for identifying the desired long-run measure of the rebound effect. Household surveys are also an important source of information that enable analysts to measure the response of individual vehicles' use to variation in their fuel economy, while also controlling adequately for household characteristics that affect travel patterns and vehicle use. Household survey data can also enable analysts to identify the vehicle substitution patterns within multiple-vehicle households that are increasingly responsible for producing the rebound effect, while even modest-scale household surveys include many more observations than are typically available in aggregate time-series or panel data.

These strengths of course need to be balanced against the potential drawbacks of relying on a one-time snapshot of households' behavior during a single time period. Surveys also frequently rely on owner-reported estimates of vehicle use and usually require analysts to impute vehicles' fuel economy ratings from limited and sometimes incomplete information on the specific vehicle models and vintages that households report owning. One result is that estimates of the rebound effect derived from household survey data may be based on inaccurate estimates of vehicles' use and fuel economy. Assuming the errors in measuring these variables are random, the errors would increase the uncertainty surrounding the estimates of the rebound effect, but would not bias the estimate.

In contrast, studies using nationwide aggregate or average measures of vehicle use and fuel economy or fuel cost rarely provide adequate independent variation to support reliable estimates of the response of vehicle use to variation in fuel economy, even where extended time series are available, while State-level measures of these variables are subject to potentially extreme measurement error that can compromise estimates of these relationships.[1903] Moreover, controlling for the many other demographic and economic factors likely to affect vehicle use using national or even State-level aggregate data presents difficult challenges.

Finally, the agencies note that no single selection criterion proposed by commenters noticeably reduces the central tendency displayed by the universe of estimates of the rebound

---

[1902] For example, drivers in Manhattan, Kansas likely respond to changes in fuel prices and fuel economy differently than drivers in Manhattan, New York.

[1903] For example, State-level estimates of travel by individual vehicle classes such as cars and light-duty trucks often exhibit implausible year-to-year variability due to the measurement procedures states employ and the difficulty of distinguishing among different types of vehicles. At the same time, the potential geographic "mismatch" between State-level vehicle use and fuel sales complicates any effort to measure fuel efficiency or fuel costs at the State level.

effect, and multiple criteria must be applied simultaneously to restrict the universe to a subset of studies that points toward a significantly lower value than the 20 percent estimate the agencies used to analyze the proposal. Applying multiple criteria drastically reduces the number of studies that remain available to guide the agencies, while at the same time discarding potentially valuable information provided by research those criteria exclude from consideration.[1904] Doing so would thereby necessarily reduce the confidence that the agencies can have in the resulting estimate.

Regarding some commenters' assertion that the rebound effect is known to decline in response to rising income, and that this observation warrants using a lower value for long-term future evaluation of the standards' effects, the agencies note that some evidence based on household and vehicle use surveys suggests that the rebound effect increases with the level of household vehicle ownership, which is itself highly correlated with income. Together with forecasts of limited future growth in most measures of U.S. household income, this finding casts some doubt on whether the rebound effect is likely to decline over the time period spanned by the agencies' analysis.[1905]

The agencies also note that one of the studies cited in Table VI-210 above (DeBorger et al., 2016) finds that the decline in the fuel economy rebound effect with income reported in the earlier analysis by Small and Van Dender (2007)—on which the agencies relied in reducing their original estimate of the rebound effect to 10 percent—results entirely from a reduction in drivers' sensitivity to fuel prices as their incomes rise, rather than from any effect of rising income on the sensitivity of vehicle use to fuel economy.[1906] This latter measure—which DeBorger et al. find is quite small and has not changed significantly as incomes have risen over time—is the most direct measure of the fuel economy rebound effect, so their analysis calls into question its widely-assumed sensitivity to income.

Finally, because there is not a clear consensus around a single rebound estimate within the literature, the agencies believe it is important to benchmark their analysis with other large scale surveys of the literature published by neutral observers. In one early survey, Greening, Greene, and Difiglio (2000) reviewed studies that estimated the rebound effect for light-duty vehicles in the U.S., concluding that those relying on aggregate time-series data found it was likely to range from 10-30 percent, while those using cross-sectional analysis of household vehicle use suggested a larger rebound effect, in the range of 25-50 percent.[1907] Sorrell et al.

[1904] As an illustration, excluding non-U.S. studies reduces the number of recent analyses surveyed in the proposal from 15 to 8, while eliminating those that rely on the 2009 National Household Travel Survey (NHTS) discards another 5, leaving only 3.
[1905] For example, the widely cited IHS Markit Long-Term Macroeconomic Outlook for Spring 2019 projects that per Capita disposable personal income in the U.S. will grow at 1.6 percent annually over the next 30 years; *see* Federal Highway Administration, Forecasts of Vehicle Miles Traveled (VMT): Spring 2019, Table 2, *available at* https://www.fhwa.dot.gov/policyinformation/tables/vmt/vmt_forecast_sum.cfm.

[1907] Greening, L.A., Greene, D.L. and Difiglio, C., "Energy efficiency and consumption—the rebound effect—a survey." *Energy Policy*, Vol. 28 (2000), at 389-401.

(2009) found that the magnitude of the rebound effect for personal automobile travel is likely to fall in the 10-30 percent range, with some evidence suggesting that the lower end of that range might be most appropriate.[1908]

Most recently, a meta-analysis of 74 published studies of the rebound effect conducted by Dimitropoulos et al. (2018) estimated that the long-run rebound effect ranges from 22-29 percent when measured by the response of vehicle use to variation in fuel efficiency (the authors' preferred measure), from 21-41 percent when it is measured using the variation fuel cost per unit distance, and from 25-39 percent using fuel price per gallon.[1909] The authors concluded that "the magnitude of the rebound effect in road transport can be considered to be, on average, in the area of 20%," but noted that the long-run estimate was about 32 percent.[1910] A subsequent published study by these same authors (Dimitropoulos et al. (2018)) concludes that the most likely estimate of the long-run rebound effect is in the range of 26-29 percent, but could range from as low as 15 percent to as high as 49 percent at income levels, development densities, and fuel prices that are currently representative of the U.S.[1911]

(c) Selecting a Value of the Rebound Effect for Evaluating the Impacts of this Rule

After reviewing the evidence on the rebound effect previously summarized in the NPRM, comments the agencies received, other recent studies of the rebound effect that were not summarized in the NPRM but suggested by commenters, and published surveys of literature, a reasonable case can be made to support values of the rebound effect at least as high as 30 percent. The totality of evidence, without categorically excluding studies on grounds that they fail to meet certain criteria, and evaluating individual studies based on their particular strengths, suggests that a plausible range for the rebound effect is 10-50 percent. The central tendency of this range appears to be at or slightly above its midpoint, which is 30 percent. Considering only those studies that the agencies believe are derived from unusually reliable data, employ identification strategies that are likely to prove effective at isolating the rebound effect, and apply rigorous estimation methods suggests a range of approximately 10-45 percent, with most of their estimates falling in the 15-30 percent range.[1912]

[1910] *Id.* at 28.
[1911] Dimitropoulos, Alexandros, Walid Oueslati, and Christina Sintek, "The Rebound Effect in Road Transport: A Meta-Analysis of Empirical Studies," *Energy Economics* 75 (2018), at 163-79; *see* esat Table 4, at 170, Table 5, at 172 (and accompanying discussion), and Appendix B, Table B.V., at 177.
[1912] As indicated previously, these are the selection criteria proposed by commenters with which the agencies concur. In chronological order, the studies the agencies feel best meet those criteria include Greene et al. (1997), Small and Van Dender (2007) and subsequent updates by Hymel, Small, and Van Dender (2010,2015), Linn (2016), Anjovic and Haas (2012), Gillingham (2014), and DeBorger et al. (2016). Other studies the agencies believe

At the same time, the agencies conclude that a reasonable case can also be made to support values of the rebound effect falling in the 5-15 percent range. This argument relies on using the criteria proposed by commenters to restrict the studies considered to include recently published analyses using U.S. data, and to accord the most weight to research that relies on measures of vehicle use derived from odometer readings, controls for the potential endogeneity of fuel economy, and estimates the response of vehicle use to variation in fuel economy itself, rather than to fuel cost per distance driven or fuel prices. This approach suggests that the rebound effect is likely in the range from 5-15 percent, and is more likely to lie toward the lower end of that range. The agencies note that estimates of very low or no rebound effect cited by some commenters are either misinterpretations of the findings reported by their authors, or do not represent measures of the fuel economy rebound effect.[1913]

Finally, the agencies note that surveys of evidence on the rebound effect have consistently found that the most appropriate estimate falls in the range of 10-40 percent. These findings have remained surprisingly consistent over time, despite a rapidly expanding universe of empirical evidence that includes estimates drawn from more diverse settings, and reflects continuing improvements in the data they rely upon, an expanding range of strategies for identifying the rebound effect and distinguishing it from other influences on vehicle use, and advances in the econometric procedures analysts use to estimate its magnitude.

For the aforementioned reasons, the agencies have elected to retain the 20 percent rebound effect used to analyze the effects of the NPRM on vehicle use and fuel consumption for analyzing the comparable effects of this final rule. As explained above and in the NPRM, older research suggests a rebound of 20 to 25 percent. The new research in Table VI-210 supports a similar—or even larger—range. Extensive survey studies support a rebound at or above 20 percent. As such, the agencies feel 20 percent is a reasonable—and probably even conservative—estimate of the totality of the evidence. While a lower estimate may be reasonable under certain circumstances, the agencies are uncomfortable making the requisite assumptions regarding which specific criteria should be used to identify relevant studies and relying on a subset of the literature for the central analysis. However, recognizing the uncertainty surrounding the rebound value, the agencies also examine the sensitivity of those estimated impacts to values of the rebound ranging from 10 percent to 30 percent, both in isolation and in conjunction with plausible variation in other key parameters.

---

warrant serious consideration because they offer some or most of these same advantages include those by Liu et al. (2014), Knittel and Sandler (2018), and Wenzel and Fujita (2018).

[1913] For example, some commenters misinterpret Greene's (2012) inability to identify a statistically significant estimate of the response of vehicle use to variation in fuel economy as evidence that its true value is zero. Similarly, some commenters misinterpret the result reported by West et al. (2017) that buyers of more fuel-efficient vehicles did not increase their driving as evidence that fuel economy itself has no effect on vehicle use, when—as the study's authors and some commenters acknowledge—it reveals instead that buyers regarded those vehicles as providing inferior transportation service and drove them less as a consequence. Because the agencies repeatedly insist that vehicle attributes other than fuel economy will not change as a consequence of this rule, those authors' finding is of limited or no relevance to the analysis supporting this rule.

(5) Vehicle Miles Traveled (VMT)

VMT directly influences many of the various effects of fuel economy and CO_2 standards that decision-makers consider in determining what levels of standards to set. For example, fuel savings is a function of a vehicle's efficiency, miles driven, and fuel price. Similarly, factors like criteria pollutant emissions and fatalities are direct functions of VMT. In the CAFE model, VMT is the product of average usage per vehicle in the fleet and fleet composition, which is itself a function of new vehicle sales and vehicle retirement decisions, otherwise known as scrappage. These three components—average vehicle usage, new vehicle sales, and older vehicle scrappage—jointly determine total VMT projections for each alternative.

As the following discussion explains, today's VMT analysis provides aggregate results comparable to other well-regarded VMT estimates. However, because the agencies' analysis looks at the incremental costs and benefits across alternatives (see Section VII), it is more important that the analysis capture the variation of VMT across alternatives than accurately to predict total VMT within a scenario. As such, the agencies note that today's VMT estimates are logical, consistent, and precise across alternatives. Furthermore, as will be described in further detail below, while the agencies, in response to comments, have decided to modify their approach to calculating VMT and to use different VMT estimates than those used in the NPRM, the general trends between alternatives are comparable.

Commenters addressed a number of topics related to the total amount of estimated VMT, the incremental differences in estimated VMT between regulatory alternatives, and per-vehicle VMT estimates in the NPRM analysis. In general, commenters felt that the NPRM's VMT numbers were inaccurate and should not be relied on for the analysis.[1914] Some commenters were more specific and argued that the total amount of estimated VMT projected in the NPRM started at too low a level, and increased too much over the years simulated. Similarly, some commenters argued that the agencies' estimates were too different from other recognized estimates and suggested that the agencies benchmark VMT projections to other sources to ensure both a consistent starting point and comparable VMT throughout the calendar years analyzed.

A few commenters objected to the underlying mileage accumulation schedules, which form the basis for per-vehicle VMT estimates in CAFE Model simulations. Such commenters speculated that revisions to these schedules undertaken in 2016 might be the reason for discrepancies in total VMT. Other commenters were less concerned about how VMT was computed within each scenario but were apprehensive about differences in VMT estimates across regulatory alternatives. For instance, Honda argued that, "[a]ssuming all other parameters are held constant—and excluding the rebound effect—it is not obvious why one scenario should have different total VMT than another."[1915] While commenters generally provided few specific recommendations about the level to which VMT estimates should be constrained among alternatives, several commenters argued that VMT projections would benefit from consideration of travel demand modeling.

[1914] *See, e.g.*, Securing America's Energy Future, NHTSA-2018-0067-11981 at 37-38.
[1915] Honda, NHTSA-2018-0067-11818, at 17.

Additionally, some commenters (RFF, IPI, NRDC) argued that a superior, and perhaps even necessary, approach would be to incorporate a model that considers jointly the decision to buy, use, and retire vehicles at the household level. As RFF posited "a household makes decisions about its vehicle ownership and use jointly: people don't buy new vehicles or get rid of existing ones without considering how these actions will affect the use of their vehicles."[1916] IPI further argued that "[i]n sum, VMT is influenced by vehicle choice and vehicle choice is influenced by VMT. And a 'unified model of vehicle choice and usage' is necessary."[1917] While the agencies agree that a joint household consumer choice model—if one could be developed adequately and reliably to capture the myriad circumstances under which families and individuals make decisions relating to vehicle purchase, use and disposal—would reflect decisions that are made at the household level, the agencies do not agree that it is necessary, or necessarily appropriate, to model the national program at that scale in order to produce meaningful results that can be used to inform policy decisions. The most useful information for policymakers relates to national impacts of potential policy choices. No other element of this analysis occurs at the household level, and the error associated with allocating specific vehicles to specific households over the course of three decades would easily dwarf any error associated with the estimation of these effects in aggregate. The agencies have attempted to incorporate estimates of changes to the new and used vehicle markets at the highest practical levels of aggregation, and worked to ensure that these effects produce fleetwide VMT estimates that are consistent with the best, current projections given our economic assumptions. While future work will always continue to explore approaches to improve the realism of CAFE/CO_2 simulation, there are important differences between small-scale econometric studies and the kind of flexibility that is required to assess the impacts of a broad range of regulatory alternatives over multiple decades. The agencies have read and evaluated the comments on the NPRM, incorporating many suggestions that improve the fidelity of this analysis—taking particular care to be conservative with the analysis. The modifications the agencies have made in response to these comments are described below (and in the RIA).

The agencies carefully assessed all comments. To address them, the agencies have revised their calculation of estimated VMT in two, significant respects. First, in response to comments regarding the mileage accumulation schedules, the agencies have revised the schedules using panel data. Second, to deal with commenters' concerns with the fluctuation of estimated "non-rebound" VMT across regulatory alternatives, the agencies have created a method that constrains "non-rebound" VMT across regulatory alternatives. The agencies believe these two changes collectively resolve the substantive issues raised by commenters. The total VMT for the final rulemaking (FRM) analysis now aligns with estimates of the Federal Highway Administration (FHWA) and the only differences in VMT between alternatives is attributable to changes in the fleet's fuel economy. The following sections discuss these changes in detail.

[1916] RFF, NHTSA-2018-0067-11789, at 5.
[1917] IPI, Appendix, NHTSA-2018-0067-12213, at 80 (internal citation omitted).

(a) Mileage Accumulation Schedule

To account properly for the average value of consumer and societal costs and benefits associated with vehicle usage under various CAFE and CO_2 alternatives, it is necessary to estimate the portion of these costs and benefits that will occur each calendar year for each model year cohort. Doing so requires some estimate of how many miles the average vehicle of each body type is expected to drive at each age. The agencies call these "mileage accumulation schedules." For this final rule, the agencies are modifying the mileage accumulation schedules, largely in response to comments.

(i) Data

As mentioned in previous sections, NHTSA purchased a data set containing 70 million vehicle odometer readings from Polk in part to create the vehicle mileage accumulation schedules used in the NPRM. In the proposal, the agencies explained that Polk data was newer and believed to be qualitatively superior to the 2001 and 2009 National Household Travel Survey (NHTS) data used in prior rules.[1918] Consistent with previous analyses,[1919] the agencies used a cross-sectional sample of the Polk data for the NPRM. Cross-sectional data is like a "snapshot" in time. Rather than tracking vehicles over a period, the sample contained a single odometer reading from each vehicle sampled. In other words, the sample contained observations of the total lifetime accumulation of miles (represented by its odometer reading) through CY2015 of all MYs still present on the road. The cross-sectional sample was limited in the number of vintages included in the sample. While the sample was suitable to capture the heaviest usage ages (age zero to 15 years), it contained no observations for vehicles older than 16 years. This required the agencies to rely on mileage accumulation schedules developed from other data sources to produce annual VMT rates for older vehicles. Furthermore, in order to develop a schedule of mileage accumulation by age, it was necessary to assume that each vehicle traveled the same number of miles each year to reach its odometer reading, e.g. if a MY 2007 vehicle had an odometer reading of 88,000 in CY2015, the analysis assumed the vehicle drove 11,000 miles each year from CY2007 to CY2015.

The agencies acknowledged that this approach missed some of the nuances of car ownership.[1920] For example, vehicles are commonly part of multi-vehicle household fleets and their usage changes over time as households buy new vehicles and replace older ones. Similarly, most vehicles belong to multiple owners over the course of their useful lives, each of whom may have different patterns of usage. The most significant limitation of using cross-sectional data is the presence of an attrition bias. As a cohort ages, vehicles that have been used more heavily are more likely to be retired at each age than vehicles that are driven less. As the most heavily-driven vehicles drop out of the fleet, the remaining vehicles, which likely have been driven less at each age throughout their lives, will have lower odometer readings. Making the common, but

[1918] *See*, *e.g.*, 83 FR at 43089-90 (Aug. 24, 2018).
[1919] Previous rules were based on odometer data from the 2001 National Household Travel Survey (NHTS). S. Lu, "Vehicle Survivability and Travel Mileage Schedules," Report Number: DOT HS 809 952 (January 2006).
[1920] *See* 83 FR at 43092 (Aug. 24, 2018).

necessary assumption that each vehicle is driven uniformly at each age results in lower miles-per-age estimates because of this attrition bias. In the schedules used for the NPRM, the effect of this bias occurred during the ages where each model year cohort typically scraps at the highest rates—9 to 15 years. These limitations led to lower estimates, which led commenters such as EDF to state "[g]iven that the Volpe Model VMT falls far short of confident measurements of gasoline consumption, these mileage accumulation schedules need to be increased."[1921] The agencies note that many of these data limitations were present in previous CAFE and CO_2 analyses.[1922]

Several commenters noted the agencies' reliance on cross-sectional data, and urged the use of panel data instead to develop mileage accumulation schedules. For example, API argued that cross-sectional data cannot accurately capture mileage accrual and suggested "the agencies re-consider the use of the [Polk] data for developing revised mileage accumulation schedules unless the data can capture mileage accumulation rates versus age on an individual-vehicle basis."[1923] The NPRM discussed the possible use of panel data in the future and the benefits that doing so could provide.[1924]

In response to these comments, the agencies created new mileage accumulation schedules based on panel data for this final rule. Unlike cross-sectional data, panel data includes a temporal element, which resolves the limitations imposed by cross-sectional data. The data source used for the final rule contains sequential readings of individual vehicles over time, and the vehicles are tracked at the VIN level. Polk accumulates readings about individual vehicles through state inspection programs, title changes, and maintenance events, among other sources. The Polk data includes observations of a specific vehicle's odometer readings over the course of many years, capturing the accumulated lifetime mileage at multiple ages. By using the observation date and accumulated miles (represented by the odometer reading), the agencies can compute the rate of driving (miles per year, or month) between observations for each vehicle. This is a superior method to assuming that the rate of accumulation, over all ages, is simply the ratio of odometer to age, as commenters noted. In particular, calculating the rates of mileage accumulation using successive observations of the same vehicle explicitly resolves the attrition bias and matches the approach to estimating driving rates with panel data in other studies.[1925]

The panel dataset has another advantage over other sources: because it tracks individual vehicles over time, the agencies have more precise information about each vehicle's useful age. In previous analyses, the agencies were forced to assume that "age" was simply equal to the calendar year minus the model year in which the vehicle was produced. For example, a MY2010

Azevedo (2015), "Heterogeneity in the Response to Gasoline Prices: Evidence from Pennsylvania and Implications for the Rebound Effect, Energy Economics," Volume 52, Supplement 1, 2015, Pages S41-S52, ISSN 0140-9883, available at https://doi.org/10.1016/j.eneco.2015.08.011.

vehicle was assumed to be five years old in 2015. This created, as API stated, a "discontinuity in the values between year 1 and year 2" within the schedules.[1926] It is common for vehicles produced in a given model year to be sold and registered over the course of multiple calendar years. Thus, a MY2010 vehicle assumed to be five years old in 2015, could have been registered for the first time in CY2012 and might have a real driving age of three years, rather than five, simply because it sat on a dealership lot for a couple of years before being purchased. The Polk data allows us to identify the first registration date of each vehicle in the sample and compute its true driving age at each point in time. This not only improves the precision of the mileage accumulation rate in the first year, but in subsequent years as well. The odometer data used in the NPRM had another limitation: odometer readings were grouped into cohorts by nameplate, for which only distributional information was available. It was necessary to use the mean odometer reading for each cohort at each age, but in cases where the distribution was skewed, the mean could be misleading. Making the same assumption about registration date, as each cohort contained information about the average registration date, further compounded the potential for distortion.

To the extent that commenters objected to the NPRM's use of Polk data on the basis of it being proprietary, the agencies note that using proprietary data is common in rulemakings, and, specifically, Polk data has been used for CAFE and CO_2 analyses on multiple occasions previously. For the 2016 final medium- and heavy-duty rule and Draft TAR, the agencies used Polk odometer data to develop the vehicle mileage accumulation schedules.[1927] Further, the specific data set was cited and is available for acquisition through Polk.

Recently, the 2017 National Household Travel Survey has become available as a possible data source to develop mileage accumulation schedules. While attractive from the standpoint of transparency, it suffers from the same flaws as data sources used to develop previous schedules. In particular, it represents a cross section of odometer readings at a single point in time, requiring the assumption that the rate of usage is simply reported odometer divided by vehicle /age, or an extrapolation of respondents' daily travel behavior into representative annual schedules, which commenters suggested was a poor assumption. Additionally, all of the odometers in the newest NHTS are self-reported, leading to questionable reliability of the individual data points (and notably round numbers in many cases). Finally, the NHTS is intended to be a representative sample of *households*, but not a representative sample of *vehicles*. Research has found that creating a *representative* sample of households can represent a significant challenge, as past iterations of the NHTS have systematically oversampled high income households. The nature of the sample also explicitly excludes vehicles used for commercial purposes, which nonetheless compose a meaningful portion of the new vehicle market, accumulate miles of travel, and consume fuel. The data set on which the mileage accumulation schedule used for this final rule is based contains at least two readings (and frequently several) for over 70 percent of the registered light duty vehicle population in 2016.

(ii) Methodology

The data used to construct the schedules initially included between two and fifty odometer readings from each of over 251 million unique vehicles. While most of the readings had plausible reading dates, odometer counts, and implied usage rates, some of the readings appeared unrealistic and received additional scrutiny. The agencies used a set of criteria to identify and remove readings that were likely record errors. For example, odometer readings predating the commercial release of the vehicle, showing negative VMT accumulation over time, or taken too closely together to provide meaningful insight into annual vehicle usage were removed from the analysis.[1928] Such sanitization of real datasets is typically necessary, and each step in the process was recorded and described in conformity with standard econometric practice.[1929]

Similar to the NPRM, the remaining readings were sorted into five categories: cars, SUV's/vans, pickups, MDHD pickups/vans, and chassis. The car, SUVs/vans and pickup categories match the definitions used to build the VMT schedules used in the NPRM, as well as those used to build the scrappage model. Table VI-211 shows the number of VINs, reading pairs, and average readings per VIN by body style.

Table VI-211 – Summary of Polk/IHS VMT VIN and Reading Data by Body Style

Body Style	**Number of VIN's Included**	**Number of Reading Pairs**	**Mean Readings per VIN**
Car	92,016,334	287,512,165	4.1
SUVs/vans	66,857,117	212,656,710	4.2
Pickups	29,926,984	83,208,986	3.8
MDHD pickups/vans*	10,515,168	27,418,353	3.6
Chassis*	486,471	1,186,653	3.4
Total	199,802,074	611,982,867	4.1

*Not used in this final rule analysis, in part in response to comments.

Once the dataset was cleaned, the agencies created a sample of one million reading pairs, where each pair represented an initial odometer/date reading and a subsequent odometer/date reading from the same vehicle. Analysis of the entire dataset was too computationally demanding and statistically unnecessary. Two conditions were created for sampling. The first controlled for Polk's censoring in the odometer readings recorded in the dataset (described below), and the second ensured the usage data was not biased by survival and that it represented usage rates over a relatively short period of time compatible with the beginning of the FRM analysis. Further analysis suggests that shorter periods between readings is still correlated with

[1928] Refer to Section VI.D.1.(5).(b) of the FRIA for a full accounting of the process used to clean the Polk odometer data.
[1929] *See, e.g.*, Osborne, Jason W., Best Practices in Data Cleaning, SAGE Publications, Inc, January 2012.

higher usage rates so that further filtering of the data sample was considered in the regression analysis. Once these filters were applied, the agencies considered several polynomial fits to the average odometer readings. These fits inform the final usage rates by age and body style used in this FRM analysis. The details are further described below.

One element of the usage data (mentioned above as the first condition control) required the agencies to filter the dataset. The odometer readings recorded are censored at 250k miles.[1930] For this reason, the agencies exclude readings recorded exactly as 250k miles. The censoring could bias estimates of usage rates if odometer readings and future usage rates are correlated, which they likely are. While the agencies hope to reconcile this limitation of the dataset in future work, the benefits of observing actual usage data through 30 years (rather than average odometer readings by model through 15 years) far outweigh the limitation. Still, the agencies filtered out these censored data points, since the actual odometer readings for such vehicles are likely higher than reported.

The Polk dataset is conditional on survival so that it represents the usage of vehicles on the road at the time of the sample (the end of the first quarter of 2017). In this way, it captures the actual observed usage rates of vehicles surviving to their current age in the dataset. An issue with this is that all readings of a vehicle are included in the sample. If usage rates from earlier ages and survival are correlated, which they likely are, then including the readings for a 30-year-old vehicle when it was 10 years old will bias the estimated usage rates of 10-year-old vehicles downward because vehicles that survive to advanced ages tend to be used less than vehicles that are retired at earlier ages for the same model year. As noted above, the NHTS data used in the NPRM suffered from the same problem. To mitigate this issue, the agencies applied a second filter when sampling the data set: the agencies only included readings where the reading date of the second reading in the pair is January 2015 or later. This reduces the potential bias from the joint probability of usage and survival to only those vehicles scrapped between January 2015 and the first quarter of 2017. This balances losing information for older, less represented ages by excluding too much data on these vehicles and severely biasing the estimates of usage by age.

For estimates within the CAFE model the average usage is the relevant measure. Table VI-212 shows the average usage rates for cars by age as well as linear, quadratic, and cubic polynomial fits on these points.[1931] The average usage rates follow a relatively smooth pattern, but appear to decline at an accelerating rate for the oldest ages. The linear equation captures this trend for older vehicles, but underestimates early ages. The quadratic fit shows a diminishing decrease in the usage of older vehicles which may overestimate their use. The cubic fit captures

[1930] Polk codes any vehicle whose odometer exceeds 250K miles as 250K miles exactly, regardless of the actual odometer reading.

[1931] In general, the objective of a polynomial regression is to capture the nonlinear relationship between two variables. While the fit produces a nonlinear curve, it is linear in the coefficients. Choosing the lowest degree of the polynomial function that captures the inflection points in the data preserved degrees of freedom and ensures that applying the polynomial function to observations outside the range of data (as done here for ages beyond 30) is well behaved.

the early age usage trends and the accelerating decrease in the usage of older ages. For this reason, the agencies used the cubic curve as the basis for the new VMT schedules by age.

Table VI-213 shows the observed and predicted average usage rates by age for SUVs/vans. All the polynomial fits predict the observed average usage rates reasonably well. However, the linear fit under predicts the usage of the oldest vehicles, and the cubic fit predicts higher usage rates for vehicle ages beyond age 30. The quadratic fit predicts reasonable usage rates for all observed and out-of-sample ages through age 40. For this reason, the quadratic fit was used as the basis for the SUV mileage schedule.

Table VI-213 – SUV/Van Averages and Predictions from Polynomial Fits by Age

Table VI-214 shows the observed and predicted average usage rates for pickups by age. The observed rates initially decline at an increasing rate, the decline diminishes and appears to accelerate again for the oldest ages. The linear fit underestimates the usage rates for the youngest and oldest ages and overestimates middle-aged vehicles. The quadratic fit reasonably predicts the observed average usage rates but predicts an increase in usage rates for the oldest ages out of the observed sample. The cubic fit reasonably predicts the observed averages and appears to capture the diminishing decline of usage for the oldest ages observed in the in-sample averages. For this reason, the agencies used the cubic fit as the basis for the pickup VMT schedules.

Table VI-214 – Pickup Averages and Predictions from Polynomial Fits by Age

As in the NPRM, the current schedule differs by body-style to represent different usage profiles that the agencies observed in the data. While more stratification is possible, it is unlikely to provide much additional value. Table VI-215 shows the annual miles driven at each age for passenger cars, SUVs (and CUVs and minivans), and pickup trucks at each age of their useful life, conditional upon surviving to that age.

Table VI-215 – Comparison of NPRM and FR mileage accumulation schedules

Age	Cars – NPRM	Cars – FR	SUV – NPRM	SUV – FR	Pickup – NPRM	Pickup – FR

(b) Benchmarking Total VMT

In order to assess the fuel consumption and environmental impacts of regulatory alternatives, it is desirable to have a representation of aggregate travel and fuel consumption that is both reasonable and internally consistent. Some commenters suggested that the aggregate totals presented in the NPRM deviated from other published estimates, and argued that the entire analysis was therefore an unreliable source of information for decision-makers to consider. For example, EDF stated, “the NHTSA model ‘projects’ aggregate, nationwide VMT levels for 2016 and 2017 that are about 20 percent lower than formal government estimates by EIA and

FHWA."[1932] EDF further stated, "[b]etween 2017 and 2025, fleetwide VMT grows by 3.1% per year in the Volpe Model, while it only grows 0.5% per year in the 2018 Annual Energy Outlook."[1933] EDF also suggested, "[o]ne obvious way to assess the accuracy of the schedules is to compare the projections of the Volpe Model of total fleetwide fuel consumption in a recent calendar year with actual gasoline sales."[1934]

The Federal Highway Administration (FHWA) publishes annual VMT estimates for the light-duty vehicle fleet, the most recent of which is calendar year 2017. The NPRM estimate of total light-duty VMT was 2.22 trillion miles in calendar year 2016. The FHWA estimate for light duty VMT in 2016 was 2.85 trillion miles.[1935] While the definitions of light-duty are not identical in the two cases (where FHWA excludes trucks with 10,000 lbs. GVW, the agencies' analysis excludes trucks with GVW greater than 8,500 lbs. from its light duty definition), that definitional discrepancy is not significant enough to account for the difference in the total VMT. While some commenters suggested that the agencies compare simulated fuel consumption to published estimates from EIA to determine the validity of our VMT assumptions, such a comparison requires accurate assumptions about the true on-road fuel efficiency of registered vehicles over forty model years in addition to their annual usage. Comparing simulated VMT directly to FHWA measurements requires fewer assumptions and is a more meaningful comparison.

Substituting the updated mileage accumulation schedules for the NPRM schedules, and using the calendar year 2016 fleet from the NPRM, produces an estimate of total light duty VMT in 2016 that is about 2.85 trillion miles—nearly identical to the FHWA estimate for 2016, despite the use of different estimation methods and data sources. FHWA's estimate of total light-duty VMT in 2017 is 2.88 trillion miles,[1936] while the estimate produced by the simple product of the mileage accumulation schedule on the estimated on-road fleet is 2.94 trillion miles, a difference of about two percent. While not as close as the estimate for calendar year 2016, the discrepancy is still small considering that the estimates are obtained through entirely different methods. One important source of discrepancy with FHWA's 2017 VMT estimate is the fact that the CAFE model simulation assumes all of the vehicles produced in a given model year are driven for the entire calendar year matching the vintage[1937]. This means, for calendar

[1936] *Id*.
[1937] The CAFE model uses an annual timestep, meaning that each time period represents one year. Because calendar years are (obviously) years, and all of the other inputs (discounting and inflation, macroeconomic variables, fuel prices, VMT, etc.) represent annual values, the timestep in the CAFE model is a calendar year. However, model years start prior to the calendar year for which they are named, and new model year sales continue (albeit only slightly) after their calendar year ends. In order to account for model year sales on their true timing relative to calendar years, the model would need to be restructured to use a quarterly timestep. While this would improve the fidelity between calendar year and model year for sales, obtaining quarterly projections of nearly every other

year 2017, the initial year of the simulation used to support this rule, MY2017 vehicles are assumed to have been both registered and driven for the entirety of CY2017. As a result, it naturally overestimates the true VMT for calendar year 2017. The analysis accounts for this discrepancy by adjusting calendar 2017 total VMT downward by one percent, and the discrepancy in total VMT caused by conflating model years and calendar years dissipates over time.

While the agencies have established that the years for which they have data are sufficiently similar to published VMT estimates, the question of projection still remains. FHWA, in its forecasts of VMT (Spring 2019),[1938] forecasts a compound annual growth rate of 0.8 percent for light-duty vehicles between 2017 and 2047 in its baseline economic outlook. However, that projection uses a different set of macroeconomic conditions and fleet assumptions than this analysis. To compare CAFE model simulations of total VMT to the FHWA projections, the agencies ran the FHWA model with a comparable set of assumptions to the greatest extent possible.[1939][1940] Using similar economic growth assumptions, our reference case total light-duty VMT grows at a compound rate of 0.63 percent per year between 2017 and 2050. Using comparable assumptions in the FHWA model produce an annual growth rate of 0.66 percent. Again, these differences are remarkably low for models created with different methods, and lead to trivial variances, for the purposes of our analysis, in total VMT. The relevant annual projections for the baseline scenario appear in Table VI-216.

Table VI-216 – Comparing projections of total light-duty VMT

Year	**FHWA Projection (Trillion VMT)**	**CAFE Model Projection (Trillion VMT)**	**Percent Difference**
2017	2.88	2.91	1.1
2018	2.97	2.98	0.5
2019	3.05	3.05	0.1
2020	3.10	3.10	0.0
2021	3.13	3.13	0.1
2022	3.17	3.18	0.2
2023	3.21	3.22	0.3
2024	3.25	3.26	0.4

variable in the analysis would be complicated (if not impossible). For this reason, the model conflates "model year" and "calendar year" for the analysis, even though it is a simplification.

2046	3.57	3.55	(0.5)
2047	3.56	3.54	(0.6)
2048	3.56	3.54	(0.7)
2049	3.56	3.53	(0.8)
2050	3.56	3.53	(1.0)

(c) Preserving Total VMT Across Regulatory Alternatives

In the NPRM, the combined effect of the sales and scrappage responses created small percentage differences in total VMT across the range of regulatory alternatives.[1941] However, as the Environmental Group Coalition noted, even a 0.4 percent difference can result in "692 billion

[1941] The agencies explained in the NPRM that some amount of this difference was due to the rebound effect, and that "non-rebound" VMT between alternatives differed by as much as 0.4 percent. *See* 83 FR at 43099 (Aug. 24, 2018).

additional VMT under the CAFE standards and 894 billion under the CO_2 program."[1942] Since VMT is related to many of the costs and benefits of the program, VMT of this magnitude can have meaningful impacts on the incremental net benefit analysis. This point was made by a number of commenters who were concerned about the magnitude and direction of differences in VMT between regulatory alternatives (IPI, EDF, CBD, CARB, EPA's Science Advisory Board).[1943]

More generally, commenters argued that non-rebound VMT should be held constant across regulatory alternatives, regardless of the number of new vehicles sold and registered vehicles scrapped. For example, CBD commented that the "total number of VMT should be determined based on demand for travel, not arbitrarily driven by fleet size." CARB added that fleet size can change across the alternatives "as long as the VMT schedules are adjusted to account for overall travel activity that is distributed over a larger number of vehicles." [1944] NCAT, Global, Auto Alliance, EDF, IPI, and Honda made similar arguments.[1945]

While commenters generally provided few specific recommendations about the level to which VMT should be constrained among alternatives, several of them argued that VMT projections would benefit from consideration of travel demand modeling. UCS, CBD, NCAT, and others suggested that the overall level of light-duty VMT in a given year should reflect the broader economic context in which travel occurs.[1946] For example, Honda stated, "[i]ncreasing VMT is closely associated with increased economic activity."[1947]

The agencies agree that the total demand for VMT should not vary excessively across alternatives and stated as much in the NPRM.[1948] That said, it is reasonable to assume that fleets with differing age distributions and inherent cost of operation will have slightly different annual VMT, absent VMT associated with rebound miles; however, the difference could conceivably be small. To address these comments and to take an intentionally conservative approach, the agencies decided to constrain "non-rebound" VMT (defined more explicitly below) to be identical across regulatory alternatives in this analysis using the FHWA VMT demand model to determine the constraint; therefore, the only difference in total VMT between regulatory alternatives is the rebound miles attributable to differences in fuel economy resulting from the regulatory alternatives. Nevertheless, as explained in the NPRM and revealed in the extensive quantitative results published with the NPRM, setting aside the rebound effect, aggregate VMT as estimated in the NPRM was roughly constant across alternatives. Although differences may have appeared large in absolute terms, especially when aggregated across many calendar years

and ignoring the underlying annual total quantities, the differences were nevertheless very small in relative terms—small enough to be well within the range of measurement or estimation error for virtually any of the other inputs to, or outputs of, the agencies' analysis. It is unclear whether a 0.4 percent change in highway travel can be measured with any degree of confidence.

To constrain non-rebound VMT, the agencies needed to create a definition of non-rebound VMT and a method for calculating it. The agencies used the FHWA VMT forecasting model to produce a forecast of non-rebound VMT, to which total non-rebound VMT in every regulatory alternative is constrained in each year, regardless of the fleet size or distribution of ages in the fleet. In calendar years where total non-rebound VMT determined by the size of the fleet and assumed usage of each vehicle is lower than the constraint produced from the FHWA model, VMT is added to that total and allocated across vehicles to match the non-rebound forecast (preserving the constraint). These additional miles are then carried throughout the analysis as vehicles accrue costs and benefits. Because non-rebound VMT is being held constant for the FRM analysis across the set of regulatory alternatives in each calendar year, the only difference in VMT among the alternatives in any calendar year results from differences in fuel economy improvement relative to MY2016 that occur as a result of the standards. Finally, in Section VII, the agencies calculate the changes in total VMT attributable to fuel economy, otherwise known as the rebound VMT.

(i) Defining Non-rebound VMT

In order to constrain non-rebound VMT, it is first necessary to define "non-rebound VMT" more precisely. The NPRM defined the rebound effect as the overall elasticity of travel with respect to changes in the cost per mile (CPM). CPM has two components. The first component of CPM is fuel prices—the agencies expect vehicles to be driven less if fuel prices go up, all else equal. The second component of CPM is fuel economy. Therefore, the NPRM defined the percentage change in CPM, for a given scenario, model year, and calendar year, as:[1949]

Equation VI-7 – Full change in cost-per-mile of travel

$$\%\Delta CPM_{SN,MY,CY} = \frac{\left(\frac{FP_{CY}}{FE_{SN,MY}} - \frac{FP_{2016}}{FE_{REF}}\right)}{\frac{FP_{2016}}{FE_{REF}}}$$

Where *FP* is fuel price, *FE* is fuel economy, and *REF* refers to the reference FE value of a given age (in particular, $FE_{2016-(CY-MY)}$, which is the FE of the MY cohort that was age CY – MY in CY 2016). In the equation above, $FE_{SN,MY,CY}$ refers to the observed fuel economy of the MY cohort (typically applied at the vehicle level) for a given scenario (SN) in calendar year CY.

[1949] *See* 83 FR at 43091 (Aug. 24, 2018).

The CAFE model uses one value, the value specified as the rebound effect, to measure CPM elasticity. Naturally, the CAFE model produces the same magnitude of change in travel for equivalent changes in fuel prices and fuel economy. Constructing such a projection of future VMT (from 2017 to 2050) that sets aside the rebound effect required constructing inputs that were consistent with that perspective. In particular, it was necessary to separate the price response associated with the change in fuel prices relative to the year on which the agencies based the mileage accumulation schedule (end of CY2016), and the change in VMT associated with only the improvements in fuel economy, relative to MY2016, that occur for future model years at the forecasted fuel price.

As vehicles age, the agencies expect their VMT to decrease in the presence of a non-zero rebound effect if rising fuel prices over time increase the per-mile cost of travel, and the rebound effect represents the degree to which their travel is reduced for a percentage change increase in operating cost. It is intuitive that, as the cost of fuel rises over time, a vehicle with a fixed fuel economy would be driven less if gasoline costs $3.50/gallon than it would be if gasoline costs $2.50/gallon. Such a response is also consistent with economic principles (and literature),[1950] and so it is included in the "non-rebound" VMT that the agencies constrain across alternatives in each calendar year.

Similarly, the annual mileage accumulation of cohorts in the inherited fleet is clearly affected by fuel price, but also by evolution. Setting aside any fuel economy improvements in vehicles sold and entering the on-road fleet between 2017 and 2050, the average fuel economy of each age cohort is going to improve over that period. The travel behavior of the on-road fleet was last observed through calendar year 2016 in the Polk data (discussed in (a)(ii)), when a 20-year-old car was part of the model year 1997 cohort, and had an average fuel economy of 23.4 MPG. However, the fleet continually turns over. In 2035, the 20-year-old car will be a member of the model year 2016 cohort, and have an average fuel economy of 29.2 MPG (assumed to be the average fuel economy of MY2016 vehicles when they were new).[1951] If fuel prices persist at 2016 levels (in real dollars), then that 25 percent improvement in fuel economy would reduce the cost per mile of travel for 20-year-old vehicles relative to the observed values in calendar year 2016, and lead to an increase in travel demand for vehicles of that age. Importantly, this transition to more efficient age cohorts occurs in all of the regulatory alternatives. Considering only the fuel economy levels of vehicles that exist prior to the first year of simulation (2017), a secular improvement in the fuel economy of the on-road fleet would occur with no further improvements in fuel economy from new vehicles in model years 2017 to 2050. As the fleet

---

[1950] *See, e.g.,*Goodwin, P., J. Dargay, and M. Hanly. Elasticities of road traffic and fuel consumption with respect to price and income: a review. Transport Reviews, 24:275-292, 2004.

[1951] In practice, vehicles will scrap at different rates over time, even within a body-style. Some nameplates and manufacturers have reputations for longevity and individual vehicle models with different fuel economies may seem like better candidates for repairs under particular fuel price scenarios. In light of this, the fuel economy for a given body-style will likely not continue to be the sales-weighted average fuel economy when the cohort was new, even without accounting for degradation and changes to the on-road gap over time. The agencies make this assumption here out of necessity.

turns over, its fuel efficiency will gradually resemble that of the model year 2016 cohort, up to the point at which each age cohort is as efficient as the model year 2016 cohort.[1952]

The notion of "non-rebound" VMT is a construct necessary to support this regulatory analysis by controlling for VMT attributable to reasons other than rebound driving, but present only in theory. Using our symmetrical definition of rebound to represent the expected response to changes in CPM, regardless of whether those changes occur as a result of changes in fuel price or fuel economy, it is well established that demand for VMT responds to the cost of travel. To isolate the change in VMT for which the regulatory alternatives are responsible, the agencies have also included the VMT attributable to secular fleet turnover (through MY2016) in the total "non-rebound" VMT projection. In particular, this means that the conventional rebound definition used in previous analyses, is replaced in the "non-rebound" VMT estimation with a more limited definition:

Equation VI-8 – Fuel price and secular improvement component of elasticity

$$\%\Delta \boldsymbol{NonRbdCPM}_{\boldsymbol{MY,CY}} = \frac{\left(\frac{\boldsymbol{FP_{CY}}}{\boldsymbol{FE_{MIN(2016,MY)}}} - \frac{\boldsymbol{FP_{2016}}}{\boldsymbol{FE_{REF}}}\right)}{\frac{\boldsymbol{FP_{2016}}}{\boldsymbol{FE_{REF}}}}$$

Where *FP* is fuel price, *FE* is fuel economy, and *REF* refers to the reference FE value of a given age (in particular, $FE_{REF} = FE_{2016 - (CY - MY)}$, which is the average FE of the MY cohort that was age (CY – MY) in CY 2016). In Equation VI-8, $FE_{MIN(2016,MY)}$ refers to the observed fuel economy of the model year being evaluated up to and including the 2016MY cohort. This construction explicitly accounts for the improvement in fuel economy between MY2016 and all the historical ages (through MY1977) with respect to the change in (real) fuel price relative to calendar year 2016. Thus, the VMT associated with the rebound effect in this analysis only accounts for changes to CPM that result from the amount of fuel economy improvement that occurs relative to MY2016. The full elasticity definition (in Equation VI-7) differs from that in Equation VI-8 in only one way; the fuel economy in the denominator of the first term is the fuel economy of the model year being evaluated, rather than being the minimum of the actual model year and model year 2016.

Combining this demand elasticity with the endogenously estimated vehicle population and the mileage accumulation schedule provides an initial estimate of non-rebound VMT, as in Equation VI-9.

[1952] Vehicles scrap at different rates over time, and there are important differences by body style for both scrappage rates and mileage accumulation. This discussion is intended to provide intuition, without all of the computational nuance that exists in the model's implementation.

Equation VI-9 – Unadjusted total non-rebound VMT in a calendar year

$$NonReboundVMT = \sum_{A}^{Ages} \sum_{S}^{Styles} VMT_{A,S} \cdot (1 + \%\Delta NonRbdCPM_{MY,CY} \cdot \varepsilon) \cdot Population_{CY.A,S}$$

In Equation VI-9, *VMT* represents the non-rebound mileage accumulation schedule (by age, *A*, and body style, *S*), *Population* is the on-road vehicle population simulated by the CAFE Model (in calendar year *CY*, for each age, *A*, and body style, *S*), ε is the elasticity of demand for travel (the rebound effect, assumed to be -0.2 in this analysis).

However, there are factors beyond the CPM that affect light-duty demand for VMT. The FHWA VMT forecasting model includes additional parameters that can mitigate or increase the magnitude of the effect of fuel price changes on demand for VMT. In particular, the model accounts for changes to per-capita personal disposable income (and U.S. population) over time. This means that even if fuel prices are increasing over the study period (as they are in the central case), and fleetwide fuel economy improves only through fleet turnover (as it does in the simulated "non-rebound" case), total demand for VMT can still grow as a result of increases in these other relevant factors. Not only does the forecast of non-rebound VMT continue to grow in the non-rebound case, it does so at a faster rate than Equation VI-9 produces. Thus, in order to preserve non-rebound VMT in a way that represents expected VMT demand, the agencies must constrain non-rebound VMT in each alternative to match the forecast produced by the FHWA model using the fuel price series from the central analysis, AEO2019 Reference case assumptions for per-capita personal disposable income, and fleetwide fuel economy values produced by simulating the effect of fleet turnover (only) in the CAFE model.[1953]

(ii) Constraining Non-rebound VMT

For this final rule, total 'non-rebound' VMT is calculated for each calendar year and reported in Section VI.D.1.b)(5)(d). In any future calendar year, "non-rebound" VMT is calculated as a product of the initial CY2017 total and a series of compound growth rates:

Equation VI-10 – Total non-rebound VMT constraint in each calendar year

$$\prod_{2017}^{CY} (1 + r_{CY}) \cdot TotalVMT_{2017}$$

Where *CY* is calendar year, *r* is the compound annual growth rate (unique to each CY), and *TotalVMT* is the calendar year total light-duty VMT estimated by the CAFE Model using the annual VMT for each body style and age in the mileage accumulation schedule (defined in Table VI-215), the population of each age/style cohort in CY2017, and the initial difference between operating costs in 2016 and 2017. The compound annual growth rates, r_{CY}, in Equation VI-10

[1953] Non_rebound_VMT_forecasting.xls in Docket No. NHTSA-2018-0067.

are derived from the inter-annual differences in the forecast of total non-rebound VMT that the agencies created using the FHWA model.

The agencies used the FHWA forecasting model to produce two distinct VMT forecasts (both of which appear in Table VI-217). The first of these is identical to the forecast of total VMT reported in Table VI-216, and represents the AEO2019 Reference case assumptions with the exception of average on-road fuel economy, which was simulated using the CAFE model to simulate new vehicle fuel economy, new vehicle sales, and vehicle retirement under the baseline standards. The forecast in the second column of Table VI-217 is identical to the first, except that the average on-road fuel economy accounts for only the effect of fleet turnover on fuel economy improvements (new vehicles are assumed to be only as fuel efficient as the MY2016 cohort, discussed above).

Table VI-217 – VMT projections (trillion miles)

Year	Total VMT (FHWA model)	Non-rebound VMT (FHWA model)	Non-rebound VMT constraint (CAFE Model)	Non-rebound VMT endogenous (CAFE Model)
2017	2.88	2.88	2.91	2.93
2018	2.97	2.97	2.97	2.91
2019	3.05	3.04	3.03	2.95
2020	3.10	3.09	3.07	2.95
2021	3.13	3.12	3.09	2.97
2022	3.17	3.16	3.12	3.00
2023	3.21	3.19	3.14	3.01

2037	3.52	3.39	3.29	3.05
2038	3.53	3.40	3.29	3.05
2039	3.54	3.40	3.29	3.04
2040	3.55	3.40	3.29	3.04

Year	Total VMT (FHWA model)	Non-rebound VMT (FHWA model)	Non-rebound VMT constraint (CAFE Model)	Non-rebound VMT endogenous (CAFE Model)
2041	3.55	3.40	3.29	3.03
2042	3.56	3.40	3.29	3.03
2043	3.56	3.39	3.29	3.02
2044	3.56	3.39	3.29	3.02
2045	3.57	3.39	3.29	3.01
2046	3.57	3.38	3.28	3.01
2047	3.56	3.38	3.28	3.00
2048	3.56	3.37	3.27	3.00
2049	3.56	3.37	3.27	2.99
2050	3.56	3.36	3.27	2.99

The third column is the non-rebound VMT constraint produced by the CAFE model, to which non-rebound VMT is constrained to in every regulatory alternative (under central analysis assumptions regarding fuel prices and economic growth). The non-rebound VMT constraint is produced endogenously by the model in each run based on the estimated VMT for calendar year 2017 and a series of growth rates intended to reproduce the general growth trend in light-duty VMT under the set of "non-rebound" assumptions in the FHWA model (Equation VI-10 –).[1954] It differs from the "non-rebound" forecast produced by the FHWA model by one to three percent in any year. This adjustment was both an attempt to match the FHWA model's projection of total VMT (including rebound) in the baseline, and an acknowledgment that differing levels of modeling resolution and construction are likely to produce slightly different projections. In general, the one to three percent difference in non-rebound VMT is within the range of projections based on the confidence intervals of the coefficients that define the FHWA forecasting model.

The fourth column in Table VI-217 represents the unadjusted "non-rebound" VMT produced by the CAFE Model using Equation VI-9. The reader will observe that in every calendar year, this total is lower than the non-rebound VMT constraint. This occurs because the projected fuel prices in the central analysis increase much faster than the fleetwide fuel economy (in the non-rebound case). This increases CPM and, as a consequence, reduces demand for VMT based on the price elasticity of demand for travel (rebound effect). However, the FHWA model accounts for additional variables that recognize the economic context in which this fuel price projection occurs. In particular, the model accounts for changes in the U.S. (human) population and changes to personal disposable income over the same period. These factors act to attenuate

[1954] This ensures internal consistency with the set of assumptions provided by the user, but can lead to differences between the non-rebound VMT constraint in the central analysis and one that is generated under a different set of assumptions (as in the sensitivity analysis, for example).

the demand response to rising fuel prices, producing a rising demand for VMT even as the CPM rises for several years.

In order to constrain non-rebound VMT to be identical in each year across regulatory alternatives, it is necessary to add VMT to the unadjusted total, endogenously calculated by the CAFE Model in each calendar year. These additional miles, denoted Δmiles for this discussion, represent the simple difference between the annual VMT constraint (column 3 of Table VI-217) and the unadjusted VMT defined in Equation VI-9 (above) in each calendar year.

Equation VI-11 - Difference between VMT constraint and unadjusted non-rebound VMT

$$\Delta Miles_{CY} = VMTConstraint_{CY} - NonReboundVMT_{CY}$$

Because each regulatory scenario produces a unique on-road fleet (in terms of the number of vehicles, the distribution of ages among them, and the resulting distribution of fuel economies), the total unadjusted VMT in each calendar year (given by Equation VI-9 –) will be unique to each regulatory scenario. As a corollary, $\Delta miles_{cy}$ will also be unique to each regulatory scenario. By distributing $\Delta miles_{cy}$ across the vehicle fleet in each calendar year, the CAFE Model scales up the unadjusted non-rebound VMT to equal the non-rebound VMT constraint in each calendar year, for each regulatory alternative. While there are a number of ways to reallocate $\Delta miles_{cy}$ across the on-road fleet in order to match the non-rebound VMT constraint, the fact that unadjusted VMT is always lower suggests an obvious approach.

The primary goal of reallocation is to adjust total non-rebound VMT so that it is identically equal to the VMT constraint in every calendar year for each regulatory alternative, while conserving the general trends of the mileage accumulation schedule—which represents a good estimate of observed usage at the start of the simulation. In particular, the reallocation approach should preserve the basic ideas that annual mileage decreases with vehicle age because newer (and more efficient) vehicles are more likely to be driven additional miles than their older counterparts, and mileage accumulation varies by body style. To accomplish the reallocation, the CAFE Model computes a ratio that varies by body style, calendar year, and regulatory alternative. The ratio captures the share of additional VMT that can be absorbed by the registered vehicle population of each body style based on their relative representation in the fleet, so that per-vehicle totals across ages remain sensible (even if the distribution of body styles should change over time as the new vehicle market evolves). Then this quantity is further scaled by the total VMT for a given body style in the calendar year for which Δmiles has been computed. The resulting ratio is then used to scale the unadjusted miles from Equation VI-9, so that the new sum of annual (non-rebound) VMT across all of the vehicles in the on-road fleet equals the constraint. For a single calendar year, *CY*, and a single body style, *S*, the scaling ratio, *R*, is computed as:

Equation VI-12 – Calculating the scaling factor to reallocate non-rebound VMT

$$R_{S,CY} = \frac{\Delta Miles_{CY} \cdot \frac{\sum_0^{39} Population_{S,A}}{\sum_S^{Styles} \sum_0^{39} Population_{S,A}}}{NonReboundVMT_{CY}}$$

In Equation VI-12, *Population*, refers to the on-road vehicle population for a given age and body style (summed over the full range of ages in the simulation, where vehicles are modeled to survive for, at most, forty years). The fraction in the numerator calculates the fleet composition by body type.[1955] As long as the unadjusted non-rebound VMT produced by the CAFE Model is smaller than the VMT constraint for all years and regulatory alternatives (and it is), this scaling ratio allows the CAFE Model to add miles to the annual total in a way that preserves the basic ideas of the mileage accumulation schedule and achieves equality with the constraint. In particular, the total *adjusted* non-rebound VMT is then calculated as:

Equation VI-13 - Total adjusted VMT that preserves non-rebound VMT constraint

$$AdjNonRbdVMT = \sum_{A}^{Ages} \sum_{S}^{Styles} NonReboundVMT_{CY.A,S} * \left(1 + R_{S,CY}\right)$$

To make each alternative match the VMT constraint, Equation VI-13 allocates miles (in this case, adds) to each vehicle in a calendar year by multiplying the product of the mileage accumulation schedule (for that style vehicle, at that age), the %ΔNrbdCPM (described in Equation VI-8), and the elasticity (the rebound effect of -0.2) with the appropriate scaling ratio (defined in Equation VI-12). The "Allocated Miles" in Table VI-211 are the result of this calculation for a passenger car in CY2020.

Unlike some of the accounting, which focuses on the impacts to a model year cohort of vehicles over the course of its useful life, the rebound constraint and reallocation are calendar year concepts. The constraint represents demand for VMT absent "rebound miles" (defined more explicitly above) in a specific calendar year. Thus, this reallocation occurs in every calendar year, and a vehicle of a model year cohort will likely experience many of these reallocation events during its simulated useful life. The resulting survival weighted mileage accumulation is discussed in detail in the discussion of VMT Resulting From Simulation found in Section (d), but an example of the annual reallocation is provided here.

In the baseline alternative, the non-rebound VMT constraint in CY2020 is about 3.068T miles, but the endogenously computed "non-rebound" VMT is only 2.955T miles. This creates a difference, $\Delta miles_{2020}$, of 112.6B miles that must be added to the total unadjusted non-rebound VMT in calendar year 2020 and allocated across the on-road fleet in that year to preserve total non-rebound VMT. Over time, this discrepancy between the FHWA model's projection and the unadjusted total non-rebound VMT grows to about 230 billion miles. While the other classes operate identically, this example uses the reallocation that occurs to passenger cars to illustrate the mechanics of reallocation. Rising fuel prices depressing non-rebound VMT (relative to the

[1955] We also considered basing this ratio on each body style's share of total VMT in that calendar year. However, that approach has the potential to result in allocations that add (or remove) too many miles per vehicle, depending on the age distribution and size of each body style cohort. While that approach better preserves the age distribution of VMT within a style, capturing the differences in age distribution of the population in each scenario is an objective of the VMT accounting. In testing, the differences in approach were small (about 0.1 percent difference).

mileage schedule) over time is a general trend that emerges for all body styles, as shown for passenger cars in Table VI-218.

Table VI-218 – CY2020 passenger car VMT reallocation to preserve non-rebound constraint

Age	Model Year	Unadjusted Non-Rebound VMT	Allocated	Adjusted Non-Rebound VMT	Vehicle Mileage Accumulation Schedule (Table VI-214)

38	1982	2,629	104	2,733	2,629
39	1981	2,116	83	2,199	2,096

The number of miles added to each age vehicle is generally less than the difference between the unadjusted non-rebound VMT (for a given age) and the mileage schedule. Thus, adding the requisite miles to each age does not distort either the shape of the schedule with age, nor does it create annual usage estimates that are out of line with observed usage. The example shown here uses the baseline alternative to illustrate the reallocation of VMT in 2020, but this reallocation differs by alternative. In less stringent regulatory alternatives, new vehicles are less expensive; this increases new vehicle sales and accelerates the retirement of older vehicles (relative to the baseline). In those cases, the unadjusted non-rebound VMT is higher, Δmiles smaller, and corresponding allocation of Δmiles smaller—though still consistently positive.

Commenters encouraged us to use a demand model to avoid creating unrealistic VMT projections that failed to account for factors that exogenously influence total demand for VMT, which the agencies have done here.[1956] Had baseline case been used instead, regardless of whether it happens to be the most or least stringent alternative, as the non-rebound VMT constraint, both the non-rebound VMT and VMT with rebound would have differed meaningfully from both other government forecasts and from the projections produced by the demand models underlying those forecasts. By producing and enforcing a non-rebound constraint based on results from a travel demand model, the agencies ensure realism in the projections of total VMT under each regulatory alternative and ensure that the costs and benefits associated with rebound VMT result only from fuel economy improvements in the regulatory alternatives considered.

(d) VMT Resulting From Simulation

This section has already demonstrated that total VMT projections from the simulation are consistent with FHWA projections of total light duty VMT using the same set of economic assumptions. Lifetime mileage accumulation is now a function of the sales model, scrappage model, mileage accumulation schedules (described in Table VI-215), and the redistribution of

[1956] *See, e.g.*, NCAT, Comments, NHTSA-2018-0067-11969, at 31-32; Environmental Group Coalition, Appendix A, NHTSA-2018-0067-12000, at 175-76; UCS, Technical Appendix, NHTSA-2018-0067-12039, at 59; Honda, Supplemental Analysis, NHTSA-2018-0067-1211, at 4.

VMT across the age distribution of registered vehicles in each calendar year to preserve the non-rebound VMT constraint.

The definition of "non-rebound" VMT in this analysis determines the additional miles associated with secular fleet turnover and fuel price changes. Conversely, rebound miles measure the VMT difference due to fuel economy improvements relative to MY2016 (independent of changes in fuel price, or secular fleetwide fuel economy improvement resulting from the continued retirement of older vehicles and their replacement with newer ones). In order to calculate total VMT *with* rebound, the agencies apply the rebound elasticity to the full change in CPM and the initial VMT schedule, but apply the rebound elasticity to the incremental percentage change in CPM between the non-rebound and full CPM calculations to the miles applied to each vehicle during the reallocation step that ensured adjusted non-rebound VMT matched the non-rebound VMT constraint.

Equation VI-14 – Total VMT with rebound miles

$$\sum_{A}^{Ages}\sum_{S}^{Styles}\left(\boldsymbol{VMT_{A,S}}\cdot\left(\mathbf{1}+\%\boldsymbol{\Delta CPM_{MY,CY}}\cdot\boldsymbol{\varepsilon}\right)+\boldsymbol{\Delta Miles_{A,S,CY}}\cdot\left(\mathbf{1}+\left(\%\boldsymbol{\Delta CPM_{MY,CY}}-\%\boldsymbol{\Delta NonRbdCPM_{MY,CY}}\right)\cdot\boldsymbol{\varepsilon}\right)\right)\cdot\boldsymbol{Population_{CY,A,S}}$$

Where $VMT_{A,S}$ is the initial VMT schedule by age and body-style, %ΔNonReboundCPM and %ΔCPM are defined in Equation VI-8and Equation VI-7, respectively, and $\Delta Miles_{A,S,CY}$ is the per-vehicle miles added by the reallocation described in Equation VI-13. The additional miles that are added to each vehicle in the reallocation step ($\Delta Miles_{A,S,CY}$) are multiplied by the difference between the percentage changes in CPM (full and non-rebound, respectively) because the %ΔNonRbdCPM was used to derive the allocated miles and using the full CPM change to scale the allocated miles would count that change twice. Taking the difference avoids overestimating the total mileage in the presence of the rebound effect. The "rebound miles" will be the difference between Equation VI-14 and Equation VI-10 for each alternative. To the extent that regulatory scenarios produce comparable numbers of rebound miles in early calendar years, the impacts associated with those miles net out across the alternatives in the benefit cost analysis.

Table VI-219 displays the annual survival-weighted VMT at each age of a MY2025 vehicle, by regulatory class including and reallocation needed to preserve the VMT constraint and all rebound miles (using a 20 percent rebound effect).[1957]

[1957] Annual survival-weighted VMT is calculated by dividing the annual VMT of a MY cohort by the total population of the cohort purchased. As such, Table VI-218 and Table VI-219 report different types of values.

Table VI-219 – MY2025 lifetime VMT comparisons, by regulatory class

Age	Passenger Car, Final Rule	Passenger Car, NPRM	Passenger Car, 2012 Rule	Light Truck, Final Rule	Light Truck, NPRM	Light Truck, 2012 Rule

39	50	54	-	124	99	-
TOTAL	210,966	175,989	213,513	231,387	183,004	225,844

As earlier portions of this section have shown, the second decade of useful life now shows significantly higher utilization than the NPRM analysis for both passenger cars and light trucks. While the current lifetime accumulation is similar to the values produced in the 2012 final rule, those values were simulated to occur under fuel prices that were consistently 40 percent higher than the prices in this analysis (when adjusted for inflation).[1958] Under comparable prices, lifetime mileage accumulation would have been considerably higher.

(e) Which Vehicles are Doing the Driving?

Deciphering which vehicles are doing the driving is just as important as how many miles are being driven. Newer vehicles are generally safer, better for the environment, and provide a more enjoyable experience than older models—all of which are explained in the following sections. Therefore, any shift from older vehicles to newer vehicles creates a corresponding shift in benefits to society.

Figure VI-132 below shows the distribution of non-rebound miles driven by the vehicle fleet by age under the augural and final standards on the left, and the percent change in the share of non-rebound miles driven at each age from the augural to the final standards on the right. These shares are for calendar year 2026, which shows the largest percent change in the share of non-rebound miles driven at any given age between the regulatory alternatives. The largest change in the share of miles driven at any age occurs for vehicles between the ages of 15-30, where the percent change in the share is between -1.0 and -1.6 percent. There is also an increase in the share of miles driven for ages 4 through 15, with the largest increase of 0.7 percent occurring for vehicles age 12. Under the final standards, more new vehicles are sold and used vehicles are scrapped faster—this shifts the distribution of non-rebound miles away from older vehicles and towards newer ones. Vehicles aged 3 through 14, in calendar year 2036, are model years 2022 through 2033, the model years whose sales increase under less stringent model year 2021 through 2026 standards. Interestingly, from the right graph, the newest vehicles in the fleet in 2036 drive a smaller share of non-rebound VMT under the final rule. This is attributable to the fact that the fleet has become saturated with new vehicles under the final standards due to increased sales in earlier calendar years prompted by lower vehicle prices. The sheer volume of

[1958] The 2012 final rule also assumed a 10 percent rebound effect, which would have further affected lifetime mileage accumulation.

vehicles sold in those earlier years causes MY2022-MY2026 to retain a larger share of VMT, and thus creating the discrepancy between new vehicles in calendar year 2036.

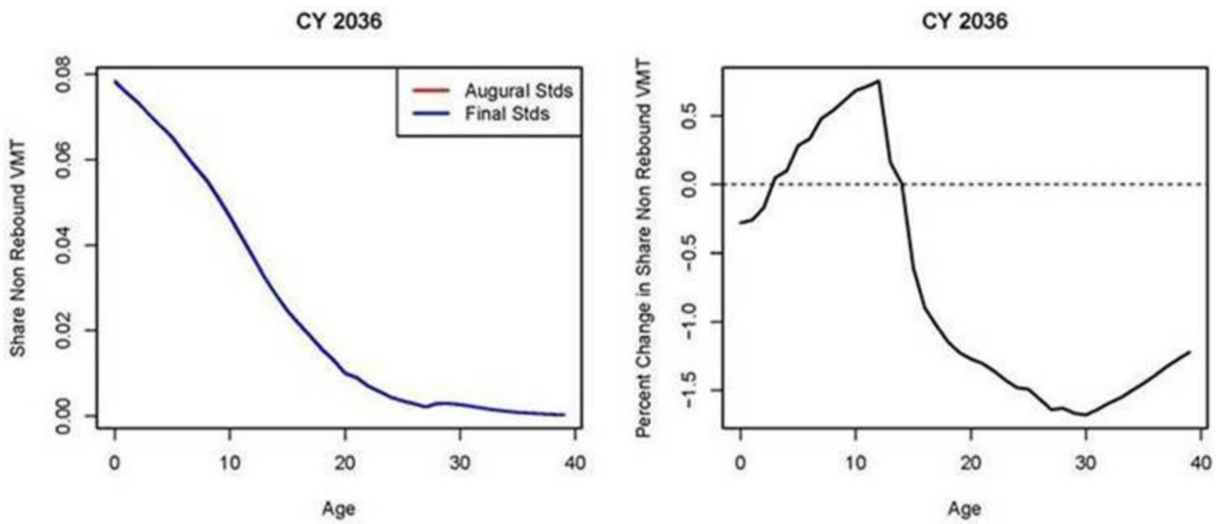

Figure VI-132 – Change in Share of Non-Rebound VMT by Age for Final vs. Augural Standards

The agencies performed a similar analysis for total VMT—which includes rebound miles—but note that this analysis answers a different, and less meaningful question by itself. Figure VI-133 below shows the same measures as Figure 1, above, but for total VMT. Instead of showing how VMT is shifting between older and newer vehicles, this analysis shows how changes in total VMT changes the proportionality of use between new and used vehicles. The total VMT between alternatives varies based on the projected MPG because of the rebound effect. As a result, even if the absolute number of miles driven by a particular vintage is constant between the scenarios, that vintage's share of VMT may change because the total number of miles is changing.[1959] Since only vehicles whose fuel economy changes across the simulation of regulatory alternatives—model years 2018 and later—drive rebound miles, only newer vehicles experience a change in total VMT. The image on the right shows that when rebound miles are included, the final standards result in a greater share of miles driven by older vehicles. This result should not be interpreted as older vehicles being driven *more* under the final standards, but rather, the miles driven by older vehicles compared to newer vehicles is proportionally larger under the final standards because newer vehicles are being driven less, since they are not driving additional rebound miles.

[1959] For example, say age 15 passenger cars are estimated to travel a combined total of 50,000 miles in a calendar year, and the total VMT for that calendar year is 1 million under the augural standards but only 800,000 under the final standards. The analysis would show the share of miles driven by age 15 cars increasing from 5% under the augural standards to 6.25% under the final standards, despite driving the same number of miles.

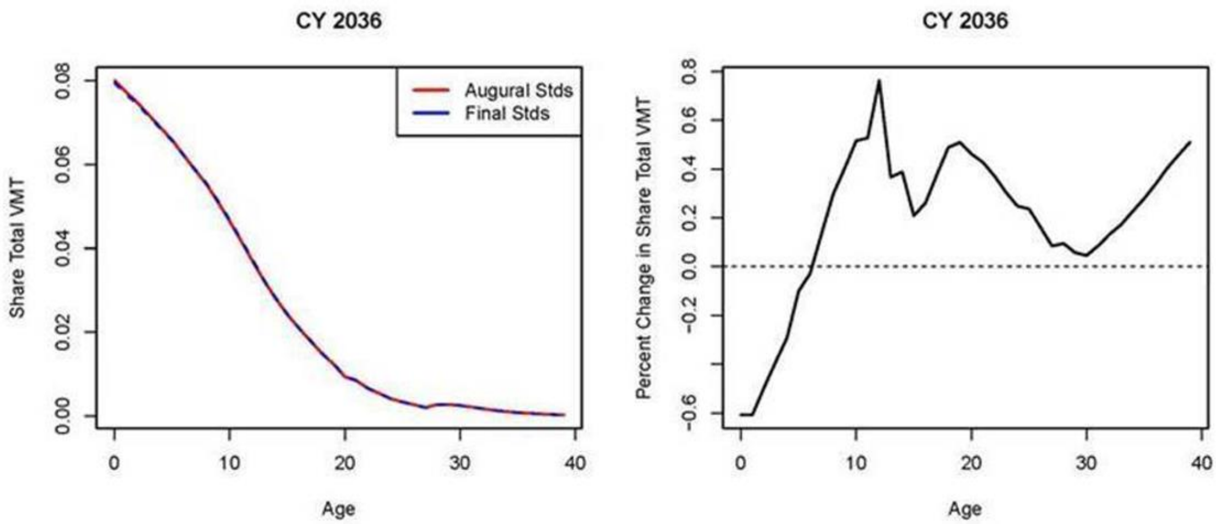

Figure VI-133 – Change in Share of Total VMT by Age for Final vs. Augural Standards

A better comparison of total VMT is to compare how VMT is changing by age between the augural and final standards. In Figure VI-134 below, the left image shows the absolute change in rebound miles driven by age in 2036 and the right image shows the percent change in rebound miles for each age. Figure VI-135 shows the same estimates, but for total VMT (rebound and non-rebound VMT). These results show that vehicle use across all vehicles is decreasing, with newer vehicles experiencing a greater change, due to fewer rebound miles. When we interpret Figure VI-133 with Figure VI-134 and Figure VI-135, we see that the "shift" towards older vehicles was a result of fewer rebound miles instead of a redistribution of miles towards older vehicles.

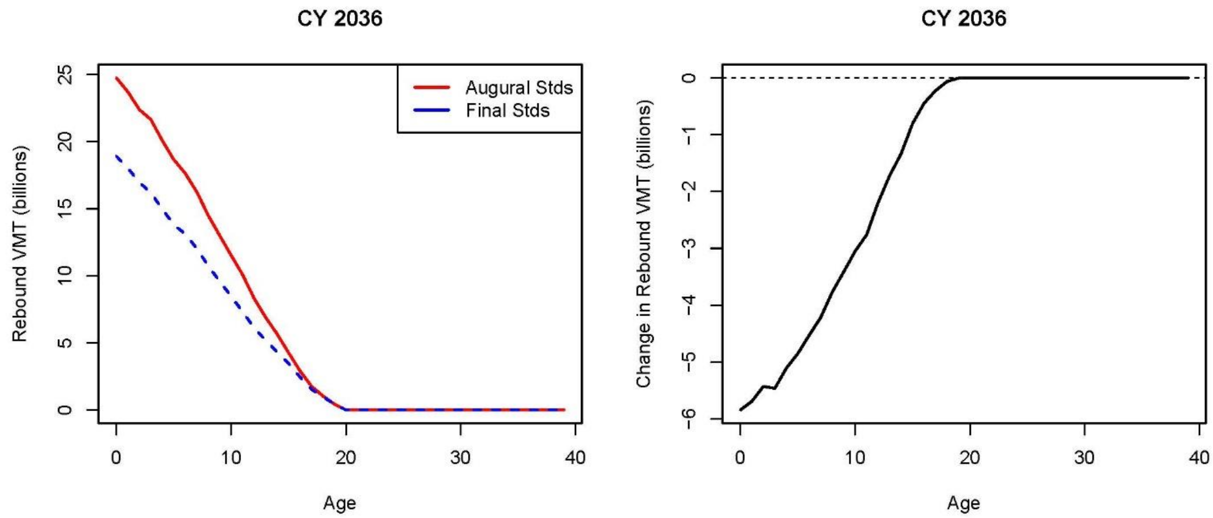

Figure VI-134 – Change in Rebound VMT by Age for Final vs. Augural Standards

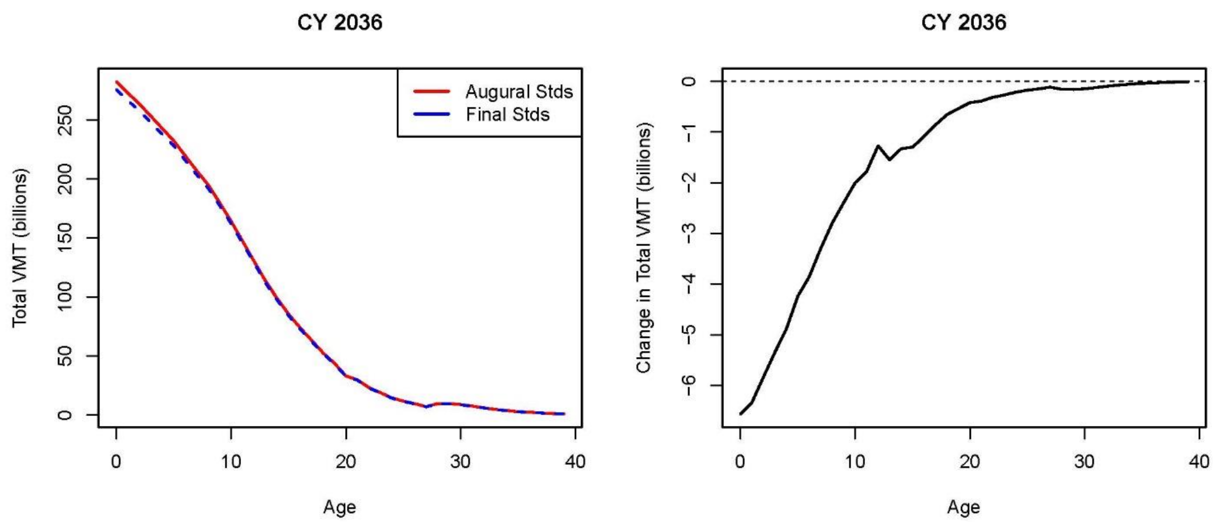

Figure VI-135 – Change in Total VMT by Age for Final vs. Augural Standards

When examining all three figures, an unambiguous trend emerges. Reducing the standards causes non-rebound VMT to shift from older vehicles to newer vehicles because of accelerated fleet turnover, and newer vehicles to be driven less because of fewer rebound miles. The net result is less miles being driven in total, and even fewer miles being driven in older vehicles that are more prone to be involved in fatal accidents. It would be erroneous to suggest that this rule increases driving in older vehicles, and it remains true that the scrappage effect increases the number of new cars on the road and improves safety.

(f) Sales, Scrappage and VMT Integration

The VMT construct described above, while an improvement over the version presented in the NPRM for the reasons explained, does not represent the fully integrated model of ownership, usage, and retirement decisions that some commenters argued would be preferred or even required to assess properly the impacts of CAFE/CO_2 standards. In particular, RFF commented that integrating sales, scrappage and VMT would "make the analysis internally consistent and will account for the fact that households do not make scrappage and vehicle use decisions in isolation."[1960] IPI concurred and expanded in their comment, stating "'a unified model of vehicle choice and usage' is necessary."[1961]

The implication of such commenters is that the agencies have ignored important benefits of more stringent standards by not explicitly considering household decisions at the level of household vehicle fleet management. However, the opposite may be true. A recent National Bureau of Economic Research ("NBER") paper finds that households engage in attribute substitution while managing the set of attributes in their vehicle portfolios.[1962] In particular, the authors argue that attribute substitution within a household's vehicle portfolio may erode up to 60 percent of the intended fuel economy benefits of the footprint-based CAFE/CO_2 standards, as the higher fuel economy of owned vehicles reduces demand for efficiency in the next bought vehicle, all else equal. This suggests that examining effects at the household level may not be as beneficial, or as meaningful, as some commenters might hope.

While commenters have suggested ambitious models of dynamic relationships at the household level, moreover, it is not clear that such a model is currently possible. Capturing the heterogeneous preferences of households across purchase, usage, and retirement decisions at the same level of detail required to produce meaningful estimates of regulatory compliance costs is beyond the current scope of this analysis. While the agencies agree that expected usage influences the household decision of which vehicle to purchase, how long to hold it, and how to manage the usage and retirement of other vehicles within a household fleet, the agencies do not agree that such a detailed model is a necessary prerequisite to assess the impacts of CAFE and tailpipe CO_2 emissions standards, nor that it is necessarily appropriate to do so given that the agencies are examining aggregate national fleetwide effects of such standards. Furthermore, in the most recent peer review of the CAFE Model, one reviewer remarked that while the sales and VMT would benefit from a household choice model, "the decision to scrap a vehicle (remove it from the national in-use fleet) and the decision to purchase a new vehicle often are not made by the same household. No U.S. national-level transportation demand models (that this reviewer is aware of) tackle the issue with this level of complexity."[1963]

Each iteration of these regulatory analyses has endeavored to improve the accuracy and breadth of modeling to capture better the relevant dynamics of the markets affected by these policies. The agencies intend to address current limitations in future rulemakings, and

meanwhile believe that the scope of the current analysis is reasonable and appropriate for informing decision-makers as to the effects of different levels of CAFE and tailpipe CO_2 emissions stringency.

(6) What is the Mobility Benefit that Accrues to Vehicle Owners?

(a) Mobility Benefits in the NPRM Analysis

As the proposal noted, the increase in travel associated with the rebound effect provides benefits that reflect the value to drivers and other vehicle occupants of the added—or more desirable—social and economic opportunities that become accessible with additional travel. The fact that drivers and their passengers elect to make more frequent or longer trips to gain access to these opportunities when the cost of driving declines demonstrates that the benefits they gain by doing so exceed the costs they incur, including the economic value of their travel time, fuel and other vehicle operating costs, and the economic cost of safety risks drivers assume. The amount by which the benefits of this additional travel exceeds its economic costs measures the net benefits drivers and their passengers experience, usually referred to as increased consumer surplus.

Under the proposal, the fuel cost of driving each mile would have increased as a consequence of the lower fuel economy levels it permitted, thus reducing the number of miles that buyers of new cars and light trucks would drive as the well-documented fuel economy rebound effect operates in reverse.[1964] The agencies' analysis of the proposed rule described the resulting loss in consumer surplus, and calculated its annual value using the conventional approximation, which is one half of the product of the increase in vehicle operating costs per vehicle-mile and the resulting decrease in the annual number of miles driven. Because the value of this loss depends on the extent of the change in fuel economy, it varied by model year, and also differed among the alternative standards that the NPRM considered.

The agencies' analysis specifically recognized that the economic value of any additional travel prompted by the fuel economy rebound effect must exceed the additional fuel costs drivers incur, plus the economic cost of safety risks they and their passengers assume.[1965] Thus, when vehicle use was projected to decline in response to lower fuel economy, the agencies noted that the resulting loss in benefits must have more than offset both the savings in fuel costs and the value of drivers' and passengers' reduced exposure to safety risks. In the accounting of benefits and costs for the preferred alternative, the loss of benefits associated with reduced mobility was recognized by reporting losses in travel benefits that exactly offset the value of reduced risks of being involved in both fatal and non-fatal crashes.

[1964] Normally, the fuel economy rebound effect refers to an *increase* in vehicle use that results when increased fuel economy reduces the fuel cost for driving each mile.

[1965] Although it did not attempt to estimate operating costs other than those for fuel or the value of drivers' and passengers' travel time, the benefits from any additional travel that occurs voluntarily must also at least compensate for these costs.

In addition, the accounting reported a loss in mobility benefits from reduced use of new cars and light trucks, which included a component that exactly offset the fuel savings from reduced driving, together with the loss in consumer surplus that foregone travel would otherwise have provided. Including this first component was necessary to offset the fact that the savings in fuel costs had already been recognized elsewhere in the accounting, by deducting those savings from the increase in fuel costs resulting from lower fuel economy to arrive at the reported *net* increase in fuel costs. Thus, the resulting value of the net loss in travel benefits was exactly equal to the loss in consumer surplus that any travel foregone in response to higher fuel costs would otherwise have provided.

(b) Comments on the Agencies' Treatment of Mobility Benefits in the NPRM

The agencies received only two comments referring to their treatment of mobility benefits in the analysis supporting the proposed CAFE and CO_2 standards. The California Air Resources Board (CARB) noted that the accounting of benefits and costs resulting from the proposal included losses in mobility benefits that offset the reduction in fatality costs related to the decline in new vehicle use from the fuel economy rebound effect. While CARB did not comment on the agencies' inclusion of losses in mobility benefits in their accounting, it did object to the fact that the agencies *also* reported the numerical change in fatalities that could be ascribed to the rebound effect, and considered the improvement in safety it reflected when selecting their proposed alternative.[1966] Similarly, the Institute for Policy Integrity (IPI) termed the agencies' reliance on the estimated change in the number of fatalities as partial justification for selecting their preferred alternative as arbitrary, while at the same time arguing that the reduction in driving due to the rebound effect had no net welfare impact.[1967]

In response to these comments, the agencies observe that considering changes in the actual number of fatalities as well as the welfare effects of changes in drivers' and passengers' exposure and valuation of the risks of being involved in fatal crashes represents a sound approach to assessing the impacts of proposed CAFE and CO_2 standards. The safety implications of alternative future standards are clearly a legitimate and highly visible consequence for the agencies to consider when evaluating their relative merits, as are the implications of changes in the safety risks for the economic welfare of car and light truck users. Thus the agencies see no inconsistency or duplication in separately considering *both* factors as part of their assessment of alternative future standards.

(c) Mobility Benefits in the Final Rule

The analysis supporting this final rule continues to treat losses in mobility benefits in the same manner the agencies previously did when analyzing the alternatives considered for the

[1966] California Air Resources Board (CARB), NHTSA-2018-0067-11873, at pp. 121.

[1967] Institute for Policy Integrity (IPI), NHTSA-2018-0067-12213, at pp. 11. In fact, the agencies did not treat the reduction in driving as having no net impact on welfare, since as explained immediately above, the loss in consumer surplus benefits on the foregone driving was not accompanied by any offsetting cost savings. Therefore, the decline in driving in response to the rebound effect resulted in a net loss in welfare.

proposed rule. Because there are several subtleties in this treatment, Figure VI-136 is included below to clarify its details. In the figure, the demand curve shows the relationship of annual use of new cars (and light trucks), which can be thought of as their total or average annual vehicle-miles driven, to the cost per mile of driving.

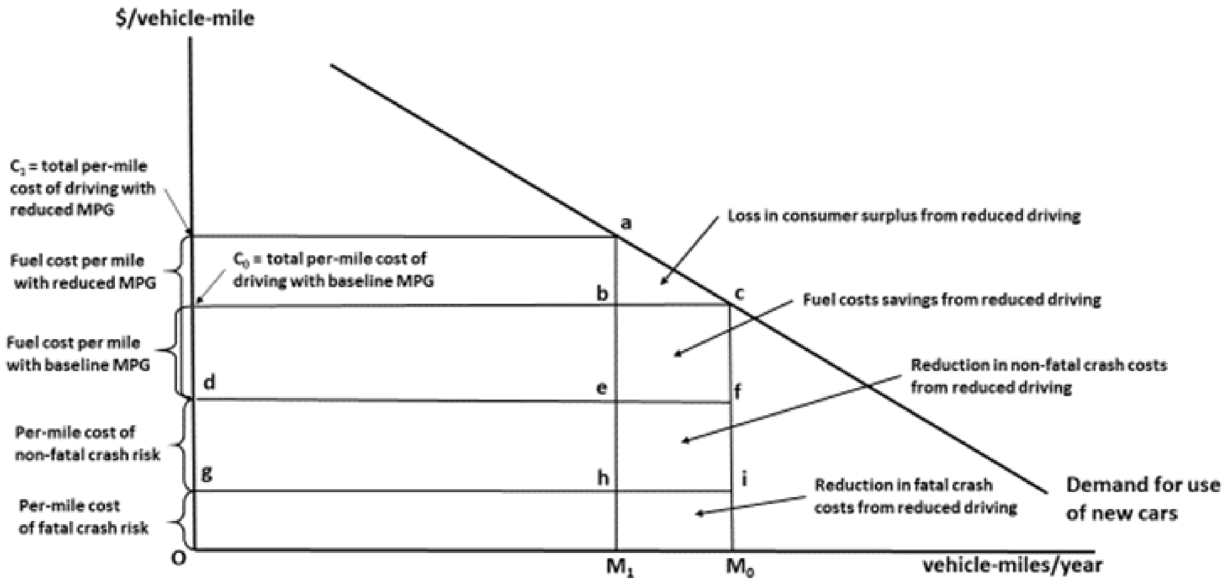

Figure VI-136 – Treatment of Mobility Benefits from Reduced Driving

The initial cost per mile OC_0 consists of the per mile economic costs of the risks of being involved in fatal and non-fatal crashes, shown by the heights of Og and gd on the vertical axis, together with per-mile fuel costs at the baseline level of fuel economy, the height of segment dC_0.[1968] Annual miles driven at this initial per-mile cost are shown by the distance OM_0 on the horizontal axis in Figure VI-136. When fuel economy declines from its baseline level under one of the regulatory alternatives considered, fuel costs per mile increase from dC_0 to dC_1, but the per-mile economic costs of crash risks (both fatal and non-fatal) are unaffected, so total costs per mile driven rise to OC_1. In response to this increase in the per-mile fuel and total cost of driving, annual use declines to OM_1.

The resulting loss in total benefits when vehicle use declines from OM_0 to OM_1 is the trapezoidal area M_1acM_0, but most of this loss is offset by cost savings from reduced driving, so the net welfare loss is considerably smaller. Specifically, the rectangle M_1hiM_0 represents a reduction in the total economic costs of the risk that drivers and passengers will be involved in fatal crashes when the decline in driving reduces their exposure to that risk. The dollar value of

[1968] Per-mile fuel costs are equal to the dollar price of fuel per gallon, divided by fuel economy in miles per gallon. For simplicity, this figure omits non-fuel operating costs, vehicle maintenance and depreciation, and the value of occupants' travel time. Including them would not change the analysis.

this area thus appears in the agencies' accounting of costs and benefits as *both* a benefit from that reduction in risk and an exactly offsetting loss in benefits from reduced mobility. The same is true of the rectangle hefi, the dollar value of which corresponds to both the reduction in the economic cost of non-fatal crash risks and an identical loss in mobility benefits.

Total fuel costs for driving OM_0 miles are initially the rectangular area dC_0cf, and the decline in driving to OM_1 that results as per-mile fuel and total driving costs rise changes total fuel costs to the rectangle dC_1ae. Because these two areas share rectangle dC_0be, the *net* change in fuel costs reported in the agencies' accounting consists of the dollar value of rectangle C_0C_1ab, minus that of rectangle ebcf. The economic value of the loss in mobility benefits the agencies report in their accounting is the trapezoid eacf, but part of that area consists of rectangle ebcf, and is thus exactly equal to the savings in fuel costs from reduced driving. Since this savings has been already incorporated in the reported change in total fuel costs, and it offsets part of the reported loss in mobility benefits, leaving only the loss in consumer surplus that travelers would otherwise have experienced on foregone reduced driving, the value of triangle bac, as the net loss in mobility benefits.[1969]

This discussion assumes that drivers correctly estimate and consider—or "internalize"—the risks of being involved in both fatal and non-fatal crashes that are associated with their additional driving. However, as is noted in the discussion of the potential effects of the rule on the mass of vehicles and its resulting impact on safety, consumers may value safety risks imperfectly. This possibility is accounted for in the final rule analysis by assuming the portion of the added safety risk that consumers internalize to be 90 percent. In Figure VI-136 above, this would be reflected by including a total social cost per mile that is higher than the C_0 and C_1 values for the baseline and reduced MPG cases shown in the graphic by 10 percent of the combined cost of fatal and non-fatal crash risks (the distance Od on the figure's vertical axis), while reducing the costs of safety risks that drivers do consider to 90 percent of the values shown. The higher social costs would offset a portion of the consumer surplus associated with additional mobility (in each case), and result in a small "deadweight loss" over the region where the social cost of driving exceeds the demand curve. These impacts are also fully accounted for in the final rule analysis.

(7) What is the Sales Surplus that Accrues to Vehicle Owners?

Buyers who would not have purchased new models with the baseline standards in effect but decide to do so in response to the changes in new vehicles' prices with less demanding standards in place will also experience increased welfare. Collective benefits to these "new" buyers are measured by the consumer surplus they receive from their increased purchases.

At the proposed rule stage, the agencies elected to exclude the consumer surplus associated with new vehicle purchases because "it is not entirely certain that sales of new cars and light trucks [would] increase in response to [the] proposed action."[1970] Consumer surplus is

[1969] Thus the change in driving is not welfare-neutral, as IPI asserted in the comment cited previously; instead, it results in a net loss in welfare.
[1970] *See* PRIA at 954.

a fundamental economic concept and represents the net value (or net benefit) a good or service provides to consumers. It is measured as the difference between what a consumer is willing to pay for a good or service and the market price. OMB circular A-4 explicitly identifies consumer surplus as a benefit that should be accounted for in cost-benefit analysis. For instance, OMB Circular A-4 states the "net reduction in total surplus (consumer plus producer) is a real cost to society," and elsewhere elaborates that consumer surplus values be monetized "when they are significant."[1971]

The decision to exclude consumer surplus for new vehicles at the proposed rule stage was an error and inconsistent with OMB's guidance on regulatory analysis. The agencies are confident that lower vehicle prices, holding all else equal, should stimulate new vehicle sales and by extension produce additional consumer surplus. That preliminary decision was also inconsistent with other parts of the agencies' analysis. For instance, the agencies calculate the lost consumer surplus associated with reductions in driving owing to the increase in the cost per mile in less stringent regulatory cases, as discussed in Section VI.D.3. The surpluses associated with sales and additional mobility are inextricably linked as they capture the direct costs and benefits accrued by purchasers of new vehicles. The sales surplus captures the savings to consumers when they purchase cheaper vehicles and the additional mobility measures the cost of higher operating expenses. It would be inappropriate to include one without the other.

The shaded area in Figure VI-137 reflects the consumer surplus calculated for new vehicle sales. Line C_0 reflects the baseline vehicle cost. The final rule is expected to reduce the cost of light duty vehicles, as represented by dotted line *C'*. Consistent with other sections of the analysis, the agencies assume that consumers value 30 months of fuel savings. Under the final rule, consumers are expected to experience higher fuel costs than they would under the baseline scenario, shifting costs from line *C'* to line C_1. The consumer surplus is equal to the area under the curve between Q_0 and Q_1.[1972]

[1971] OMB Circular A-4, at 37-38.
[1972] The exact calculation is 0.5 * the increase in sales * the reduction in the cost of light duty vehicles net of the increased fuel cost.

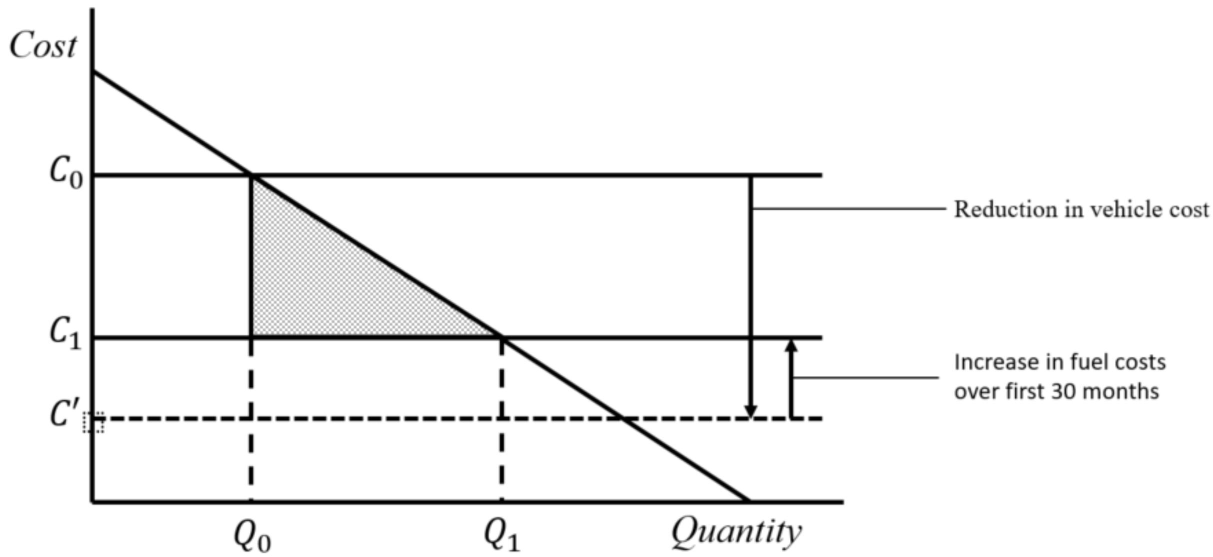

Figure VI-137 – New Vehicle Consumer Surplus Net of Increased Fuel Costs]

(8) Implicit Opportunity Cost

The agencies' central analysis assumes the selling price for new vehicles will be reduced to fully reflect manufacturers' savings in technology costs for complying with less stringent CAFE and CO_2 emission standards. Specifically, new car and light truck prices are assumed to decline by the average savings in technology costs per vehicle that manufacturers would realize from complying with the standards this rule establishes, instead of with the more demanding baseline standards. The agencies' analysis assumes that under these final standards, attributes of new cars and light trucks *other than fuel economy* would remain identical to those under the baseline standards, so that changes in sales prices and fuel economy would be the only sources of benefits or costs to new car and light truck buyers. Furthermore, the agencies recognize that buyers may have time preferences that cause them to discount the future at higher rates than the agencies are directed to consider in their regulatory evaluations. In either case, the agencies' central analysis may overstate both the net private and social benefits from adopting more stringent fuel economy and CO_2 emissions standards. For instance, in the Preamble, Table VII-93 (Combined LDV Societal Net Benefits for MYs 1975-2029, CAFE Program, 7 percent Discount Rate) shows that the CAFE final rule would generate $16.1 billion in total social net benefits using a 7 percent discount rate, but without the large net private loss of $26.1 billion, the net social benefits would equal the external net benefits, or $42.4 billion. Therefore, given that government action cannot improve net social benefits absent a market failure, if no market failure exists to motivate the $26.1 billion in private losses to consumers, the net benefits of these final standards are $42.2 billion.

As indicated earlier, EPA's Science Advisory Board urged the agencies to account for "consumer preferences for performance and other vehicle attributes" in their analysis.[1973] To explore further the possibility that the central analysis is incomplete regarding the consumer benefits of other vehicle attributes, the agencies conducted a sensitivity analysis using a conservative estimate of this value. In the proposal, the agencies considered the lost value of other vehicle attributes in two sensitivity cases that reduced the total consumer benefit.[1974] The agencies received several comments suggesting that the analysis of other vehicle attributes lost could be improved. For example, CARB commented that the "analyses do not adequately model how vehicle values will change in response to improving fuel economy, or the competing effects of other attributes."[1975] In response to commenters, the agencies have revised their sensitivity analyses to model better the impact of the standards on other vehicle attributes.

The agencies considered, such as they did in the proposal, offsetting the net private costs associated with enabling more choices in fuel-saving technologies in a manner similar to rebound driving. However, the agencies believe that this approach is unnecessary, as such an analysis would produce nearly identical net benefits to the external net benefits—which the primary analysis already generates. Furthermore, given that consumers are free to choose more fuel-efficient vehicles absent more stringent regulations, consumers who prefer certain vehicle attributes instead of fuel economy necessarily value those attributes *more* than the fuel efficiency technologies they voluntarily forgo. As such, a sensitivity analysis including a value for other vehicle attributes should more than offset the net private costs to consumers from the primary analysis.

For the final rule, instead of keeping the same approach as the preliminary analysis, the agencies have elected to estimate consumer benefits of other vehicle attributes in a sensitivity case using similar logic to that used for the sales and scrappage models. In those models, the agencies assume that consumers value thirty months of undiscounted fuel savings. Given this assumption, it would be reasonable for the agencies then to assume that the value of other vehicle attributes must be greater than the fuel savings for the remaining term of the useful life of the vehicle—as these are fuel economy savings that consumers are clearly willing to forgo. The agencies acknowledge that vehicles are typically sold more than once, but evidence suggests that fuel savings are capitalized into sales prices in the used car market.[1976] If this is the case, new car purchasers would internalize the additional value on resale owing to fuel efficiency technologies, and the fuel savings over the remaining useful life less thirty months would be an appropriate value to use for the value of other vehicle attributes. Nevertheless, the agencies have elected to be conservative and, instead, opted to use the fuel savings over the first seventy-two months (less the first thirty months), which approximates the amount of time the first owner typically holds a new vehicle.[1977] This value is referred to as the "implicit opportunity cost" of

---

[1973] SAB at 10.
[1974] *See* PRIA at 954. *See also*, PRIA at 1539.
[1975] CARB, Detailed Comments, NHTSA-2018-0067-11873 at 189.
[1976] For further discussion of the evidence, see section VI.D.2 of the preamble.
[1977] There are several reasons why 72 months is an appropriate approximation. According to a report from the Federal Reserve bank of Chicago the average new vehicle is owned for over 77 months as of 2015. From the same

forgoing other vehicle attributes in favor of increased fuel economy (or using their scarce financial resources to invest in savings or the purchase of other goods that they prefer more than fuel economy),[1978] showing a cost savings for less stringent alternatives.[1979] Unlike the sales surplus, which measures the consumer surplus of new vehicle buyers entering the market, the implicit opportunity cost contained in this sensitivity case represents the forgone benefits to consumers the model assumes would have purchased a vehicle regardless of the standards (but would prefer to take the upfront cost of fuel economy technologies and invest that money elsewhere, whether it be on different vehicle attributes or different goods altogether). These results are shown in the Preamble in Table VII-91 through Table VII-95 for MYs 1975-2029 CAFE Program, 3 percent Discount Rate and 7 percent Discount Rate, as well as the C02 Program, 3 percent Discount Rate and 7 percent Discount Rate).

The agencies note that the central analysis of the final rule features a conservative treatment of private benefits and costs that may bias the results in the favor of more stringent regulatory alternatives. This bias arises from the agencies' treatment of rebound driving. The agencies assume that drivers make a rational decision when electing to drive additional miles, which considers not only the risks the additional driving poses to their own lives and property, but also most of the risks their behavior poses to their passengers as well as the person and property of other road users. In such a case, drivers "internalize" most of these risks, and it can be assumed that benefits to drivers must be more valuable to them than the risks they considered when deciding whether to undertake the additional driving. Therefore, the agencies have appropriately offset the loss in safety benefits, which are associated with the increased cost of driving in the final rule, with commensurate lost benefits of additional driving.

In contrast, the agencies can be *assured* the private benefits and costs of fuel saving technologies (aside from the external environmental damages) are internalized—as there is no doubt that the owners of the vehicles will accrue the fuel costs/savings. The agencies believe it would be entirely contradictory to assert that consumers are rational, informed, and considerate enough to internalize the risks of additional driving to themselves, their passengers, as well as other drivers and passengers; but are not similarly rational and informed enough to consider the additional fuel costs of purchasing a vehicle without a particular fuel-saving technology. After

report, the average new car financing term was over 67 months in 2016. (https://www.chicagofed.org/publications/working-papers/2019/2019-04; accessed: December 23, 2019). Data from R.L. Polk suggest that the average new car is held for 71.4 months (as cited in https://www.autotrader.com/car-shopping/buying-car-how-long-can-you-expect-car-last-240725). State Comptrollers and Treasurers referred to an IHS Markit report that the average length of time a consumer keeps a new car is approximately 6.6 years (78 months). EPA-HQ-OAR-2018-0283-4153, at 2. CFA commented that new vehicle leases are running, on average, 68 months and new vehicles are being held, on average, longer than 60 months. Comments, NHTSA-2018-0067-12005, at 76. The agencies selection of 72 months is comfortably within the range of these estimates, but errs towards the lower-end and therefore provides a conservative estimate.

[1978] These vehicle attributes may include any that consumers may value and are not explicitly modeled to be neutral across regulatory alternatives. For instance, trim levels, entertainment systems, crash avoidance technologies, etc. may be sacrificed to pay for higher fuel economy technology levels.

[1979] The implicit opportunity cost must be considered a value that consumers place on other vehicle attributes that is net of the cost of those attributes. This is the forgone consumer surplus of other vehicle attributes. As such it is appropriately additive to the technology cost/savings estimated in the primary analysis.

all, existing regulations require that the estimated annual fuel costs of a vehicle are disclosed *on the new vehicle a consumer intends to purchase*—and no such disclosure exists for the risks associated with driving a rebound mile. The agencies' decision to offset rebound miles, but not net private costs stemming from enabling more choices in fuel-saving technologies, significantly favors more stringent alternatives.

Another possibility, however, is that manufacturers could redirect some or all of their savings in technology costs to instead improve other attributes of cars and light trucks—passenger comfort, safety, carrying and towing capacity, or performance—that potential buyers value. For example, they could redeploy the energy efficiency improvements from some technologies that would otherwise have been used to increase fuel economy to instead improve vehicles' performance, or redirect spending on fuel economy technology to improve safety or interior comfort. Producers could also offer combinations of price reductions and more limited improvements in these other attributes on some of their models, while continuing to offer high levels of fuel economy on other models, and channeling their entire cost savings into price reductions on yet other vehicles. Individual manufacturers would presumably select different combinations of these strategies, each in an effort to realize maximum additional sales and profits.

The agencies' analysis does not quantify specific improvements in other attributes manufacturers could make, or identify potential combinations of lower prices and improvements in other attributes they might offer when they face less demanding fuel economy and CO_2 standards. Nevertheless, there is ample empirical evidence that tradeoffs among fuel economy and other attributes that buyers value are important considerations in vehicle design and marketing strategy, and that manufacturers commonly offer combinations of both higher fuel economy and improvements in other attributes when standards do not require them to focus exclusively on improving fuel economy.

Table VI-220 summarizes empirical estimates of the tradeoffs among fuel economy, horsepower (for cars) or torque (for light trucks), and weight derived from different authors' econometric estimates of the "curvature" of technology frontiers for cars and light trucks. Such frontiers describe the combinations of fuel economy and other attributes that manufacturers can provide with different levels of spending on vehicle design and technology, accounting for the gradual improvements in technology and energy efficiency that occur over time. The entries in the table show different authors' estimates of the percent increases in horsepower, torque, and weight that car and light truck manufacturers could *instead* achieve if they reduced fuel economy by one percent. (Although increased weight is not desirable in and of itself, it is associated with features such as a vehicle's passenger- and cargo-carrying capacity, interior volume, comfort, and safety, which potential buyers do value.). It is important to note that these tradeoffs apply to the overall average values of each attribute for cars and light trucks produced during recent model years, rather than to the features of specific individual models.

Table VI-220 – Estimated Tradeoffs among Fuel Economy and Other Attributes of Cars and Light Trucks

Source	Vehicle Class	% Increase in Other Attributes per 1%		
		Horsepower	Torque	Weight
Klier and Linn	Cars	0.24%	--	0.34%
	Light Trucks	--	0.16%	0.36%
Knittel	Cars	0.26%	0.08%	0.39%
	Light Trucks	0.06%	0.31%	0.36%

For example, Table VI-220 shows that Klier & Linn estimate reducing the average fuel economy of cars by one percent would enable producers to increase their average horsepower by 0.24 percent, and Knittel's estimate of that tradeoff is very similar (0.26 percent). Similarly, those two studies estimate that reducing the average fuel economy of cars and light trucks by one percent would enable their weight to be increased by 0.34-0.39 percent, which would in turn enable manufacturers to make modest improvements in their passenger- and cargo-carrying capacity, interior volume, comfort, or safety. (Note that reducing average fuel economy by one percent would permit either power *or* weight to increase as indicated in the table, but *not* both at the same time.).

The tradeoffs summarized in Table VI-220 provide some indication of changes in attributes other than fuel economy that manufacturers are likely to offer under the less demanding CAFE and CO_2 standards. For example, the agencies estimate that the baseline CAFE standards would have required increases in fuel economy approximately 5 percent annually over model years 2020-26 for cars, while this rule reduces the required rate of increase to 1.5 percent annually. This less demanding standard would thus enable producers to accompany higher fuel economy with significant improvements in other features that new car buyers also value, as an alternative to simply reducing prices to reflect their savings in technology costs. As noted previously, they would do so only if they thought such a strategy would be more attractive to buyers, so the agencies' estimates of benefits to new car and light truck buyers represents the minimum improvement in utility they would realize.

The historical evolution of car and light truck characteristics under CAFE standards may also provide some indication about how manufacturers are likely to respond to the less aggressive standards this rule establishes. Figure VI-138 and Figure VI-139 show that during the period when CAFE standards remained unchanged or increased slowly—approximately 1985-2010—manufacturers gradually improved cars' and light trucks' average fuel economy as well as their power (or torque) and weight, while only modestly increasing the average interior volume of cars.

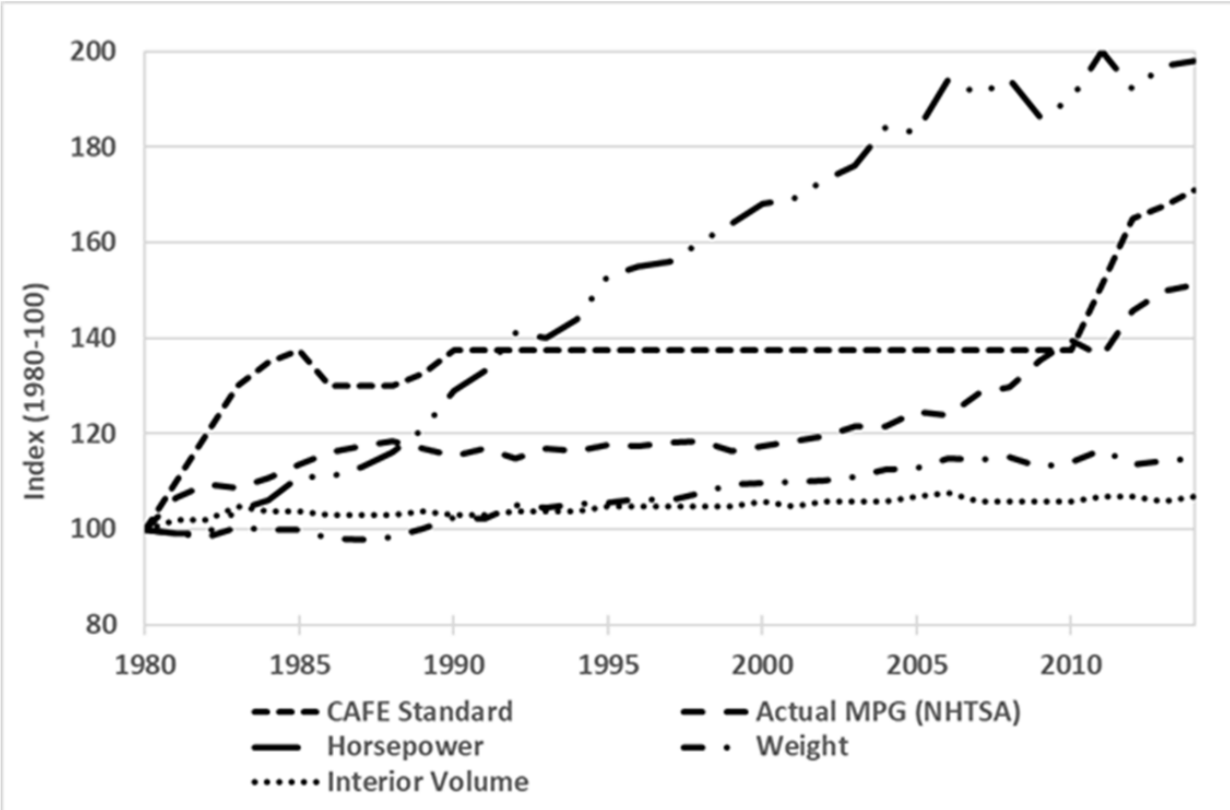

Figure VI-138 – Historical Evolution of Car Attributes under CAFE Standards

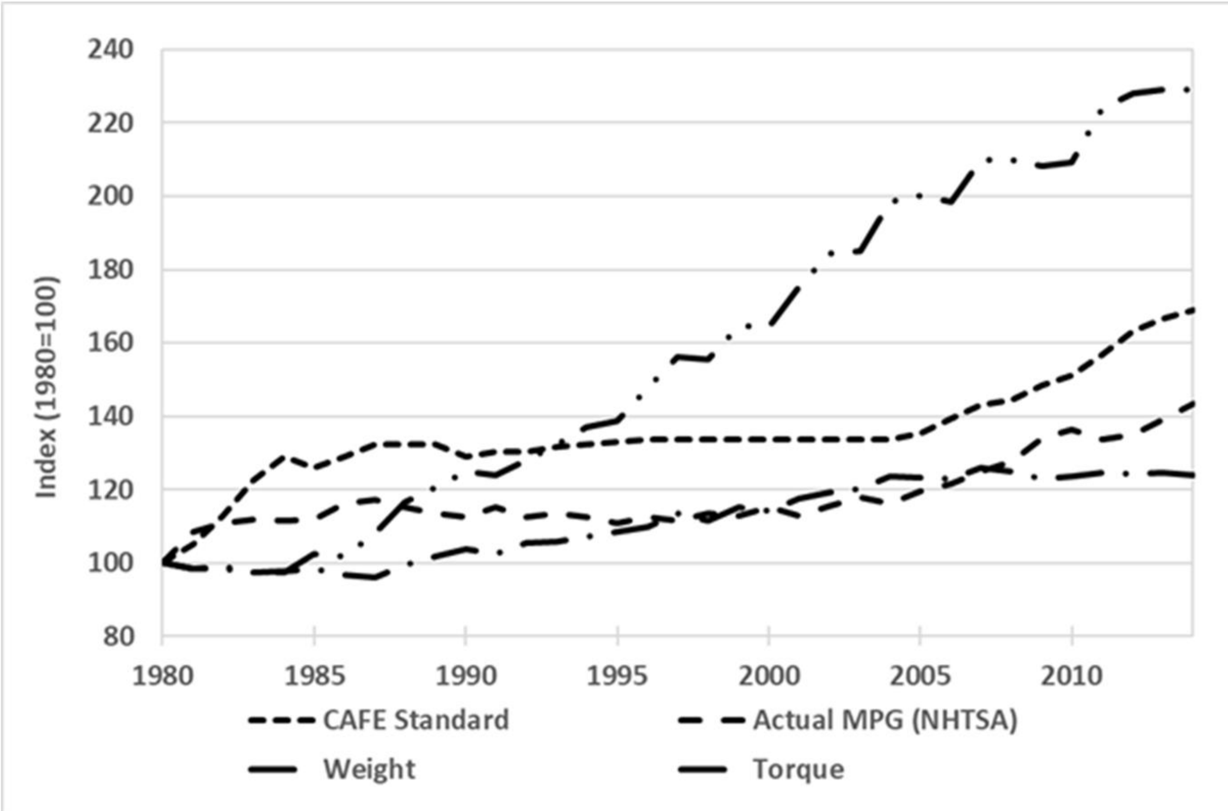

Figure VI-139 – Historical Evolution of Light Truck Attributes under CAFE Standards

Table VI-221 summarizes the rates of change in fuel economy and other attributes of cars and light trucks over that period. As it shows, most advances in cars' drive train technology were used to increase power and fuel economy, while most of the improvement in light trucks' energy efficiency was channeled into higher torque and weight, with relatively little used to improve fuel economy.

Table VI-221 – Annual Rates of Change in Car and Light Truck Attributes under CAFE Standards

Source	Period of Approximately Flat Standrds	Compound Annual % Increases					
		Actual MPG	Horse-Power	Torque	Weight	Interior Volume	Potential MPG
Passenger Cars	1985-2010	0.83%	2.17%	--	0.53%	0.07%	1.56%
Light Trucks	1984-2004	0.21%	--	3.54%	1.21%		1.48%

The last column of Table VI-221 combines the actual historical rates of increase in attributes other than fuel economy with the tradeoffs between fuel economy and other attributes shown previously in Table VI-220 to estimate the annual rates of increase in fuel economy that could have been achieved if all technological progress had been channeled into improving fuel economy. As it indicates, manufacturers could have increased the fuel economy of both cars and light trucks over the period spanned by Table VI-221 at almost exactly the 1.5 percent annual rate this rule requires, if they had believed that sacrificing other improvements in the interest of achieving higher fuel economy was the most effective strategy to meet potential customers' demands.

While this result should be regarded as illustrative, it appears to show that meeting even these relaxed standards may require manufacturers to focus on improving fuel economy instead of other vehicle attributes. It also suggests that meeting the more demanding baseline standards may have required manufacturers to make significant sacrifices in other attributes, rather than simply holding those other features at or near their current levels. Viewed from this perspective, while this rule might not enable manufacturers to improve other desirable features of cars and light trucks at the same time as they provide the improvements in fuel economy it requires, it may nevertheless prevent them from having to sacrifice other improvements that buyers regard as valuable in order to focus solely on complying with more demanding CAFE and CO_2 standards.

(9) Additional Consumer Purchase Costs

Some costs of purchasing and operating new and used vehicles scale with the value of the vehicle. When fuel economy standards increase the price of new vehicles, both taxes and registration fees increase, too, because they are calculated as a percentage of vehicle price. Increasing the price of new vehicles also affects the average amount paid on interest for financed vehicles and the insurance premiums for similar reasons. The agencies compute these additional costs as scalar multipliers on the MSRP of new vehicles. These costs are included in the consumer per-vehicle cost-benefit analysis, but, for the reasons described below, are not included in the societal cost-benefit analysis.

It is worth noting that these costs are not included in the sales and scrappage models, discussed above. The agencies do not expect that the omission of these costs affects the sales and scrappage models because of how these additional costs are calculated in the modeling. These costs are assumed to be a fixed scalar on the average MSRP of new vehicles, so that their inclusion would simply scale the coefficients in the sales and scrappage models. While these costs have not stayed constant over time (particularly not over the times series from 1970 to today), the agencies do not have a time series dataset to accurately estimate these costs.

The agencies hope to reconsider including sales taxes, registration fees, additional interest payments and insurance costs in the sales and scrappage models in future research.

(a) Sales Taxes and Registration Fees

In the analysis, sales taxes and registration fees are considered transfer payments between consumers and the government and are therefore not considered a cost from the societal perspective. However, these costs do represent an additional cost to consumers and are accounted for in the private consumer perspective. To estimate the sales tax for the analysis, the agencies weighted the auto sales tax of each state by its population—using Census population data—to calculate a national weighted-average sales tax of 5.46%.[1980]

The agencies recognize that weighting state sales tax by new vehicle purchases within a state would likely produce a better estimate since new vehicle purchasers represent a small subset of the population and may differ between states. The agencies explored using Polk registration data to approximate new vehicle sales by state by examining the change in new vehicle registrations across several recent years. The results derived from this examination resulted in a national weighted-average sales tax rate slightly above 5.5%, which is almost identical to the rate calculated using population instead. The agencies opted to utilize the population estimate, rather than the registration-based proxy of new vehicle sales, because the results were negligibly different and the analytical approach involving new vehicle registrations has not been as thoroughly reviewed.

(b) Financing Costs

Consumers who purchase new vehicles with financing options incur an additional cost above the new vehicle price—interest. Based off an Experian data, [1981] the analysis assumes 85% of automobiles are purchased through financing options. The analysis used data from Wards Automotive and JD Power on the average transaction price of new vehicle purchases, average principle of new auto loans, and the average OEM-offered incentive as a percent of MSRP to compute the ratio of the average financed new auto principal to the average new vehicle MSRP for calendar years 2011-2016. Table VI-222 shows that the average financed auto principal was between 82% and 84% of the average new vehicle MSRP. Applying the assumption that 85% of new vehicle purchases involve some financing, the average share of the MSRP financed for all vehicles purchased, including non-financed transactions, was computed. Table-II-34 shows that the average percentage of MSRP financed ranges between 70% and 72%. From this, the agencies chose to assume that 70% of the value of all vehicles' MSRP is financed. It is likely that the share financed is correlated with the MSRP of the new vehicle purchased, but for simplification purposes, it is assumed that 70% of all vehicle costs are financed, regardless of the MSRP of the vehicle. The agencies note that this simplification does not impact the accuracy of the calculation of the average cost to consumers, but concede that it obfuscates which consumers bear the additional financing burden when vehicle prices increase (selection of specific vehicles is likely not independent of consumer characteristics). For sake of simplicity, the model also assumes that increasing the cost of new vehicles will not change the share of new

---

[1980] *See* Car Tax by State, FactoryWarrantyList.com, http://www.factorywarrantylist.com/car-tax-by-state.html (last visited June 22, 2018). Note: County, city, and other municipality-specific taxes were excluded from weighted averages, as the variation in locality taxes within states, lack of accessible documentation of locality rates, and lack of availability of weights to apply to locality taxes complicate the ability to reliably analyze the subject at this level of detail. Localities with relatively high automobile sales taxes may have relatively fewer auto dealerships, as consumers would endeavor to purchase vehicles in areas with lower locality taxes, therefore reducing the effect of the exclusion of municipality-specific taxes from this analysis.

[1981] A report by Experian found that 85.2% of 2016 new vehicles were financed, as were 85.9% of 2015 new vehicle purchases. Zabritski, M. *State of the Automotive Finance Market: A look at loans and leases in Q4 2016*, Experian, https://www.experian.com/assets/automotive/quarterly-webinars/2016-Q4-SAFM-revised.pdf (last visited June 22, 2018).

vehicle MSRP that is financed; the relatively constant share from 2011-2016 when the average MSRP of a vehicle increased 10% supports this assumption. The agencies recognize that this is not indicative of average individual consumer transactions but provides a useful tool to analyze the aggregate marketplace.

Table VI-222 – Share of Average MSRP Financed

Year	Of the Vehicles Purchased through Financing Options—Average Percentage of MRSP Financed	Average Percentage of MSRP Financed of All New Vehicles
2016	84%	71%
2015	84%	71%
2014	82%	70%
2013	82%	70%
2012	84%	72%
2011	84%	72%

From Wards Auto data, the average 48- and 60-month new auto interest rates were 4.25% in 2016, and the average finance term length for new autos was 68 months. The agencies recognize that longer financing terms generally include higher interest rates. The share financed, interest rate, and finance term length are added as inputs in the parameters file so that they are easier to update in the future.

Using these inputs the model computes the stream of additional costs associated with financing options paid for the average financed purchases as follows:[1982]

$$Annual\ interest = \frac{interest * MSRP * (share\ financed)}{1 - (1 + (interest/12))^{-term}} - \frac{MSRP * (share\ financed)}{(term/12)}$$

Note: The above assumes the interest is distributed evenly over the period, when in reality more of the interest is paid during the beginning of the term. However, the incremental amount calculated as attributable to the standard will represent the difference in the annual payments at the time that they are paid, assuming that a consumer does not repay early. This will represent the expected change in the stream of financing payments at the time of financing.

The above stream does not equate to the average amount paid to finance the purchase of a new vehicle. In order to compute this amount, the share of financed transactions at each interest rate and term combination would have to be known. Without having projections of the full distribution of the auto finance market into the future, the above methodology reasonably accounts for the increased amount of financing costs due to the purchase of a more expensive vehicle, on an average basis taking into account non-financed transactions. Financing payments

[1982] As alluded to above, the principle portion of repayments do not represent an additional cost to consumers since it represents the sales price.

are also assumed to be an intertemporal transfer of wealth for a consumer; for this reason, it is not included in the societal cost and benefit analysis. However, because it is an additional cost paid by the consumer, it is calculated as a part of the private consumer welfare analysis.

It is recognized that increased financing terms, combined with rising interest rates, lead to longer periods before a consumer will have positive equity in the vehicle to trade in toward the purchase of a newer vehicle. This has impacts in terms of consumers either trading vehicles with negative equity (thereby increasing the amount financed and potentially subjecting the consumer to higher interest rates and/or rendering the consumer unable to obtaining financing) or delaying the replacement of the vehicle until they achieve suitably positive equity to allow for a trade.

(c) Insurance Costs

More expensive vehicles will require more expensive collision and comprehensive (e.g., fire and theft) car insurance. Actuarially fair insurance premiums for these components of value-based insurance will be the amount an insurance company will pay out in the case of an incident type weighted by the risk of that type of incident occurring. For simplicity of this calculation, the agencies assume that the vehicle has the same exposure to harm throughout its lifetime. However, the value of vehicles will decline at some depreciation rate so that the absolute amount paid in value-related insurance will decline as the vehicle depreciates. This is represented in the model as the following stream of expected collision and comprehensive insurance payments:

$$(Comprehensive\ \&\ Collision)_{age} = \frac{MSRP * (share\ MSRP)}{(1 + depreciation\ )^{age}}$$

To utilize the above framework, estimates of the share of MSRP paid on collision and comprehensive insurance and of annual vehicle depreciations are needed to implement the above equation. Wards has data on the average annual amount paid by model year for new light trucks and passenger cars on collision, comprehensive and damage and liability insurance for model years 1992-2003; for model years 2004-2016, they only offer the total amount paid for insurance premiums. The share of total insurance premiums paid for collision and comprehensive coverage was computed for 1979-2003. For cars the share ranges from 49 to 55%, with the share tending to be largest towards the end of the series. For trucks the share ranges from 43 to 61%, again, with the share increasing towards the end of the series. It is assumed that for model years 2004-2016, 60% of insurance premiums for trucks, and 55% for cars, is paid for collision and comprehensive. Using these shares the absolute amount paid for collision and comprehensive coverage for cars and trucks is computed. Then each regulatory class in the fleet is weighted by share to estimate the overall average amount paid for collision and comprehensive insurance by model year as shown in Table VI-223. The average share of the initial MSRP paid in collision and comprehensive insurance by model year is then computed. The average share paid for model years 2010-2016 is 1.83% of the initial MSRP. This is used as the share of the value of a new vehicle paid for collision and comprehensive in the future.

Table VI-223 – Average Share of MSRP Paid for Collision and Comprehensive Insurance

Model Year	Collision and Comprehensive	Average MSRP	Percent MSRP

2016	$681	$33,590	2.03%
2015	$601	$32,750	1.84%
2014	$567	$31,882	1.78%
2013	$548	$31,056	1.76%
2012	$530	$30,062	1.76%
2011	$517	$29,751	1.74%
2010	$548	$29,076	1.88%

2017 data from Fitch Black Book was used as a source for vehicle depreciation rates; two- to six-year-old vehicles in 2016 had an average annual depreciation rate of 17.3%.[1983] It is assumed that future depreciation rates will be like recent depreciation, and the analysis used the same assumed depreciation. Table VI-224 shows the cumulative share of the initial MSRP of a vehicle assumed to be paid in collision and comprehensive insurance in five-year age increments under this depreciation assumption, conditional on a vehicle surviving to that age—that is, the expected insurance payments at the time of purchase will be weighted by the probability of surviving to that age. If a vehicle lives to 10 years, 9.9% of the initial MSRP is expected to be paid in collision and comprehensive payments; by 20 years 11.9% of the initial MSRP; finally, if a vehicle lives to age 40, 12.4% of the initial MSRP.

Table VI-224 – Cumulative Percentage of MSRP Paid in Collision/Comprehensive Premiums by Age

Age	Percentage of Value Remaining	Cumulative Percentage of MSRP Paid
5	59%	6.8%
10	26.6%	9.9%
15	12.0%	11.3%
20	5.4%	11.9%
25	2.4%	12.2%
30	1.1%	12.3%
35	0.5%	12.4%
40	0.2%	12.4%

The increase in insurance premiums resulting from an increase in the average value of a vehicle is a result of an increase in the expected amount insurance companies will have to pay out in the case of damage occurring to the driver's vehicle. In this way, it is a cost to the private consumer, attributable to the CAFE standard that caused the price increase.

[1983] *Fitch Ratings Vehicle Depreciation Report February 2017*, Black Book, http://www.blackbook.com/wp-content/uploads/2017/02/Final-February-Fitch-Report.pdf (last visited June 22, 2018).

(10) Refueling Benefit

Increasing CAFE/CO_2 standards, all else being equal, affect the amount of time drivers spend refueling their vehicles in several ways. First, they increase the fuel economy of ICE vehicles produced in the future and, consequentially, decrease the number of refueling events for those vehicles. Second, given increased production costs, they reduce sales of new vehicles and scrappage of existing ones, causing more VMT to be driven by older and less efficient vehicles which require more refueling events for the same amount of VMT driven. Finally, they may change the number of electric vehicles that are produced, and shift refueling to occur at a charging station, rather than at the pump—changing per-vehicle lifetime expected refueling costs. While there are multiple ways that fuel economy standards alter refueling costs, the proposal accounted for only the first. Before the inclusion of the sales and scrappage models, which first appeared in the NPRM analysis for the first time a CAFE/ CO_2 rulemaking, the agencies did not have the means to capture the other two effects. While the agencies modeled sales and scrappage effects, they did not extend the results to refueling time. This oversight was noted by commenters, and the final rule model now includes these additional factors. The basic calculation for all three effects is the same: the agencies multiply the additional amount of time spent refueling by the value of time of passengers, which is assumed to be the same for all three effects.

(a) Value of Time

The calculation of the value of time remains relatively unchanged from the proposal and follows the guidance from DOT's 2016 *Value of Travel Time Savings* memorandum ("VTTS Memo").[1984] The economic value of refueling time savings is calculated by applying valuations for travel time savings from the VTTS Memo to estimates of how much time is saved across alternatives.[1985]

IPI commented that the agencies used old data to calculate the refueling benefit in the proposal. Specifically, IPI pointed out that the data used in the proposal seemed "to come from the 2003 version of [the VTTS Memo]."[1986] For the final rule, the analysis uses the most recent VTTS memo along with updated wages. The value of travel time depends on average hourly valuations of personal and business time, which are functions of annual household income and total hourly compensation costs to employers. As designated by the 2016 VTTS memo, the nationwide median annual household income, $56,516 in 2015, is divided by 2,080 hours to yield an income of $27.20 per hour. Total hourly compensation cost to employers, inclusive of benefits, in 2015$ is $25.40.[1987] Table VI-225 demonstrates the agency's approach to estimating the value of travel time ($/hour) for both urban and rural (intercity) driving. This approach relies

---

[1984] United States Department of Transportation, The Value of Travel Time Savings: Departmental Guidance for Conducting Economic Evaluations, (2016), available at https://www.transportation.gov/sites/dot.gov/files/docs/2016%20Revised%20V.

[1985] VTTS Memo Tables 1, 3, and 4.

[1986] IPI, Appendix, NHTSA-2018-0067-12213, at 51.

[1987] *Ibid* at11.

on the use of DOT-recommended weights that assign a lesser valuation to personal travel time than to business travel time, as well as weights that adjust for the distribution between personal and business travel.[1988] In accordance with DOT guidance, wage valuations are estimated with base year 2015 dollars and end results are adjusted to 2018 dollars.

Table VI-225 – Estimating the Value of Travel Time for Urban and Rural (Intercity) Travel ($/hour, 2015 Dollars)

Urban Travel			
	Personal Travel	Business Travel	Total
Wage Rate ($/hour)	$27.20	$25.40	-
DOT - Recommended Value of Travel Time Savings, as % of Wage Rate	50%	100%	-
Hourly Valuation (=Wage Rate * DOT-Recommended Value)	$13.60	$25.40	-
% of Total Urban Travel	95.4%	4.6%	100%
Hourly Valuation (Adjusted for % of Total Urban Travel)	$12.97	$1.17	$14.14
Rural (Intercity) Travel			
	Personal Travel	Business Travel	Total
Wage Rate ($/hour)	$27.20	$25.40	
DOT - Recommended Value of Travel Time Savings, as % of Wage Rate	70%	100%	
Hourly Valuation (=Wage Rate * DOT-Recommended Value)	$19.04	$25.40	
% of Total Rural Travel	78.6%	21.4%	100%
Hourly Valuation (Adjusted for % of Total Rural Travel)	$14.97	$5.44	$20.40

Estimates of the hourly value of urban and rural travel time ($14.14 and $20.40, respectively) shown in Table VI-225, must be adjusted to account for the nationwide ratio of urban to rural driving.[1989] This adjustment, which gives an overall estimate of the hourly value of travel time—independent of urban or rural status—is shown in Table VI-226.

Table VI-226 – Estimating Weighted Urban/Rural Value of Travel Time ($/hour, 2015 Dollars)

	Unweighted Value of Travel Time ($/hour)	**Weight (% of Total Miles Driven)**	**Weighted Value of Travel Time ($/hour)**
Urban Travel	$14.14	69.9%	$9.89
Rural Travel	$20.40	30.1%	$6.14

[1988] Business travel is higher than personal travel because an employer has additional expenses, *e.g.* taxes and benefits costs, above and beyond an employee's hourly wage. In the proposal, the agencies erroneously used the same value for personal and business travel, which was inconsistent with the VTTS Memo.

[1989] Estimate of Urban vs. Rural travel weights from FHWA December 2018 Traffic Volume Trends, Monthly Report, Table 2 - Cumulative Monthly Vehicle-Miles of Travel in Billions. Available at https://www.fhwa.dot.gov/policyinformation/travel_monitoring/18dectvt/page3.cfm.

	Unweighted Value of Travel Time ($/hour)	Weight (% of Total Miles Driven)	Weighted Value of Travel Time ($/hour)
Total	-	100.0%	$16.03

Note that the calculations above consider the value of travel time for only one occupant. To estimate fully the average value of vehicle travel time per vehicle, the agencies must account for the presence of all additional passengers during refueling trips. The agencies estimated average vehicle occupancy using survey data gathered as part of our 2010-2011 National Automotive Sampling System's Tire Pressure Monitoring System (TPMS) study.[1990] The study was conducted at fueling stations nationwide and researchers made observations regarding a variety of characteristics of thousands of individual fueling station visits from August, 2010 through April, 2011. Among these characteristics of fueling station visits, the total number of occupants per vehicle were observed. Average vehicle occupancy was calculated and multiplied by the value of travel time per occupant. As shown in Table VI-227, this adjustment is performed separately for passenger cars and for light trucks, yielding occupancy-adjusted valuations of vehicle travel time during refueling trips for each fleet. Lastly, the occupancy-adjusted value of vehicle travel time is converted to 2018 dollars using the GDP deflator as shown in Table VI-228.[1991]

Table VI-227 – Estimating the Value of Travel Time for Light-Duty Vehicles ($/hour, 2015 Dollars)

	Passenger Cars	Light Trucks
Average Vehicle Occupancy During Refueling Trips (persons)	1.21	1.23
Weighted Value of Travel Time ($/hour)	$16.03	$16.03
Occupancy-Adjusted Value of Vehicle Travel Time During Refueling Trips ($/hour)	$19.39	$19.71

Table VI-228 – Value of Vehicle Travel Time in 2018 Dollars ($/hour, 2018 Dollars)

	Passenger Cars	Light Trucks
Occupancy-Adjusted Value of Vehicle Travel Time During Refueling Trips ($/hour)	$20.45	$20.79

IPI commented that the exclusion of children from the NPRM's refueling time analysis was inconsistent with DOT's 2016 *Value of Travel Time Savings* memorandum ("VTTS Memo"). IPI claimed that the VTTS Memo "consider[ed] whether the value of travel time is

[1990] Docket for Peer Review of NHTSA/NASS Tire Pressure Monitoring System, available at https://www.regulations.gov/docket?D=NHTSA-2012-0001
[1991] Bureau of Economic Analysis, NIPA Table 1.1.9 Implicit Price Deflators for Gross Domestic Product, available at https://apps.bea.gov/iTable/index_nipa.cfm.

different for parents versus children, but ultimately conclude[d] that 'it must be assumed that all travelers' VTTS are independent and additive.'" IPI also quoted language from page 13 of the VTTS Memo that "[a]lthough riders may be a family with a joint VTTS or passengers in a car pool or transit vehicle with independent values, these circumstances can seldom be distinguished […] therefore, all individuals are assumed to have independent values," and that it is "inappropriate to use different income levels or sources for different categories of traveler."[1992]

IPI further asserted that excluding passengers under age 16 from the calculation of travel time savings was inconsistent with the best practices of benefit-cost analysis. IPI noted that Circular A-4 does not distinguish between children and adults except when monetizing health effects. IPI then cited Dale Whittington and Duncan MacRae as stating "there is a clear consensus that children should be counted in cost-benefit analysis." Finally, IPI commented that Congress intended that the agencies consider the economic impact to children when setting standards.[1993]

The agencies point out that the first passage from the VTTS Memo cited by IPI does not conclude, or even deliberate, that the VTTS of children is the same as adults, but instead states that the VTTS of children, parents and other passengers should be independent and additive.[1994] Assuming that the opportunity cost of children's time is zero is compatible with this practice. Likewise, IPI concluded from the text on page 12 that it was inappropriate to use different incomes for children. However, IPI's analysis suffers from two errors.

First, the two quotes from page 12 reside in a section of the VTTS Memo entitled *Special Issues*, which provides guidance on three distinct topics. The first quoted text comes from a paragraph advising how to treat vehicles with multiple passengers, while the second is from an ensuing topic about passenger incomes. It is baseless to assume that the conclusion of the second topic holds true for the first.

Second, assuming IPI intended to comment that age is a "category of traveler" for which "it is inappropriate to use different income levels," the agencies note that such an interpretation is tenuous. The VTTS Memo clearly recognizes that some categories of travelers should have different levels of income,[1995] and provides two examples.[1996] As children are not part of the workforce, they do not have wage incomes. Therefore, it is not wild speculation that they do not

---

[1993] *See* IPI, Appendix, NHTSA-2018-0067-12213, at 53-54 (internal citations omitted).
[1994] *See* VTTS Memo at 5.
[1995] The full text quoted by IPI reads, "*[e]xcept for specific distinctions*, we consider it inappropriate to use different income levels or sources for different categories of traveler." VTTS Memo at 12 (emphasis added). The VTTS Memo further contemplates that it is appropriate to assign different incomes if "estimates [of income are] derived by reliable and focused research […] in specific cases." *Id*.
[1996] The VTTS Memo provides specific guidance on how to differentiate between personal and business travel, and air or high speed rail from other modes of transportation. *See* VTTS Memo at 12.

bear a financial opportunity cost associated with their time spent in vehicles during refueling.[1997] As such, excluding children from the calculation of the refueling benefit is consistent with DOT's guidance.

Turning to IPI's comments on best practices and Congress' intent, the agencies agree that the benefit-cost analysis should include children when appropriate. The majority of the components of the CAFE model (e.g., safety analyses) include children. However, children are excluded from the analysis when it is appropriate (e.g. employment). For this specific valuation, it is reasonable to assume the value of a child's time is not equivalent to an adult's. Nonetheless, the agencies have examined the impact of valuing children's time as equal to adults' by including them in the average vehicle occupancy rates applied in the refueling analysis and using the full VTTS for personal travel. Results indicate that the effect of this issue is minor and impacts total benefits by about one-quarter percent. The agencies will continue to consider this issue in future CAFE and CO_2 rulemakings. IPI also noted that the only portion of the TPMS publicly available was the "User's Coding Manual." Specifically, IPI argued that "the agencies' failure to make available the full data and methodology used to calculate these average occupancy figures frustrates any meaningful public review." The agencies disagree. IPI was able to submit a meaningful comment about the agencies' decision to exclude children from the occupancy-adjusted value of vehicle travel time. Furthermore, commenters knew that the agencies intended to use occupancy estimates to calculate the refueling benefit; however, the agencies did not receive any alternative estimates or methodologies from commenters. Nonetheless, the agencies have provided reference to the docket folder containing peer review documents, analysis documentation, and data for the 2011 TPMS survey.

(b) Accounting for Improved Fuel Economy of ICE Vehicles

The methodology for calculating the refueling benefits associated with improved fuel economy in new vehicles remains unchanged from the proposal. The CAFE model calculates the number of refueling events for each ICE vehicle in a calendar year. This is calculated as the number of miles driven by each vehicle in that calendar year divided by the product of that vehicle's on road fuel economy, tank size, and an assumption about the average share of the tank refueled at each event, as follows:

$$Refuel\ Events_{CY,Veh} = \frac{Miles_{CY,Veh}}{FE_{Veh} * Tank_{Veh} * Share_{Veh}}$$

The model then computes the cost of refueling as the product of the number of refueling events, total time of each event and value of the time spent on each event (computed as average salary), as below:

[1997] The TMPS study affords the agencies the opportunity to distinguish between adults and passengers, a luxury not available in every instance. Furthermore, there may be certain instances where it is appropriate to value the VTTS of children the same as adults, *e.g.* rules focusing primarily on the VTTS of children.

$$Cost_{CY,Veh} = Refuel\ Events_{CY,Veh} * (Event\ Time_{Veh}) * Time\ Value$$

The event time of a vehicle is calculated by summing a fixed and variable component. The fixed component is the number of minutes it is assumed each event takes, independent of any assumptions about tank size or share refueled at each event (the time it takes to get to and from the pump). The variable component is the ratio of the average number of gallons refueled for each event (the product of the tank size and share refueled) and the rate at which gallons flow from the pump. This is shown below:

$$Event\ Time_{Veh} = Fixed_{\ Veh} + \frac{Tank_{Veh} * Share_{Veh}}{Rate}$$

In order to calculate the refueling time cost, as described above, the CAFE model takes the following inputs: the value of time, the fixed time component of each refueling event, share of the tank refueled at each event, rate of flow of fuel from the pump, and vehicle tank size. The first of these is taken from DOT guidance on travel time savings. The fixed time component, share refueled, and rate of flow are calculated from survey data gathered as part of our 2010-2011 National Automotive Sampling System's Tire Pressure Monitoring System (TPMS) study.[1998] Finally, the vehicle fuel tank sizes are taken from manufacturer specs for the reference fleet and historical averages are calculated from popular models for the existing vehicle fleet, as described, below, in discussion of the legacy fleet.

The agencies estimated the amount of saved refueling time using survey data gathered as part of the aforementioned TPMS study. In this nationwide study, researchers gathered information on the total amount of time spent pumping and paying for fuel. From a separate sample (also part of the TPMS study), researchers conducted interviews at the pump to gauge the distances that drivers travel in transit to and from fueling stations, how long that transit takes, and how many gallons of fuel are purchased.

The agencies focused on the interview-based responses in which respondents indicated the primary reason for the refueling trip was due to a low reading on the gas gauge. Such drivers experience a cost due to added mileage driven to detour to a filling station, as well as added time to refuel and complete the transaction at the filling station. The agencies believe that drivers who refuel on a regular schedule or incidental to stops they make primarily for other reasons (e.g., using restrooms or buying snacks) do not experience the cost associated with detouring in order to locate a station or paying for the transaction, because the frequency of refueling for these reasons is unlikely to be affected by fuel economy improvements. This restriction was imposed to exclude distortionary effects of those who refuel on a fixed (*e.g.*, weekly) schedule and may be unlikely to alter refueling patterns as a result of increased driving range. The relevant TPMS survey data on average refueling trip characteristics are presented below in Table VI-229.

[1998] Docket for Peer Review of NHTSA/NASS Tire Pressure Monitoring System, *available at* https://www.regulations.gov/docket?D=NHTSA-2012-0001

Table VI-229 – Average Refueling Trip Characteristics for Passenger Cars and Light Trucks

	Gallons of Fuel Purchased	Round-Trip Distance to/from Fueling Station (miles)	Round-Trip Time to/from Fueling Station (minutes)	Time to Fill and Pay (minutes)	Total Time (minutes)
Passenger Cars	10	0.97	2.28	4.1	6.38
Light Trucks	13	1.08	2.53	4.3	6.83

The agencies assume that all of the round-trip time necessary to travel to and from the fueling station is a part of the fixed time component of each refueling event. However, some portion of the time to fill and pay is also a part of the fixed time component. Given the information in Table VI-229, the agencies assume that each refueling event has a fixed time component of 3.5 minutes. E.g., (for passenger cars) the sum of 2.28 minutes round trip time to/from fueling station and roughly 1.2 minutes to select and pay for fuel, remove/recap fuel tank, remove/replace fuel nozzle, etc. The time to fill the fuel tank is the variable time component; e.g., about 2.9 minutes for passenger cars (2.28 + 1.2 + 2.9 = 6.38 total minutes). However, the CAFE model uses a different methodology to determine the variable time component, which is explained below.

Cars have average tank sizes of about 15 gallons, SUVs/vans of about 18 gallons, and pickups of about 27 gallons (*see* Table VI-230 through Table VI-232 in discussion of the legacy fleet). It is a reasonable assumption that the average passenger car has a tank of 15 gallons and the average light truck has a tank of 20 gallons (there are more SUVs/vans than pickups in the light truck fleet). From these assumptions, it is calculated that the average refueling event fills approximately 65 percent of the fuel tank for both passenger cars and light trucks. This value is used as an input in the CAFE model for all three body styles (cars, SUVs/vans, and pickups).

Finally, the rate of the pump flow can be calculated either as the total gallons pumped over the assumed variable time component (approximately 3 minutes) or as the difference in the average number of gallons filled between light trucks and passenger cars over the difference in the time to fill and pay between the two classes. The first methodology implies a rate between 3 and 4 gallons per minute. Although the second methodology implies a rate of 15 gallons per minute, there is a legal restriction on the flow of gasoline from pumps of 10 gallons per minute.[1999] Thus, the agencies assume the rate of gasoline pumps range between 4 and 10 gallons per minute, and use 7.5 gallons per minute—a value slightly above the midpoint of that range—as the average flow rate in the CAFE model.

[1999] 40 CFR 80.22 (j), Regulation of Fuels and Fuel Additives - subpart B. Controls and Prohibitions, *available at* https://www.law.cornell.edu/cfr/text/40/80.22.

The calculations described above are repeated for each future calendar year that light-duty vehicles of each model year affected by the CAFE standards considered in this rule would remain in service for each regulatory alternative. The resulting cumulative lifetime valuations of time savings account for both the reduction over time in the number of vehicles of a given model year that remain in service and the reduction in the number of miles (VMT) driven by those that stay in service. After calculating the absolute value for each regulatory alternative using the methodology and inputs described above, the model calculates the incremental value relative to the baseline as the refueling cost or benefit for that regulatory alternative. More efficient vehicles have to be refueled less often and refueling costs per vehicle decline. In previous rules this was sufficient to account for the majority of any changes in cost of refueling under different CAFE standards as the modelling permitted, since the volumes of new vehicles and existing vehicles on the road was assumed to be constant under all possible standards. However, when sales and scrappage models are included the distribution of new and vehicles varies and a different number of miles will be driven by new and used vehicles in each regulatory alternative.

IPI commented that it was inappropriate for the agencies to exclude benefits from reducing the frequency of refueling events where the primary reason for stopping at a fuel station was not to refuel a vehicle. IPI argued that fuel efficiency impacts from relaxed standards would affect all drivers regardless of their rationale for refueling, by requiring either more frequent or marginally longer refueling events.[2000] The agencies note that the language in the NPRM suggested that the agencies eliminated 40 percent of the potential benefit from fewer refueling stops—where 40 percent represents the fraction of refueling stops that were routinely scheduled or otherwise not made in response to a low fuel reading—and this appears to have been the origin of IPI's concern.[2001] In fact, the agencies did *not* apply a 40 percent discount factor to the refueling benefits; instead, the total number of additional refueling events that would result from alternative CAFE levels was calculated, and these were valued based on an assumption that their characteristics (e.g. vehicle occupancy) would match those of drivers who refueled due to a low fuel reading.

To the extent that lower fuel economy affects those who refuel on a routine schedule or incidental to stops made primarily for other reasons, the per-event cost would actually be limited to the extra time spent pumping a slightly larger volume of fuel. However, the agencies note that by assuming that all extra fuel consumed under lower CAFE standards results in added refueling trips, the agencies are adopting a conservative assumption, in the sense that it maximizes the disbenefits of alternatives to the current standards.

IPI also expressed concern that the agencies may have excluded the fuel costs and added emissions from additional miles driven in the course of the more frequent refueling events that would be required with more lenient CAFE standards, and correspondingly lower on-road fuel economy.[2002] In the NPRM, the agencies asserted that these added costs are reflected in their overall estimates of fuel cost savings, while any increase in emissions is also reflected in the

[2000] IPI, Appendix, NHTSA-2018-0067-12213, at 54-55.
[2001] *See* 83 FR 43088 (Aug. 24, 2018).
[2002] IPI, Appendix, NHTSA-2018-0067-12213, at 55.

reported changes in total emissions. However, IPI noted that the agencies did not clearly explain how these cost savings and emissions reductions are actually accounted for in their methodology.

The agencies' methodology fully accounts for both of these impacts through its calculation of changes in the use of new cars and light trucks due to the fuel economy rebound effect, which captures the impact on their aggregate use (VMT) that results from changes in the fuel cost of driving each mile. Studies that estimate the rebound effect analyze the relationship between VMT per time period and fuel economy or per-mile fuel costs, using data for individual vehicles, fleet-wide average values, or aggregate estimates for an entire fleet. Regardless of the level of aggregation they employ, their measures of vehicle use invariably include travel for all purposes, including any extra miles driven in the course of refueling.

Thus, the estimates of the rebound effect—the response of vehicle use to changes in fuel economy or per-mile fuel costs—inevitably capture any change in the number of miles driven for the purpose of refueling that occurs in response to higher or lower fuel economy. This change reflects the net effect of more or less frequent refueling trips required by their baseline or "pre-rebound" level of use, and any change in the number of refueling trips associated with increased or reduced driving in response to the rebound effect.

As a consequence, the agencies' estimates of changes in aggregate fuel consumption and fuel costs incorporate—that is, are net of—the volume and cost of fuel consumed by changes in vehicle use that result from the rebound effect, *including* any change in driving associated with more or less frequent refueling. Similarly, the agencies' estimates of changes in emissions resulting from vehicle storage and use (referred to as "tailpipe" or "downstream" emissions) are derived by applying per-mile emission factors to changes in aggregate vehicle travel, so they necessarily incorporate changes in vehicle use for all purposes, including more or less frequent refueling.

Furthermore, as the agencies demonstrated in the proposal with a practical example, the benefit associated with fewer miles spent refueling is *less than* 23¢ per year for new vehicles. The cumulative impact of this benefit amounts to less than one tenth of percent of the costs of the rule.[2003]

Because all of the alternative standards evaluated in this rulemaking would permit lower fuel economy levels than under the baseline standard, per-mile driving costs would be higher and total vehicle use would decline in response. Although some (perhaps most) new vehicles would require more frequent refueling, the agencies' estimates of the change in aggregate use of new vehicles reflects (i.e., is net of) any increase in driving associated with more frequent refueling stops. As a result, the agencies' estimates of changes in total fuel consumption, aggregate fuel costs, and emissions resulting from the lower fuel economy levels that relaxing CAFE standards would permit reflect the *net* reduction in use of new cars and light trucks due to the fuel economy

[2003] *See* 83 FR at 43088. Also, note that the 23 cents estimate was derived for a less stringent alternative than today's standards and included taxes which would have been removed had the agencies calculated this number separately.

rebound effect, after considering any additional miles that would be driven in the course of more frequent refueling stops.

(c) Including the Legacy Fleet

Under more stringent regulatory alternatives, more miles will be driven by older and less efficient vehicles, and the effect is to reduce or eliminate any refueling benefit from increasing the fuel efficiency of new vehicles. Failing to include the existing fleet makes the costs of refueling artificially lower under more stringent standards because new vehicle sales are lower and not only because new vehicles are more efficient. This update to the calculation of the absolute refueling costs corrects this oversight present in the NPRM cost-benefit analysis by calculating fleet-wide absolute refueling costs before considering the incremental change relative to the baseline.

For other portions of the CAFE model, the agencies track the legacy vehicles by body style and vintage, using average measures for fuel economy, horsepower and curb weight. To estimate refueling costs for these vehicles, measures of average fuel tank sizes by body style and vintage are needed. The agencies are unaware of any data that directly estimates this value, but an estimate can be derived from publicly available data on fuel tank sizes of 17 high-volume nameplates with long histories. The tank sizes are averaged by body style, and these historical values are used as estimates of the average by body style and vintage. The vehicles included, their fuel tank sizes, and the averages are reported in Table VI-230 through Table VI-232 for cars, vans/SUVs, and pickups, respectively. The averages are used to represent the fuel tank sizes by vintage and vehicle body style. The agencies used the fuel tank sizes from Table VI-230 to Table VI-231 to determine the number of refueling events and time spent refueling to compute refueling costs using the methodology described above.

(d) Including Electric Vehicle Recharging

In addition to adding the refueling costs associated with the "legacy fleet," this update adds the cost to recharge electric vehicles to the total refueling costs. Excluding the time spent recharging ignores a real cost borne by owners of electric vehicles, one which was noted by multiple commenters. For example, Ariel Corp. and VNG.co LLC commented that, "EVs require significant changes in consumer fueling behavior given the need to park at recharging points for long periods of time."[2004]

In order to do so, it is important to first understand how many electric vehicle charging events will require the driver to wait and for how long. The answer to this question depends on the range of the electric vehicle and the length of the trip.[2005] For trips shorter than the range, the driver can recharge the vehicle at times that will not require them to be actively waiting and thus there is no recharging cost. Only for trips where the vehicle is driven more miles than the range will the driver have to stop at mid-trip, a time that is assumed to be inconvenient, to recharge the vehicle at least enough to reach the intended destination.

The agencies use trip data from the National Household Transportation Survey (NHTS) to estimate the frequency and expected length of trips that exceed the range of the electric vehicle technologies in the simulation (200 and 300 mile ranges).

The NHTS data is collected from a representative random sample of U.S. households. The survey collects data on individual trips by mode of transportation. A trip is defined by the starting and ending point for any personal travel, so that vehicle trips will capture any time a car is driven. The survey includes identification numbers for households, individuals, and vehicles, and mode of transportation (including the body style of the vehicle for vehicle trips), and the date of the trip. Although some trips made in the same day may allow for convenient charging in between trips, the agencies assume that travel in the same day exceeding the range will involve the driver waiting for the vehicle to charge. Thus, the total number of miles driven by the same vehicle in a single day is summed, and it is assumed that charging stations are not conveniently available to the driver in between.

Some of the trips in the NHTS have missing information about the duration or length of the trip; these trips are excluded from the dataset. The agencies subset the dataset into three body styles—cars, vans/SUVs, and pickups—consistent groupings with how the VMT schedules and scrappage rates are estimated. The agencies exclude data on taxis and rental cars as the body

[2004] Ariel Corp. and VNG.co LLC, Comment, NHTSA-2018-0067-7573, at 13.
[2005] While the range of EVs is dependent on a number of factors, such as that grade, acceleration, and weather, the agencies take a conservative approach and assume a best-case scenario.

style of the vehicle for these trips is not specified (they make up only 0.3 percent of the dataset, so their exclusion is unlikely to alter the estimate). Table VI-233, below, shows the resulting quantiles of the distribution of daily travel for all vehicles considered in the final dataset. This will include multiple days of travel for the same vehicle if more than one day of trip data is recorded in the NHTS.

Table VI-233 – Distribution of Per-Vehicle Daily Miles by Vehicle Type

Percentile	No. Obs.	0th	25th	50th	75th	100th
Car	113,256	0	8	18	38	1,256
SUVs/Vans	79,260	0	8	18	38	1,425
Pickups	31,733	0	9	20	42	1,343
Rentals	723	0	13	32	91	910
Taxis	1,673	0	3	7	15	422

The data in Table VI-233 shows that excluding taxis and rentals may be the best choice even if their body styles were known. For taxi trips, only the number of trips an individual driver makes in a day is known. The number of trips that the taxi cab itself makes in a day is unknown. As can be seen, the distribution of "daily" travel is to the left for taxis because not all trips for those vehicles are reported. Thus, including these vehicles would incorrectly skew the daily travel rates downwards.

The distribution of trip lengths for rental cars, on the other hand, is generally to the right of trips taken privately-owned vehicles. This is likely because individuals are travelling longer distances when they are on vacation or otherwise out-of-town. It seems likely that individuals renting cars for longer trips will not choose electric vehicles for such temporary travel. Thus, including these trips in the dataset would likely overestimate the number of mid-trip charging events necessary for ordinary travel in a way that will not match what actually occurs.

From the final body style datasets, the agencies are able to calculate two measures that allow for the construction of the value of recharging time. First, the expected distance between trips that exceed the range of 200-mile and 300-mile BEVs (BEV200 and BEV300, respectively) is calculated. This is calculated as the quotient of the sum of total miles driven by each individual body style and the total number of trips exceeding the range, as shown below:

$$Charge\ Frequency_{Style,Range} = \frac{\sum_{Trip\ \epsilon\ Style} Trip\ Length}{\sum_{Trip\ \epsilon\ Style}[Trip\ Length > Range]}$$ [2006]

This calculates the expected frequency of enroute recharging events, or the amount of miles traveled per inconvenient recharging event. This is used later used to calculate the total expected time to recharge a vehicle.

[2006] The denominator counts the number of incontinent recharging events by body style. It is not a measurement of VMT.

The second measure needed to calculate the total expected recharging time is the expected share of miles driven that will be charged in the middle of a trip (causing the driver to wait and lose the value of time). In order to calculate this measure the difference of the trip length and range is summed, conditional on the trip length exceeding the range for each body style. This figure is then divided by the sum of the length of all trips for that body style. See the equation below:

$$Share\ Charged_{Style,Range} = \frac{\sum_{Trip\ \epsilon\ Style}([Trip\ Length > Range] * (Trip\ Length - Range))}{\sum_{Trip\ \epsilon\ Style} Trip\ Length}$$

The calculated frequency of inconvenient charging events and share of miles driven that require the driver to wait for BEV's with 200 and 300-mile ranges are presented in Table VI-234, below. As the table shows, cars are expected to require less frequent inconvenient charges and a smaller share of miles driven will require the driver to charge the vehicle in the middle of a trip. Pickups and vans/SUVs have fairly similar measures, with vans and SUVs requiring slightly more inconvenient charging than pickups.

Table VI-234 – Electric Vehicle Recharging Thresholds by Body Style and Range

Body Style	**Cars**	**Vans/SUVs**	**Pickups**
Miles until mid-trip charging event, BEV200	2,000z	1,500	1,600
Miles until mid-trip charging event, BEV300	5,200	3,500	3,800
Share of miles charged mid-trip, BEV200	6%	9%	8%
Share of miles charged mid-trip, BEV300	3%	4%	4%

The measures presented in Table VI-234, above, can be used to calculate the expected time drivers of electric vehicles of a given body style and range will spend recharging at a time that will require them to wait. First the agencies calculate the expected number of refueling events for a vehicle of a given style and range in a given calendar year. This is shown below as the expected miles driven by a vehicle in a given calendar year divided by the charge frequency of a vehicle of that style and range (from Table VI-234).

$$Recharge\ Events_{CY,Veh\ \epsilon\ (Style\ \cup\ Range)} = \frac{Miles_{CY,Veh}}{Charge\ Frequency_{Style,Range)}}$$ [2007]

Next the agencies calculate the number of miles charged for a vehicle of a given style and range in a specific calendar year. This is the product of the number of miles driven by the

[2007] Note that $\sum_{Trip\ \epsilon\ Style} Trip\ Length$ and $Miles_{CY,Veh}$ are different values. $Miles_{CY,Veh}$ is the estimated amount of VMT predicted by VMT while $\sum_{Trip\ \epsilon\ Style} Trip\ Length$ is the sum of trips observed by the NHTS study.

vehicle and the share of miles driven that require an inconvenient charge for a vehicle of that style and range (from Table VI-234), as presented below:

$$Miles\ Charged_{CY,Veh\ \epsilon\ (Style\ \cup\ Range)} = Miles_{CY,Veh} * Share\ Charged_{Style,Range}$$

Then, the expected time that a driver of an electric vehicle of a given style and range will spend waiting for the vehicle to charge is calculated. This is the product of the fixed amount of time it takes to get to the charging station and the number of recharging events plus the quotient of the expected miles that will require inconvenient charging over an input assumption of the rate of which a vehicle of that style and range can be charged in a given calendar year (expressed in units of miles charged per hour). The fixed amount of time it takes to get to a charging station is set equal to the average time it takes for an ICE vehicle to get to a gas station for a refueling event, as discussed above.[2008] This is shown below:

$$Charge\ Time_{CY,Veh\ \epsilon\ (Style\ \cup\ Range)} = (Fixed_{Veh} * Recharge\ Events_{CY,Veh}) + \frac{Miles\ Charged_{CY,Veh}}{Charge\ Rate_{CY,Veh}}$$

The expected time that a driver will wait for their vehicle to charge can then be multiplied by the value of time estimate, as is done with gasoline, diesel, and E85 vehicles (see description above of the current approach to accounting for refueling time costs).

It is worth a final note to talk about how plug-in hybrids are treated in the modelling (which remains unchanged from the NPRM). Presumably, plug-in hybrids that are taken on a trip that exceeds their electric range will be driven on gasoline and the driver will recharge the battery at a time that is convenient. For this reason, the electric portion of travel should be excluded from the refueling time calculation. The gasoline portion of travel is treated the same as other gasoline vehicles so that when the tank reaches some threshold, the vehicles is assumed to be refueled with the same fixed event time and the same rate of refueling flow.

The NPRM calculation of refueling benefits did not account for the impacts of fleet turnover—specifically the impact on “legacy” fleet vehicles and new electric vehicles. However, when the quantities of vehicles on the road varies between scenarios it becomes important to calculate the refueling costs for all vehicles since fuel economy and tank sizes (and therefore range before refueling) vary with vintage. This updated analysis adds these elements to the calculation of the refueling time and costs and is thus a more accurate estimation of the refueling benefit.

(11) Energy Security

By amending existing standards, the final rule is expected to increase domestic consumption of gasoline by a relatively minimal amount relative to the baseline standards finalized in 2012, producing a correspondingly small increase in the Nation’s demand for crude

[2008] The agencies note that this is a conservative estimate. Gas stations vastly outnumber publicly available recharging stations and are often in more convenient locations.

petroleum, a commodity that is traded actively in a worldwide market. Specifically, the agencies project that this rule will increase gasoline consumption by cars and light trucks produced during model years 1978 through 2029 by 3.1 percent.[2009] Although the U.S. accounts for a sufficient (albeit diminishing) share of global oil consumption that the resulting increase in global petroleum demand will exert some upward pressure on worldwide prices, the rule is projected to increase global petroleum demand by less than one half of one percent from 2017 through 2050, so its effects on global prices is likely to be minimal.

U.S. consumption and imports of petroleum products has three potential effects on the domestic economy that are often referred to collectively as "energy security externalities," and increases in their magnitude are sometimes cited as possible social costs of increased U.S. demand for petroleum.m First, any increase in global petroleum prices that results from higher U.S. gasoline demand will cause a transfer of revenue to oil producers worldwide from consumers of petroleum, because consumers throughout the world are ultimately subject to the higher global price that results. Although this transfer is simply a shift of resources that produces no change in global economic welfare, the financial drain it produces on the U.S. economy is sometimes cited as an external cost of increased U.S. petroleum consumption, because consumers of petroleum products are unlikely to consider it.

As the U.S. approaches self-sufficiency in petroleum production (the nation is expected to become a net exporter of petroleum by 2020), this transfer is increasingly *from U.S. consumers of refined petroleum products to U.S. petroleum producers*, so it not only leaves welfare unaffected, but even ceases to be a financial burden on the U.S. economy.[2010] In fact, as the U.S. becomes a net petroleum exporter, any transfer from global consumers to petroleum producers would become a financial benefit to the U.S. economy. Nevertheless, uncertainty in the nation's long-term import-export balance makes it difficult to project precisely how these effects might change in response to increased consumption.

Higher U.S. petroleum consumption can also increase domestic consumers' exposure to oil price shocks and thus increase potential costs to all U.S. petroleum users (including those outside the light duty vehicle sector, whose consumption would be unaffected by today's final rule) from possible interruptions in the global supply of petroleum or rapid increases in global oil prices. Because users of petroleum products are unlikely to consider the effect of their increased purchases on these risks, their economic value is often cited as an external cost of increased U.S. consumption. Finally, some analysts argue that domestic demand for imported petroleum may also influence U.S. military spending; because the increased cost of military activities would not be reflected in the price paid at the gas pump, this is often alleged to represent a third category of external costs form increased U.S. petroleum consumption.

[2009] This includes fuel consumed by cars and light trucks produced during model years 1978-2017 that are on the road today during their remaining lifetimes, as well as fuel consumed by cars and light trucks projected to be manufactured during model years 2018-2029 over their entire lifetimes.

[2010] The United States became a net exporter of oil on a weekly basis several times in late 2019, and EIA's AEO 2019 projects that will do so on a sustained, long-term basis by 2020; *see* EIA, AEO 2019 Reference Case, Table 21 https://www.eia.gov/dnav/pet/hist/LeafHandler.ashx?n=pet&s=wttntus2&f=4

Each of these three costs could rise incrementally—albeit by a very limited magnitude—as a consequence of increases in U.S. petroleum consumption—likely to result from the final rule. This section describes the extent to which each cost is expected to increase as a result of this action, whether it represents a significant economic cost (or simply a transfer of resources), and how the agencies have measured each cost and incorporated it into their analysis.

(a) U.S. Petroleum Demand and its Effect on Global Prices

Figure VI-140 illustrates the effect of the increase in U.S. fuel and petroleum demand anticipated to result from reducing CAFE and CO_2 standards on global demand for petroleum and its market price. The marginal increase in domestic demand can be represented as an outward shift in the U.S. demand curve for petroleum from its position at $D_{US,0}$ with the baseline standards for future model years in effect, to $D_{US,1}$ with the final rule standards replacing them. Because global demand is simply the sum of what each nation would purchase at different prices, the outward shift in U.S. demand causes an identical shift in the global demand schedule, as the figure shows.[2011]

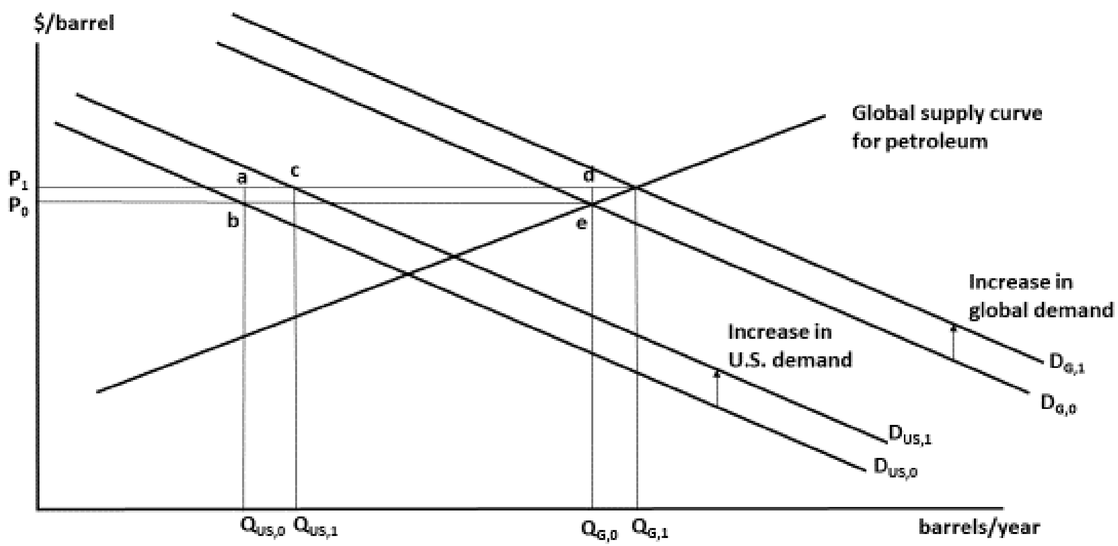

Figure VI-140 – Effect of U.S. Petroleum Demand on Global Prices and Purchases

The global supply curve for petroleum slopes upward, reflecting the fact that it is progressively costlier for oil-producing nations to explore for, extract, and deliver additional

[2011] The figure exaggerates the U.S. share of total global consumption, which currently stands at 20 percent, for purposes of illustration.

supplies of oil to the world market.[2012] Thus the upward shifts in the U.S. and world demand schedules cause an increase in the global price for oil, from P_0 to P_1 in the figure. U.S. purchases of petroleum increase from $Q_{US,0}$ to $Q_{US,1}$, but the resulting increase in global consumption from $Q_{G,0}$ to $Q_{G,1}$ will be slightly smaller than the increase in U.S. demand and purchases, because the amount of petroleum other nations purchase will decline slightly in response to its higher price. Spending on petroleum by U.S. buyers who purchase the additional oil will increase by the area $Q_{US,0}acQ_{US,1}$, the product of its new, higher price P_1 and the increase in U.S. consumption, $Q_{US,1} – Q_{US,0}$, while spending by U.S. consumers whose purchases remain unchanged will increase by the product of their previous purchases $Q_{US,0}$ and the price increase P_1-P_0, or the area P_1abP_0.

CARB asserted in their comments, that the NPRM analysis was biased against the baseline standards because the fuel prices in the NPRM were based on a unique run of DOE's NEMS model that included the baseline.[2013] They argued that the proposal would have reduced fleet average fuel economy, leading to increased demand and subsequently higher fuel prices faced by consumers. As a result, the additional fuel costs associated with the proposal (relative to the baseline) should have been even higher than estimated because the fuel price faced by drivers in that scenario would have been higher than in the baseline. However, while the difference between the baseline and preferred alternative could create differences in fleet fuel economy in a manner that could influence prices at the pump, those differences are likely to be small. In response to CARB's comments, the agencies conducted additional runs with NEMS to compare the fuel price under the baseline standards and the fuel price under the proposed standards. Through 2050, the fuel price difference between the alternatives was never higher than two percent. The standards being finalized in this rule are considerably closer to the baseline than were those in the proposal.

SAFE commented that the United States is a "price-taker" in the global market and "must accept the prevailing global oil price since it lacks sufficient market power to influence decisively this price."[2014] This comment, however, is directly at odds with both the economics of the world oil market shown in Figure VI-140 above and other comments asserting that the increase in U.S. gasoline demand resulting from this rule will increase U.S. and global petroleum demand, thus increasing world oil prices. In response to the comment from SAFE, the agencies utilized a forecast of fuel prices in today's analysis that considers the effect of the revised standards on global petroleum demand and prices. This assumption slightly increases the cost of forgone fuel savings in the preferred alternative, compared to their value under the assumption that U.S. demand cannot change global prices and the nation acts as a price-taker.

[2012] The figure depicts the relationship between the global supply of petroleum and its worldwide price during a single time period. The global supply curve for petroleum has been shifting outward over time in response to increased investment in exploration, the ability of refineries to utilize feedstocks other than conventional petroleum, and technological innovations in petroleum extraction. The combination of these developments may also have reduced its upward slope, meaning that global supply now increases by more in response to increases in the world price than it once did.
[2013] NHTSA-2018-0067-11873.
[2014] NHTSA-2018-0067-11981.

In Figure VI-140, the increase in the price of oil from P_0 to P_1 will mean that global consumers who previously purchased the quantity of oil $Q_{G,0}$ at its lower price will now pay more for that same amount. Specifically, previous purchasers will pay the additional area P_1deP_0, whose value is the increase in price P_1-P_0 multiplied by the volume they originally bought, $Q_{G,0}$. Of this increase in revenue to oil producers, the rectangular area P_1abP_0—which as indicated above is the product of the increase in price P_1-P_0 and previous U.S. purchases $Q_{US,0}$, and thus measures the increase in spending by previous U.S. consumers—is simply transferred from U.S. consumers to global oil suppliers.[2015] The remaining fraction of increased payments to producers, the rectangular area adeb, whose value is the product of the price increase P_1-P_0 and previous purchases by other nations, which were $Q_{G,0} – Q_{US,0}$, is a transfer from consumers outside the U.S. to global oil producers.

The total increase in global spending—including the additional spending by U.S. consumers as well as by those in other nations—on the amount of oil they previously purchased is simply a transfer of revenue from consumers of petroleum products to oil producers. This transfer can be described as a "pecuniary" externality, since it describes the effect of the price increase on wealth allocation, but is considered separately from any effects on quantity produced and consumed. Some of the increase in payments by U.S. consumers for the petroleum products they originally consumed may be made to foreign-owned oil producers, and thus represents a financial drain on the U.S. economy, while the remainder is received by domestic producers and thus remains within the U.S. economy.[2016]

To an increasing extent, however, the additional payments by U.S. consumers that result from upward pressure on the world oil price are a transfer *entirely within* the Nation's economy, because a growing fraction of domestic petroleum consumption is supplied by U.S. producers. The U.S. is projected to become a net *exporter* of petroleum in 2020—and in fact became a net exporter in September 2019—and as the Nation moves toward that status, an increasing share of any higher costs paid by U.S. consumers of petroleum products becomes a gain to U.S. oil producers. [2017] When the U.S. becomes self-sufficient in petroleum supply—which is now anticipated to occur in the year this final rule publishes—the *entire* value of increased payments by U.S. petroleum users that results from relaxing CAFE and CO_2 standards will have the same effect as if it were simply a transfer within the U.S. economy. As a consequence, the financial burden that transfers from U.S. consumers to foreign producers places on the U.S. economy will disappear.

Over almost the entire time period spanned by the analysis of this final rule, any increase in domestic spending for petroleum caused by the effect of higher U.S. fuel consumption and petroleum use on world oil prices is expected on balance to be a transfer within the U.S. economy and thus produce no drain on domestic economic resources. For this reason—and

[2015] Note that global oil suppliers include domestic as well as US-owned foreign suppliers.
[2016] Neither transfer, however, has an effect on domestic or global economic welfare.
[2017] The U.S. Energy Information Administration EIA estimates that the United States exported more total crude oil and petroleum products in September and October of 2019, and expects the United States to continue to be a net exporter. *See Short Term Energy Outlook November 2019,* available at https://www.eia.gov/outlooks/steo/archives/nov19.pdf.

because in any case such transfers do not create real economic costs or benefits—increased U.S. spending on petroleum products that results from increased U.S. fuel demand and any resulting upward pressure on petroleum prices stemming from this action is not included among the economic costs accounted for in this final rule.

(b) Macroeconomic Costs of U.S. Petroleum Consumption

In addition to influencing global demand and prices, U.S. petroleum consumption imposes further costs that are unlikely to be reflected in the market price for petroleum, or in the prices paid by consumers of refined products such as gasoline.[2018] Petroleum consumption imposes external economic costs by exposing the U.S. economy to increased risks of rapid increases in prices triggered by global events that may also disrupt the supply of imported oil, and U.S. consumers of petroleum products are unlikely to take such costs into account when making their decisions about how much to consume.

Sudden interruptions in oil supply and rapid increases in its price can impose significant economic costs, because they raise the costs of producing all commodities whose manufacturing and distribution consumes petroleum, thus temporarily reducing the level of output that the U.S. economy can produce using its available supplies of labor and capital. The magnitude of any reduction in economic output depends on the extent and duration of the increases in prices for petroleum products that result from a disruption in global oil supplies, as well as on whether and how rapidly prices return to their pre-disruption levels—which in turn depends largely on the rest of the world's capability to respond to interruptions by increasing production elsewhere. Even if prices for oil return completely to their original levels, however, economic output will be at least temporarily reduced from the level that would have been possible with uninterrupted oil supplies and stable prices, so the U.S. economy will bear some transient losses it cannot subsequently recover.

Supply disruptions and price increases caused by global political events tend to occur suddenly and unexpectedly, so they can also force businesses and households to adjust their use of petroleum products more rapidly than if the same price increase occurred gradually. Rapid substitutions between energy derived from oil and other forms of energy, as well as between energy and other inputs, and other changes such as adjusting production levels and downstream prices, can be costly for businesses to make. As with businesses, sudden changes in energy prices and use are also difficult for households to adapt to quickly or smoothly, and doing so may impose at least temporary costs or losses in utility for the various adjustments they make.

Interruptions in oil supplies and sudden increases in petroleum prices are both uncertain prospects, and the costs of the disruptions they can cause must be weighted or adjusted by the

[2018] *See, e.g.*, Bohi, D. R. & W. David Montgomery (1982), *Oil Prices, Energy Security, and Import Policy* Washington, D.C. - Resources for the Future, Johns Hopkins University Press; Bohi, D. R., & M. A. Toman (1993), "Energy and Security - Externalities and Policies," *Energy Policy* 21:1093-1109; and Toman, M. A. (1993). "The Economics of Energy Security - Theory, Evidence, Policy," in A. V. Kneese and J. L. Sweeney, eds. (1993), *Handbook of Natural Resource and Energy Economics, Vol. III*, Amsterdam - North-Holland, pp. 1167-1218.

probability that they will occur, as well as for their uncertain duration. The agencies estimate this expected cost of such disruptions by combining the probabilities that price increases of different magnitudes and durations will occur during the future period spanned by their analysis with the costs of reduced U.S. economic output and abrupt adjustments to sharply higher petroleum prices. Any *change* in the probabilistic "expected value" of such costs that can be traced to higher U.S. fuel consumption and petroleum demand stemming from this final rule to establish less demanding fuel economy standards is considered to be an external cost of the adopting it.

A variety of mechanisms exist to "insure" against higher petroleum prices and reduce their costs for adjusting to sudden price increases, including making purchases or sales in oil futures markets, adopting energy conservation measures, diversifying the fuel economy levels within the set of vehicles owned by the household, locating where public transit provides a viable alternative to driving, and installing technologies that permit rapid fuel switching. Growing reliance on such measures, coupled with continued improvements in energy efficiency throughout the economy, has certainly reduced the vulnerability of the U.S. economy to the costs of oil shocks in recent decades.

Thus, there is now considerable debate about the magnitude and continued relevance of potential economic damages from sudden increases in petroleum prices. The petroleum intensity of the U.S economy has declined considerably and global oil prices are dramatically lower than when analysts first identified and quantified the risks they create to the U.S. economy. Further, not only has the Nation dramatically increased its own petroleum supply, but other new global supplies have emerged as well, both of which reduce the potential impact of disruptions that occur in unstable or vulnerable regions where oil is produced.

As a consequence, the potential macroeconomic costs of sudden increases in oil prices are now likely to be considerably smaller than when they were original identified and estimated. Research by the National Research Council (2009) argued that non-environmental externalities associated with dependence on foreign oil are small, and perhaps trivial.[2019] Research by Nordhaus and by Blanchard and Gali have also questioned how harmful to the economy oil price shocks have been, noting that the U.S. economy actually expanded immediately after the most recent oil price shocks, and that there was little evidence of higher energy prices being passed through to higher wages or prices.[2020]

[2019] National Research Council, *Hidden Costs of Energy - Unpriced Consequences of Energy Production and Use,* National Academy of Sciences, Washington, D.C. (2009).

[2020] Nordhaus argues that one reason for limited vulnerability to oil price shocks is that monetary policy has become more accommodating to the price impacts, while another is that U.S. consumers and businesses may determine that such movements are temporary and abstain from passing them on as inflationary price increases in other parts of the economy. He also notes that changes in productivity in response to recent oil price increases are have been extremely modest, observing that "energy-price changes have no effect on multifactor productivity and very little effect on labor productivity." at p. 19. Blanchard and Gali (2010) contend that improvements in monetary policy, more flexible labor markets, and the declining energy intensity of the U.S. economy (combined with an absence of concurrent shocks to the economy from other sources) lessened the impact of oil price shocks after 1980. They find

Since these studies were issued in 2009 and 2010, the petroleum intensity of the U.S. economy has continued to decline while domestic energy production has increased in ways and to an extent that experts failed to predict, so that the U.S. became the world's largest producer in 2018.[2021] The U.S. shale oil revolution has both established the potential for energy independence and placed downward pressure on prices. Lower oil prices are also a result of sustained reductions in U.S. consumption and global demand resulting from energy efficiency measures, many undertaken in response to previously high oil prices.

Reduced petroleum intensity and higher U.S. production have combined to produce a decline in U.S. petroleum imports—to approximately 20 percent of domestic consumption in 2017—which permits U.S. supply to act as a buffer against artificial or natural restrictions on global petroleum supplies due to military conflicts or natural disasters. In addition, the speed and relatively low incremental cost with which U.S. oil production has increased suggests that both the magnitude and (especially) the duration of future oil price shocks may be limited, because U.S. production offers the potential for a large and relatively swift supply response.

And while some risk of price shocks certainly still exists, even the potential for a large and swift U.S. production response may be playing a role in limiting the extent of price shocks attributable to external events. The large-scale attack on Saudi Arabia's Abqaiq processing facility—the world's largest crude oil processing and stabilization plant—on September 14, 2019 caused "the largest single-day [crude oil] price increase in the past decade," of between $7 and $8 per barrel, according to EIA.[2022] The Abqaiq facility has the capacity to process 7 million barrels per day, or about 7 percent of global crude oil production capacity. EIA declared, however, that by September 17, only three days after the incident:

> Saudi Aramco reported that Abqaiq was producing 2 million barrels per day, and they expected its entire output capacity to be fully restored by the end of September. In addition, Saudi Aramco stated that crude oil exports to customers will continue by drawing on existing inventories and offering additional crude oil production from other fields. Tanker loading estimates from third-party data sources indicate that loadings at two Saudi Arabian export facilities were restored to the pre-attack levels. Likely driven

that "the effects of oil price shocks have changed over time, with steadily smaller effects on prices and wages, as well as on output and employment...The message…is thus optimistic in that it suggests a transformation in U.S. institutions has inoculated the economy against the responses that we saw in the past." at p. 414; *See* William Nordhaus, "Who's Afraid of a Big Bad Oil Shock?" Available at http://aida.econ.yale.edu/~nordhaus/homepage/Big_Bad_Oil_Shock_Meeting.pdf; and Blanchard, Olivier and Jordi Gali, J., "The Macroeconomic Effects of Oil price Shocks - Why are the 2000s so Different from the 1970s?," in Gali, Jordi and Mark Gertler, M., eds., *The International Dimensions of Monetary Policy*, University of Chicago Press, February (2010), pp. 373-421, available at http://www.nber.org/chapters/c0517.pdf.

[2021] *See* U.S. Energy Information Administration EIA, *Today in Energy August 20, 2019*, available at https://www.eia.gov/todayinenergy/detail.php?id=40973; *Today in Energy September 12, 2018*, available at https://www.eia.gov/todayinenergy/detail.php?id=37053

[2022] https://www.eia.gov/todayinenergy/detail.php?id=41413 by news of the expected return of the lost production capacity, both Brent and WTI crude oil prices fell on Tuesday, September 17.[2023]

Thus, the largest single-day oil price increase in the past decade was largely resolved within a week, and assuming very roughly that average crude oil prices were $70/barrel in September 2019 (slightly higher than actual), an increase of $7/barrel would represent a 10 percent increase as a result of the Abqaiq attack. Contrast this with the 1973 Arab oil embargo, which lasted for months and raised prices 350 percent.[2024] Saudi Arabia could have experienced increased revenue resulting from higher prices following the Abqaiq attack, but instead moved rapidly to restore production and tap reserves to control the risk of resulting price increases. In doing so, the Saudis likely recognized that sustained, long-term price increases would reduce their ability to control global supply (and thus prices and their own revenues) by relying on their lower cost of production.[2025]

Some commenters asserted that U.S. shale oil resources cannot serve as "swing supply" to provide stability in the face of a sudden, significant global supply disruption (Jason Bordoff, SAFE).[2026, 2027] Despite its greater responsiveness to price changes, commenters argued that lead time to bring new shale resources to market (6-12 months) is inferior to "true spare capacity" (like Saudi Arabia's large oil fields) because it cannot be deployed quickly enough to mitigate the economic consequences resulting from rapidly rising oil prices. Bordoff, however, also notes that shale oil projects' lead times are still shorter—and possibly much shorter—than conventional oil resource development. So, while new U.S. oil resources may take some time to respond to supply disruptions, they are nevertheless likely to provide a stabilizing influence on supply.

This is especially true for price increases that occur more slowly. When Beccue and Huntington updated their 2005 estimates of supply disruption probabilities in 2016,[2028] they found that the probability distribution was generally flatter—suggesting that supply disruptions of most potential magnitudes were less likely to occur under today's market conditions than they had estimated previously in 2005. In particular, Beccue and Huntington find that supply disruptions of between two and four million barrels per day are significantly less likely than their previous estimates suggested. Although their recent study also estimated that larger supply disruptions (nine or more million barrels per day) are now slightly more likely to occur than in

previous estimates, disruptions of that magnitude are extremely unlikely under either set of estimates.

Based on this review of the literature, the agencies concede that shale resources may not be able to stabilize oil markets fully to prevent a price increase associated with a large supply disruption elsewhere in the world. However, if supply disruptions are small enough, or move slowly enough, U.S. resources may be an adequate stabilizer.

The agencies reviewed further research that emphasizes the continued threat to the U.S. economy posed by the potential for sudden increases in global petroleum prices.[2029] For example, Ramey and Vine (2010) note "remarkable stability in the response of aggregate real variables to oil shocks once we account for the extra costs imposed on the economy in the 1970s by price controls and a complex system of entitlements that led to some rationing and shortages."[2030] In contrast, another recent study found that while the likely effects of sudden oil price increases have become smaller over time, the declining sensitivity of petroleum demand to prices means that any future disruptions to oil supplies will have larger effects on petroleum prices, so that on balance their economic impact is likely to remain significant.[2031]

Some commenters (SAFE, CARB, Fuel Freedom Foundation, IPI) expressed skepticism that the United States could become a net petroleum exporter in the future without the continuation of the baseline standards. They cautioned that the global oil market is inherently uncertain, and Bordoff cautioned that America's shale resources may not last as long, or be as easy to develop, as they currently appear.[2032] If the U.S. does not become a net exporter of petroleum as anticipated, any wealth effects from a high price of oil would continue to accrue to foreign owners of oil reserves. In addition, several of these commenters (CARB, SAFE, Bordoff, Zozana) argued that, regardless of whether or not the U.S. becomes a net petroleum exporter, its levels of petroleum consumption make it still vulnerable to price shocks arising in the global oil market.

The agencies believe that the United States lacks the power (significantly) to control the global oil price and as a consequence remains vulnerable to the effects of oil price spikes, regardless of our own oil output. Geopolitical factors influence the global oil price—unstable regimes are often unreliable suppliers, large suppliers attempt strategically to manage supply to

---

[2029] Hamilton (2012) reviewed the empirical literature on oil shocks and concluded that its findings are mixed, noting that some recent research (*e.g.,* Rasmussen and Roitman, 2011) finds either less evidence for significant economic effects of oil price shocks or declining effects (Blanchard and Gali 2010), while other research finds evidence of their continuing economic importance. *See* Hamilton, J. D., "Oil Prices, Exhaustible Resources, and Economic Growth," *in Handbook of Energy and Climate Change* available at http://econweb.ucsd.edu/~jhamilto/handbook_climate.pdfhttp://econweb.ucsd.edu/~jhamilto/handbook_climate.pdf.

[2032] NHTSA-2018-0067-10718.

influence price or retain market share, and international negotiations around politically sensitive topics can influence the production behavior of firms in oil-rich nations. All of these factors, as well as wars and natural disasters, can influence the global supply and the market price for oil.

In this analysis, any increase in the expected value of potential costs from economy-wide disruptions caused by sudden price increases that results from higher U.S. fuel and petroleum demand is accounted for separately from the direct cost for increased purchases of petroleum products. Consumers of petroleum products are unlikely to consider their contributions to these costs when deciding how much energy to consume, because those costs will be distributed widely throughout the economy, falling largely on businesses and households other than those whose decisions impose them. Thus, they represent an external (or "social") cost that users of petroleum energy such as transportation fuel are unlikely to internalize fully, and the agencies analysis includes the estimated increase in these costs among of the social costs stemming from the final rule. While increased U.S. petroleum production may impose some limits on their potential magnitude, their underlying source continues to be domestic petroleum *use* rather than imports.

Although the vulnerability of the U.S. economy to oil price shocks depends on aggregate petroleum consumption rather than on the level of oil imports, variation in U.S. oil imports may itself have some effect on the frequency, size, or duration of sudden oil price increases. The expected value of the resulting economic costs would also depend partly on the fraction of U.S. petroleum use that is supplied by imports. While total U.S. petroleum consumption is the primary determinant of potential economic costs to the Nation from rapid increases in oil prices, the estimate of these costs that have been relied upon on in past regulatory analyses—and in this analysis—is nevertheless expressed per unit (barrel) of *imported* oil. When they are converted to a per-gallon basis, they thus apply to fuel that is either imported in refined form, or refined domestically from imported crude petroleum.

Table VI-235 reports the per-barrel estimates of external costs from potential oil price shocks this analysis uses to estimate the increase in their total value likely to result from this final rule. These values differ from those used in previous analysis of CAFE and CO_2 standards. In their comments on the NPRM, SAFE pointed out recent studies that have updated the estimates of the oil security premium since the study—on which the agencies relied upon in the NPRM—had been published. They depend in part on projected future oil prices, the elasticities of consumption with respect to price, income, and U.S. GDP. Since the NPRM values were last updated by the agencies, all of these factors have evolved in directions that would reduce the magnitude of the oil security premium, so continuing to use the NPRM values would have overestimated the increase in expected costs to the U.S. economy from potential oil price shocks calculated in this analysis, perhaps significantly.[2033]

[2033] The costs reported in Table VI-235 also depend on the probabilities or expected frequencies of supply interruptions or sudden price shocks of different sizes and durations. The most recent reassessment of the probabilities on which these estimates are based (which were originally developed in 2005) was conducted in 2016; *see* Beccue, Phillip C. and Hillard G. Huntington, An Updated Assessment of Oil Market Disruption Risks - Final

Specifically, the global petroleum prices projected in EIA's Annual Energy Outlook 2018 Reference Case range from 33-57 percent below those used to develop the estimates used in the NPRM and reported in Table VI-235. U.S. petroleum consumption and imports are now projected to be 3-8 percent and 20-27 percent lower than the forecast values used to construct the NPRM estimates in the table. Finally, total petroleum expenditures are now projected to average 1.5-2.4 percent of U.S. GDP, in contrast to the 3.8-4.0 percent shares reflected in those values. Each of these differences suggests that the values in the NPRM overstated the current magnitude of potential costs to the U.S. economy from the risk of petroleum price shocks, and together they suggest that this overstatement may be significant. Indeed, the values used to support this final rule analysis are sourced from a recent paper by Brown.[2034] Brown updates the underlying parameters used to estimate the oil security premium and finds a range of $0.60 – $3.45 per barrel of imported oil, with a mean of $1.26 per barrel. The study, which was cited by SAFE, determines that the U.S. is less much less sensitive to oil price shocks than earlier estimates imply.[2035] The values used in today's rule reflect that conclusion.

Table VI-235 – Expected Cost of Petroleum Price Shocks from Increased Fuel Imports

Year	**Oil Security Premium (2018$/barrel)[2036]**

2050	10.75	2.61

Because they are expressed per barrel of petroleum that is imported (either in already-refined form as gasoline, or as crude petroleum to be refined domestically), applying these estimates requires the agencies to project of any changes in U.S. petroleum imports that are likely to result from the higher level of fuel consumption anticipated to occur as a result of this final rule. As discussed in detail in Section VI.D.3.c(b)(i) of this final rule, the agencies have elected to retain their previous assumptions that 50 percent of any increase in fuel consumption attributable to the rule will be accounted for through imports in refined form, and that 90 percent of the remaining increase would be refined domestically from imported petroleum. As a consequence, the oil security premiums shown in Table VI-235 are considered to be an external cost associated with 95 percent of the increase in gasoline consumption projected to result from this final rule.[2037]

(c) Potential Effects of Fuel Consumption and Petroleum Imports on U.S. Military Spending

A third potential effect of increasing U.S. demand for petroleum is an increase in U.S. military spending to secure the supply of oil imports from potentially unstable regions of the world and protect against their interruption. If an increase in fuel consumption that results from reducing CAFE and CO_2 standards lead to higher military spending to protect oil supplies, this increase in outlays would represent an additional external or social cost of the agencies' action. Such costs could also include increased costs to maintain the U.S. Strategic Petroleum Reserve (SPR), because it is intended to cushion the U.S. economy against disruptions in the supply of imported oil or sudden increases in the global price of oil.

While several commenters argued that current U.S. military expenditures are uniquely attributable to securing U.S. supplies of petroleum from unstable regions of the globe—the Middle East, in particular—should be considered as a cost of this action (CARB, SAFE, Zonana), they seemed to confuse those costs with the *marginal* impact of increased oil consumption (relative to the baseline) on U.S. military activity and its costs. However, the agencies disagree with commenters that incremental changes to domestic consumption of oil for light-duty transportation could meaningfully change the scope or scale of the U.S. Department of Defense mission in the Persian Gulf region. Instead, they side with the Fuel Freedom Foundation, which noted in its comment, "[i]ncrementally decreasing petroleum consumption does not significantly decrease the military spending to protect and ensure its flow around the world."[2038]

SAFE estimated a per-gallon cost of military externalities associated with U.S. dependence on petroleum products, and imported petroleum specifically.[2039] Their low estimate of $0.28/gallon assumes $81 billion per year for protection of the global petroleum supply and divides those costs by the number of gallons consumed by U.S. drivers. In contrast, a similar analysis by Crane et al. stated, "our analysis addresses the incremental cost to the defense budget of defending the production and transit of oil. It does not argue that a partial reduction of the U.S. dependence on imported oil would yield a proportional reduction in U.S. spending that is focused on this mission. The effect on military cost from such changes in petroleum use would be minimal."[2040] The agencies thus do not believe that any incremental petroleum consumption that may result from this final rule will influence any fraction of U.S. defense spending that can be ascribed to protecting the global oil network.

[2037] The 95 percent figure is calculates at 50 percent plus 90 percent of the remaining 50 percent, or 50 percent plus 45 percent.
[2038] NHTSA-2018-0067-12016.
[2039] NHTSA-2018-0067-11981.
[2040] Crane, K., A. Goldthau, M. Toman, T. Light, S. E. Johnson, A. Nader, A. Rabasa, & H. Dogo, *Imported Oil and U.S. National Security*, Santa Monica, CA, The RAND Corporation (2009) available at https://www.rand.org/pubs/monographs/MG838.html.

Eliminating petroleum imports (to both the U.S. and its national security allies) *entirely* might permit the Nation to scale back its military presence in oil-supplying regions of the globe to the extent that such interventions are driven by narrow concerns for oil production rather than other geopolitical considerations, but there is little evidence that U.S. military activity and spending in those regions have varied over history in response to fluctuations in the Nation's oil imports, or are likely to do so over the future period spanned by this analysis. Figure VI-141 shows that military spending as a share of total U.S. economic activity has gradually declined over the past several decades, and that any temporary—although occasionally major—reversals of this longer-term decline have been closely associated with U.S. foreign policy initiatives or overseas wars.

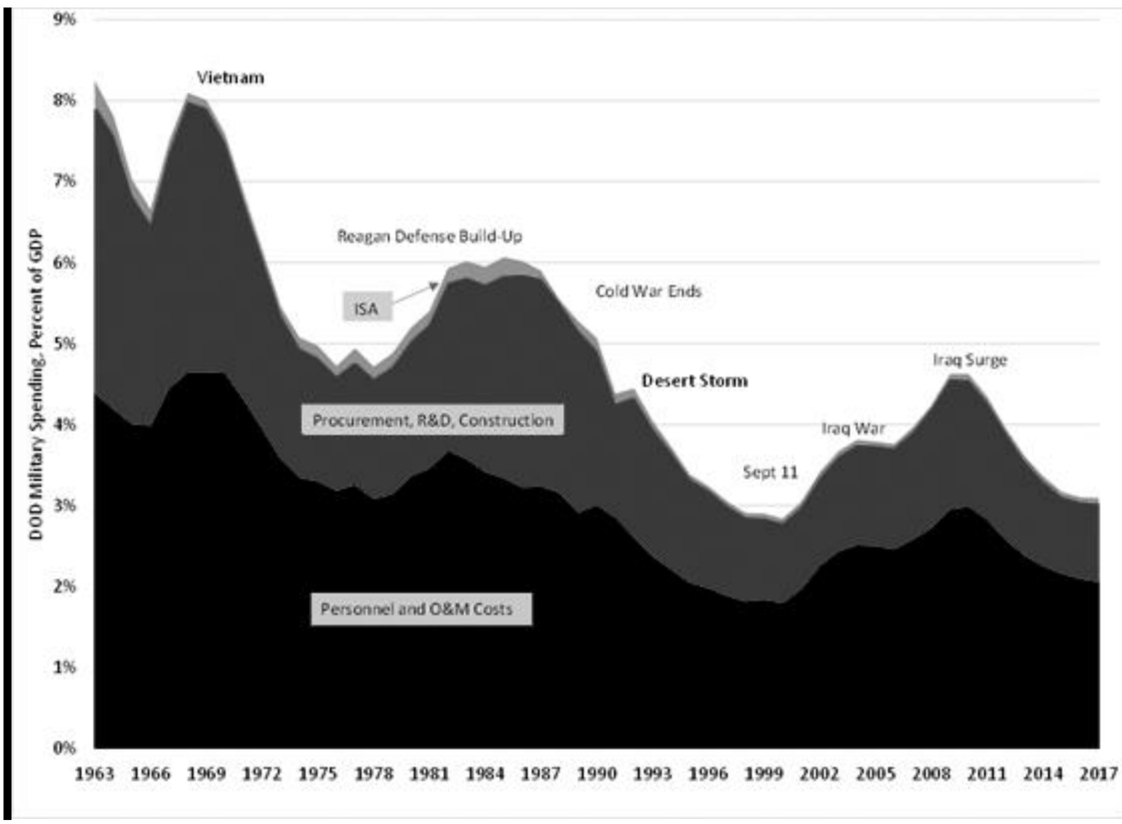

Figure VI-141 – Historical Variation in U.S. Military Spending (Percent of U.S. Gross Domestic Product)

Figure VI-142 superimposes U.S. petroleum consumption and imports on the history of military spending shown in the previous figure. Doing so shows that variation in U.S military spending throughout this period has had little association with the historical pattern of domestic petroleum purchases, changes in which instead primarily reflected the major increases in global petroleum prices that occurred in 1978-79, 2008, and 2012-13. More important, Figure VI-142 also shows that U.S. military spending varied almost completely independently of the nation's imports of petroleum over this period. This history suggests that U.S. military activities—even in regions of the world that have historically represented vital sources of oil imports—serve a far broader range of security and foreign policy objectives than simply protecting oil supplies. Thus, reducing the nation's consumption or imports of petroleum is unlikely by itself to lead to reductions in military spending.

SAFE further argued in its comments that the America's involvement in wars in the Persian Gulf region, starting with the first Gulf War and continuing through the Iraq War, has been a direct consequence of our dependence upon oil. In particular, they state that "[w]hile there is debate over the precise role of oil in America's wars in the greater Middle East, several retired military members of SAFE's ESLC and other defense budget experts that were consulted for this report believe the connection is clear."[2041] However, neither today's action, nor the baseline standards, has the ability to change the historical wealth transfer that created powerful nations in the Middle East. Attributing the cost of the Iraq War, for example, to oil dependence does not directly support an assertion that a marginal reduction in oil dependence could have reduced the cost of that conflict.

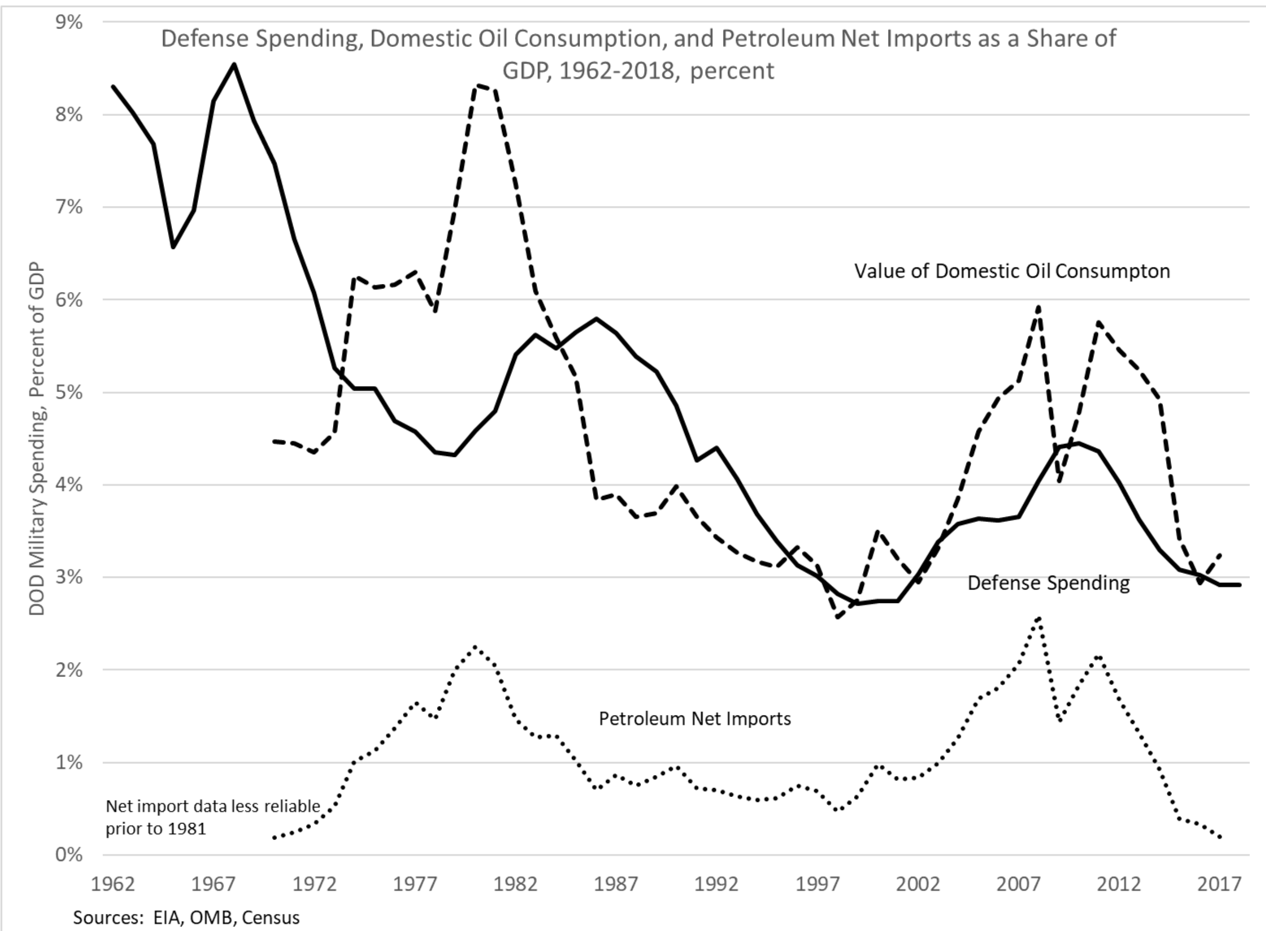

Figure VI-142 – Historical Variation in U.S. Military Spending in Relation to U.S. Petroleum Consumption and Imports (Percent of U.S. Gross Domestic Product)

[2041] NHTSA-2018-0067-11981.

Further, the agencies were unable to find a record of the U.S. government attempting to calibrate U.S. military expenditures, force levels, or deployments to any measure of the Nation's petroleum use and the fraction supplied by imports, or to an assessment of the potential economic consequences of hostilities in oil-supplying regions of the world that could disrupt the global market.[2042] Instead, changes in U.S. force levels, deployments, and spending in such regions appear to have been governed by purposeful foreign policy initiatives, unforeseen political events, and emerging security threats, rather than by shifts in U.S. oil consumption or imports.[2043]

The agencies thus conclude that U.S. military activity and expenditures are unlikely to be affected by even relatively large changes in consumption of petroleum-derived fuels by light duty vehicles. Certainly, the historical record offers no suggestion that U.S. military spending is likely to adjust significantly in response to the increase in domestic petroleum use that would result from reducing CAFE and CO_2 standards.

Nevertheless, it is possible that more detailed analysis of military spending might identify some relationship to historical variation in U.S. petroleum consumption or imports. A number of studies have attempted to isolate the fraction of total U.S. military spending that is attributable to protecting overseas oil supplies.[2044] These efforts have produced varying estimates of how much

---

[2042] Crane et al. (2009) analyzed reductions in U.S. forces and associated cost savings that could be achieved if oil security were no longer a consideration in military planning, and disagree with this assessment. After reviewing recent allocations of budget resources, they concluded that "…the United States *does* include the security of oil supplies and global transit of oil as a prominent element in its force planning" at p. 74 (emphasis added). Nevertheless, their detailed analysis of individual budget categories estimated that even eliminating the protection of foreign oil supplies *completely* as a military mission would reduce the current U.S. defense budget by approximately 12-15 percent. *See* Crane, K., A. Goldthau, M. Toman, T. Light, S. E. Johnson, A. Nader, A. Rabasa, & H. Dogo, *Imported Oil and U.S. National Security*., Santa Monica, CA, The RAND Corporation (2009) available at https://www.rand.org/pubs/monographs/MG838.html.

[2043] Crane et al. (2009) also acknowledge the difficulty of reliably allocating U.S. military spending by specific mission or objective, such as protecting foreign oil supplies. Moore et al. (1997) conclude that protecting oil supplies cannot be distinguished reliably from other strategic objectives of U.S. military activity, so that no clearly separable component of military spending to protect oil flows can be identified, and its value is likely to be near zero. Similarly, the U.S. Council on Foreign Relations (2015) takes the view that significant foreign policy missions will remain over the foreseeable future even without any imperative to secure petroleum imports. A dissenting view is that of Stern (2010), who argues that other policy concerns in the Persian Gulf derive from U.S. interests in securing oil supplies, or from other nations' reactions to U.S. policies that attempt to protect its oil supplies. *See* Crane, K., A. Goldthau, M. Toman, T. Light, S.E. Johnson, A. Nader, A. Rabasa, and H. Dogo, *Imported Oil and U.S. National Security*., Santa Monica, CA, The RAND Corporation (2009) available at https://www.rand.org/pubs/monographs/MG838.html; Moore, John L., E.J. Carl, C. Behrens, and John E. Blodgett, "Oil Imports - An Overview and Update of Economic and Security Effects," Congressional Research Service, Environment and Natural Resources Policy Division, Report 98, No. 1 (1997), pp. 1-14; Council on Foreign Relations, "Automobile Fuel Economy Standards in a Lower-Oil-Price World," November 2015; and Stern, Roger J. "United States cost of military force projection in the Persian Gulf, 1976–2007," *Energy Policy* 38, no. 6 (June 2010), pp. 2816-25, https://www.sciencedirect.com/science/article/pii/S0301421510000194?via%3Dihub.

[2044] These include Copulos, M R. "America's Achilles Heel - The Hidden Costs of Imported Oil," Alexandria VA - The National Defense Council Foundation, September 2003 - 1-153, available at http://ndcf.dyndns.org/ndcf/energy/NDCFHiddenCostsofImported_Oil.pdf; Copulos, M R. "The Hidden Cost of Imported Oil--An Update." The National Defense Council Foundation (2007) available at it might be reduced if the U.S. no longer had *any* strategic interest in protecting global oil supplies. However, none has identified an estimate of spending that is likely to vary incrementally in response to changes in U.S. petroleum consumption or imports.

Nor have any of these studies tracked changes in spending that can be attributed to protecting U.S. interests in foreign oil supplies over a prolonged period, so they have been unable to examine whether their estimates of such spending vary in response to fluctuations in domestic petroleum consumption or imports. The agencies conclude from this review of research that U.S. military commitments in the Persian Gulf and other oil-producing regions of the world contribute to worldwide economic and political stability, and insofar as the costs of these commitments are attributable to petroleum use, they are attributable to oil consumption throughout the world, rather than simply U.S. oil consumption or imports.

It is thus unlikely that military spending would rise in response to any increase in U.S. imports that did result from this final rule. As a consequence, the analysis of alternative CAFE and CO_2 emission standards for future model years applies no increase in government spending to support U.S. military activities as a potential cost of allowing new cars and light trucks to achieve lower fuel economy and thus increasing domestic petroleum use.

Similarly, while the ideal size of the Strategic Petroleum Reserve from the standpoint of its potential stabilizing influence on global oil prices may be related to the level of U.S. petroleum consumption or imports, its actual size has not appeared to vary in response to either of those measures. The budgetary costs for maintaining the SPR are thus similar to U.S. military spending in that, while they are not reflected in the market price for oil (and thus do not enter consumers' decisions about how much to use), they do not appear to have varied in response to changes in domestic petroleum consumption or imports.

As a consequence, the analysis does not include any potential increase in the cost to maintain a larger SPR among the external or social costs of the increase in gasoline and petroleum consumption likely to result from reducing future CAFE and CO_2 standards. This view aligns with the conclusions of most recent studies of military-related costs to protect U.S. oil imports, which generally conclude that savings in military spending are unlikely to result from incremental reductions in U.S. consumption of petroleum products on the scale of those that would resulting from adopting higher CAFE or CO_2 standards.

(12) Social Cost of Carbon

In the proposal, the agencies projected costs resulting from fuel consumption and emissions of CO_2 using estimates of anticipated climate-related economic damages within U.S. borders per ton of CO_2 emissions, which the agencies referred to as the domestic social cost of

---

http://ndcf.dyndns.org/ndcf/energy/NDCF_Hidden_Cost_2006_summary_paper.pdf; Delucchi, Mark A. & James J. Murphy. "US military expenditures to protect the use of Persian Gulf oil for motor vehicles," *Energy Policy* 36, no. 6 (June 2008), pp. 2253-64; and National Research Council Committee on Transitions to Alternative Vehicles and Fuels, *Transitions to Alternative Vehicles and Fuels* (2013).

carbon (domestic SC-CO_2). The domestic SC-CO_2 estimates, which were originally developed by EPA for an earlier regulatory analysis, represent the monetary value of damages to the domestic economy likely to be caused by future changes in the climate that result from incremental increases in CO_2 emissions during a given year.[2045] The agencies did not consider climate-related damage costs resulting from emissions of other greenhouse gases (GHGs), such as methane or nitrous oxide, in their analysis supporting the proposal.

Climate-related damages caused by emissions of CO_2 and other GHGs include changes in agricultural productivity, adverse effects on human health, property damage from increased flood risk, and changes in costs for managing indoor environments in commercial and residential buildings (such as costs for heating and air conditioning), among other possible damages.

The agencies described the SC-CO_2 estimates used in the NPRM analysis as interim values developed under Executive Order 13783, which are to be used in regulatory analyses until revised values that incorporate recommendations from NAS can be developed.[2046] E.O. 13783 directed agencies to ensure that estimates of the social cost of greenhouse gases used in regulatory analyses are consistent with the guidance contained in OMB Circular A-4, "including with respect to the consideration of domestic versus international impacts and the consideration of appropriate discount rates."[2047]

Circular A-4 states that analysis of economically significant regulations "should focus on benefits and costs that accrue to citizens and residents of the United States," and the agencies followed this guidance by using estimates of the SC-CO_2 that included only domestic economic damages. In response to Circular A-4's further guidance that regulatory analyses "should provide estimates of net benefits using [discount rates of] both 3 percent and 7 percent," the agencies presented estimates of the proposed rule's economic impacts—including the costs of climate damages likely to result from increased CO_2 emissions—that incorporated both discount

---

[2045] For a description of the procedures EPA used to develop these values, see U.S. Environmental Protection Agency, *Regulatory Impact Analysis for the Proposed Emission Guidelines for Greenhouse Gas Emissions from Existing Electric Utility Generating Units; Revisions to Emission Guideline Implementing Regulations; Revisions to New Source Review Program*, EPA-452/R-18-006, August 2018 (https://www.epa.gov/sites/production/files/2018-08/documents/utilities_ria_proposed_ace_2018-08.pdf), Section 4.3, at 4-2 to 4-7. The sources and potential magnitude of uncertainties surrounding the SC-CO_2 estimates are described in Chapter 7 of that same document, at 7-1 to 7-10.
[2046] The guidance followed by EPA in developing the SC-CO_2 values used in the NPRM analysis appears in President of the United States, Executive Order 13783, "Promoting Energy Independence and Economic Growth," March 28, 2017, Federal Register, Vol. 82, No. 61, Friday, March 31, 2017, 16093-97. (https://www.govinfo.gov/content/pkg/FR-2017-03-31/pdf/2017-06576.pdf) The recommendations of the National Academies are reported in National Academies of Sciences, Engineering, and Medicine, *Valuing Climate Damages: Updating Estimation of the Social Cost of Carbon Dioxide*, Washington, D.C., January 2017. Revised values incorporating this guidance have not yet been developed. https://www.nap.edu/catalog/24651/valuing-climate-damages-updating-estimation-of-the-social-cost-of
[2047] E.O. 13783, at 16096.

rates. The PRIA included a detailed discussion of the analyses used to construct estimates of the domestic SC-CO_2 using these discount rates.[2048]

The estimates of the domestic SC-CO_2 the agencies used in their analysis supporting the proposal increased over future years, partly because emissions during future years are anticipated to contribute larger incremental costs. Future values of the SC-CO_2 also increase because U.S. GDP is growing over time, and many categories of climate-related damage are estimates as proportions of GDP. The agencies' estimates of the domestic SC-CO_2 for emissions occurring in the year 2020 were $1 and $8 (in 2016$) per metric ton of CO_2 emissions using 7 and 3 percent discount rates, and these values were projected to increase to $2 and $10 (again in 2016$) by the year 2050.

As the agencies indicated in the NPRM, the SC-CO_2 estimates are subject to several sources of uncertainty. In accordance with guidance provided by OMB Circular A-4 for treating uncertainty in regulatory analysis, the PRIA included a detailed discussion of how the analysis used to develop the interim SC-CO_2 estimates incorporated sources of uncertainty that could be quantified. It also demonstrated how considering the uncertainty introduced by applying discount rates over extended time horizons could affect the estimated values.[2049] To reflect this uncertainty, the analysis supporting the proposed rule examined the sensitivity of its estimated costs and benefits to using higher values for the SC-CO_2 ($9-14 per metric ton), which were derived using a lower "intergenerational" discount rate of 2.5 percent.[2050]

(a) Comments on the NPRM Value for the SC-CO_2

The agencies received extensive comments on the values of the SC-CO_2 used in the NPRM analysis. Broadly, these comments stressed the following concerns:

- Using a domestic value for SC-CO_2 systemically underestimates the benefits of adopting stricter standards.
- The agencies' SC-CO_2 omits potential costs due to foreign social and political disruptions caused by climate change that can affect the U.S.
- The 7 percent discount rate used in the agencies' main or central analysis is inappropriate because it represents an opportunity cost of capital rather than a rate of time preference for current versus future consumption opportunities, and climate change will affect future consumption.

(b) Domestic vs. Global Value for SC-CO_2

Many commenters asserted that it was inappropriate for the agencies to use a domestic SC-CO_2 value for analyzing benefits or costs from changing required levels of fuel economy in

[2048] *See* NHTSA and EPA, PRIA, Chapter 8, Appendix A.
[2049] *See* PRIA, Chapter 8, Appendix A.
[2050] PRIA, Tables 13-8 and 13-9, at 1547-50.

the NPRM analysis, primarily because doing so could lead regulatory agencies to adopt measures that provide inadequate reductions in emissions and protection from potential climate change.

As noted in the NPRM and above, the SC-CO_2 estimates the agencies used to estimate climate-related economic costs from adopting less demanding fuel economy and CO_2 emission were developed in response to the issuance of E.O. 13783. The agencies remind commenters that E.O. 13783 directed federal agencies to ensure that estimates of the social cost of greenhouse gases used in their regulatory analyses are consistent with the guidance contained in OMB Circular A-4, "including with respect to the consideration of domestic versus international impacts and the consideration of appropriate discount rates."[2051] Circular A-4 states that analysis of economically significant proposed and final regulations "should focus on benefits and costs that accrue to citizens and residents of the United States."[2052] The agencies adhered closely to this guidance in evaluating the economic costs and benefits in the proposal and this final rule by using the domestic value of the SC-CO_2 in our central analysis.

Commenters argued that Circular A-4 allows the agencies to use a global SC-CO_2 in their central analysis. For example, IPI et al. commented that "Circular A-4's reference to effects 'beyond the borders' confirms that it is appropriate for agencies to consider the global effects of U.S. greenhouse gas emissions."[2053] While the agencies agree that Circular A-4 authorizes the agencies to consider foreign impacts in certain circumstances, the agencies would also like to note that Executive Order 13783 stipulates "when monetizing the value of changes in greenhouse gas emissions resulting from regulations, including with respect to the consideration of domestic versus international impact […] agencies shall ensure […] any such estimates are consistent with the guidance contained in OMB Circular A-4."[2054] Using a global SC-CO_2 in our central analysis would be inconsistent with Circular A-4's directive that any non-domestic effects calculated "should be reported separately."[2055] As such, if the agencies had used a global SC-CO_2, this rulemaking would be compelled by Circular A-4 to separate the SC-CO_2 into domestic and foreign components, and to include only the former in our central analysis.

Furthermore, today's analysis will likely have global impacts beyond climate change. For example, freeing manufacturers who compete in the U.S. domestic automobile market from burdensome fuel efficiency standards may enable them to dedicate time and resources to becoming more competitive in global markets, and is thus likely to affect product innovation and performance throughout the global auto market.[2056] It would be inconsistent to report the global

[2054] Executive Order 13,783, at 16096.
[2055] Specifically, OMB Circular A-4 directs federal agencies as follows: "Where you choose to evaluate a regulation that is likely to have effects beyond the borders of the United States, these effects should be reported separately." OMB Circular A-4, at 15.
[2056] Some commenters assert that weakening U.S. fuel economy standards could make domestic auto companies *less* competitive in international markets, since several other nations have also adopted similar standards. For reasons discussed Section VIII.B.6. of this rule, however, the agencies find these comments unpersuasive.

$SC\text{-}CO_2$ while ignoring other global costs and benefits. The agencies do not have a method for analyzing the comprehensive impacts of CAFE and CO_2 standards—including their many likely impacts beyond climate change—on a global scale, and did not receive any suggestions about how to conduct such an analysis from commenters. Because it would be inconsistent to quantify only climate change and none of these other potential global-scale impacts, the agencies have decided to focus their attention on domestic impacts, which are more readily measurable.

Several commenters argued that the agencies are still obligated to report the global impacts of carbon. For example, the North Carolina Department of Environmental Quality commented that "by omitting any analysis of the global social cost of carbon, [the agencies] failed to adhere to OMB's Circular A-4."[2057] The agencies note Circular A-4 grants agencies discretion to choose which impacts to report. However, to be fully informed of the gamut of potential effects of today's rule, the agencies have included two sensitivity cases analyzing the impacts of the standards using a global $SC\text{-}CO_2$.

(c) Scope of Domestic Climate Damages

Some commenters asserted that even if the agencies are required to use a domestic $SC\text{-}CO_2$, the specific value employed by the agencies underestimated the domestic impacts of climate change. They argued the agencies failed to incorporate economic costs associated with social or economic disruptions caused by climate change in regions of the world that were more vulnerable to its effects, but that could "spill over" to impose damages to the U.S. via their effects on migration patterns, international trade flows, or other mechanisms that connect nations. Other commenters argued that E.O. 13783 does not *prohibit* the agencies from using the estimates or practices developed by the IWG to develop new estimates of the $SC\text{-}CO_2$, and asserted that the IWG's methods and resulting estimates continue to represent the best available practices.

However, all of the IWG's estimates measure the global $SC\text{-}CO_2$, and as discussed previously, E.O. 13783, in conjunction with Circular A-4, directs the agencies to use a domestic $SC\text{-}CO_2$ which precludes the use of the IWG estimates. To develop interim estimates of the domestic $SC\text{-}CO_2$ that were consistent with the IWG's procedures, EPA used the same three climate economic models the IWG employed previously to calculate the domestic $SC\text{-}CO_2$. Two of those three models directly estimate the U.S. domestic $SC\text{-}CO_2$, which represents the economic costs resulting from climate change that are likely to be borne within U.S. borders.[2058] The third model the IWG used previously does not estimate the domestic $SC\text{-}CO_2$ directly, but

[2057] North Carolina Department of Environmental Quality, Comments, NHTSA-2018-0067-12025, at 39.

[2058] The Policy Analysis of the Greenhouse Effect (PAGE) model is described in Hope, C., "The marginal impact of CO_2 from PAGE2002: an integrated assessment model incorporating the IPCC's five reasons for concern," The Integrated Assessment Journal, Vol. 6 No. 1 (2006), at 19-56; and Hope, C., "Optimal carbon emissions and the social cost of carbon under uncertainty," The Integrated Assessment Journal Vol. 8, No. 1 (2008), at 107-22. The Climate Framework for Uncertainty, Negotiation, and Distribution (FUND) model is documented in Tol, Richard, "Estimates of the damage costs of climate change. Part I: benchmark estimates," and "Estimates of the damage costs of climate change. Part II: dynamic estimates." Environmental and Resource Economics Vol 21 (2002), at 47-73 and 135-60.

EPA approximated domestic U.S. costs from future climate change as 10 percent of its estimate of their global value, based on results from a companion model developed by the same author.[2059] Thus the agencies believed that the SC-CO_2 values they used in the NPRM analysis represented the most reliable estimates of domestic economic costs from future climate change that were available for use in evaluating the proposal.

The agencies were unable to develop an estimate of the domestic value for SC-CO_2 that incorporated any of these alleged spillover effects, due both to their speculative nature and to the absence of credible empirical estimates of their potential magnitude. Nor did commenters provide credible explanations for how such spillovers might arise, or reliable empirical estimates of their potential magnitude.

(d) Discount Rate Used to Construct the SC-CO_2 Value

Many commenters also objected to the agencies use of an SC-CO_2 value that incorporated a 7 percent discount rate in the NPRM analysis. Some of these comments reflected a misperception that the agencies used such a value in their main or central analysis, when in fact it was only used in a sensitivity analysis case as described below. Other comments appeared to object to the agencies' use of an SC-CO_2 value incorporating a 7 percent discount rate even as a sensitivity case.

E.O. 13783 directed agencies to ensure that any estimates of the social cost of CO_2 and other greenhouse gases they used for purposes of regulatory analyses are consistent with OMB Circular A-4's guidance "with respect to the consideration of…appropriate discount rates."[2060] In turn, Circular A-4 refers agencies to OMB's earlier guidance on discounting contained in its Circular A-94, noting that "[a]s a default position, OMB Circular A-94 states that a real discount rate of 7 percent should be used as a base-case for regulatory analysis."[2061] OMB continues to use the 7 percent rate to estimate the average pre-tax rate of return to private capital investment throughout the U.S. economy. Because it is intended to approximate the opportunity cost of capital, it is the appropriate discount rate for evaluating the economic consequences of regulations that affect private-sector capital investments.

At the same time, however, OMB's guidance on discounting also recognizes that some federal regulations are more likely to affect private consumption decisions made by households

---

[2059] The third model is the Dynamic Integrated model of Climate and the Economy (DICE), described in Nordhaus, William, "Estimates of the Social Cost of Carbon: Concepts and Results from the DICE-2013R Model and Alternative Approaches." Journal of the Association of Environmental and Resource Economists, Vol. 1, No. 2 (2014), at 273-312 (https://www.jstor.org/stable/pdf/10.1086/676035.pdf). The 10 percent figure is based on the results from a regional version of that model (RICE 2010), as described in Nordhaus, William D. 2017, "Revisiting the social cost of carbon," Proceedings of the National Academy of Sciences of the United States, 114 (7), at 1518-23, Table 2.
(https://pdfs.semanticscholar.org/f83b/3a7431e0ae2d4e8be3d0ee5f3787a802c34c.pdf?_ga=2.211824467.636056015.1572384992-158339427.1562696454).
[2060] E.O. 13,783, at 16096.
[2061] OMB Circular A-4, at. 33.

and individuals, such as when they affect prices or other attributes of consumer goods. In these cases, Circular A-4 advises that a lower discount rate is likely to be more appropriate, and that a reasonable choice for such a lower rate is the real consumer (or social) rate of time preference. This is the rate at which individual consumers discount future consumption to determine its present value to them.

OMB estimated that the rate of consumer time preference has averaged 3 percent in real or inflation-adjusted terms over an extended period, and continues to use that value. In summary, Circular A-4 reiterates the guidance provided in OMB's earlier Circular A-94 that "[f]or regulatory analysis, you should provide estimates of net benefits using both 3 percent and 7 percent."[2062]

Finally, OMB's guidance on discounting indicates that it may be appropriate for government agencies to employ an even lower rate of time preference when their regulatory actions entail tradeoffs between improving the welfare of current and future generations. Recognizing this situation, Circular A-4 advises if the "rule will have important intergenerational benefits or costs [an agency] might consider a further sensitivity analysis using a lower but positive discount rate in addition to calculating net benefits using discount rates of 3 and 7 percent."[2063]

The agencies adhered closely to each of these provisions of OMB's guidance on discounting future climate-related economic costs in their analysis supporting the NPRM. Specifically, their central analysis relied exclusively on a SC-CO_2 value that was constructed by applying a 3 percent discount rate to future climate-related economic damages. This value ranged from $6 per metric ton in 2015 to nearly $11 per metric ton (both figures in 2016$) by the end of the analysis period, the year 2050.

Throughout the NPRM central analysis, costs resulting from increased emissions of CO_2 were also discounted from the year when those increases in emissions occurred to the present using a 3percent rate, even when all other future costs and benefits were discounted at a 7 percent rate. Thus the agencies' central analysis for the NPRM did not use SC-CO_2 values for future years that were constructed by applying a 7 percent rate to discount distant future climate-related economic damages, and did not use a 7 percent rate to discount costs of increased CO_2 from the years when they were projected to occur to 2018 (the base year used in the analysis).

Notwithstanding concerns raised by commenters about including a sensitivity analysis that used a higher discount rate, OMB's guidance clearly directs the agencies to report estimates of the present value of the economic costs resulting from increased CO_2 emissions that reflect discount rates of *both* 3 and 7 percent. Thus to supplement their central analysis, which as indicated previously employed a 3 percent discount rate throughout, the agencies also reported an estimate of the economic costs of increased CO_2 emissions based on a value for the SC-CO_2 that was constructed using a 7 percent discount rate as a sensitivity case, which they termed the

[2062] OMB Circular A-4, at 34.
[2063] OMB Circular A-4, at 36.

"Low Social Cost of Carbon" sensitivity analysis.[2064] The values for the SC-CO_2 used in the Low Social Cost of Carbon sensitivity analysis varied from $1 per metric ton in 2015 to $3 per metric ton (both figures in 2016$) by the end of the analysis period. Using these values reduced the loss in total economic benefits resulting from the proposed alternative by 1.1 percent, thus increasing its net benefits by slightly less than 2 percent.[2065]

For the proposal, the agencies also included a second sensitivity analysis using a value for the SC-CO_2 that reflected a lower "intergenerational" discount rate of 2.5 percent, which is within the 1 to 3 percent range for discount rates that have previously been applied to economic costs and benefits that span multiple generations, as reported in OMB guidance.[2066] Because using a lower discount rate results in a higher value for the SC-CO_2, this analysis was termed the "High Social Cost of Carbon" sensitivity case.[2067] The values for the SC-CO_2 used in this additional sensitivity analysis varied from $8 per metric ton in 2015 to $14 per metric ton (both figures in 2016$) in 2050, the last year of the analysis. Using these higher values increased the magnitude of the estimated loss in economic benefits resulted from adopting the proposed rule (versus retaining the Augural standards) by 0.5 percent from that estimated in the central analysis, thus reducing its net benefits by 1.0 percent.[2068] Thus it appeared that when used to construct alternative estimates of the SC-CO_2, the range of discount rates specified in OMB Circular A-4 had little or no effect on the estimated total benefits of the proposed rule, and the sensitivity analyses conducted in support of this Final Rule confirm this result.[2069]

(e) SC-CO_2 for the Final Rule

After carefully considering the concerns raised by commenters, the agencies decided to leave the SC-CO_2 values unchanged for the final rule. This means the SC-CO_2 estimate used in this analysis is still a domestic value that was constructed using a 3 percent discount rate, and that costs from increased CO_2 emissions are discounted from the year those emissions occur to the present using a 3 percent rate. The agencies have again included "High Social Cost of Carbon" and "Low Social Cost of Carbon" sensitivity analyses, which continue to use domestic SC-CO_2 values that incorporate alternative discount rates of 2.5 percent and 7 percent.

The agencies have also added two sensitivity cases using global values for the SC-CO_2, which reflect discount rates of 3 percent and 7 percent. Finally, the agencies have also included

[2064] PRIA, Table 13-1, at 1531-34.
[2065] PRIA, Tables 13-8 and 13-9, at 1547-50. Using a lower value for the SC-CO_2 had opposite effects on the proposal's total and net economic benefits, because its net benefits represented the difference between the loss in benefits and the savings in costs that would result from adopting the proposed rule, compared to the baseline of adopting the Augural standards.
[2066] OMB Circular A-4, at 36.
[2067] PRIA, Table 13-1,at 1531-34.
[2068] PRIA, Tables 13-8 and 13-9, at 1547-50. As in the Low Social Cost of Carbon sensitivity case, using a higher value for the SC-CO_2 had opposite effects on the total and net economic benefits, because its net benefits were the difference between the sacrifice in benefits and the savings in costs from adopting the proposed rule, where both were measured against the baseline of adopting the Augural standards.
[2069] *See* section VII.B. of this Final Rule for results of the "High Social Cost of Carbon" sensitivity case.

an additional sensitivity case that incorporates estimates of the domestic climate damage costs caused by emissions of the GHGs methane (CH_4) and nitrous oxide (N_2O). Like the SC-CO_2 values used in this analysis, the estimates of the domestic values for SC-CH_4 and SC-N_2O are interim estimates developed by EPA for use in regulatory analyses conducted under the guidelines specified in E.O 13783 and OMB Circular A-4, and incorporate a 3 percent discount rate.

(13) External Costs of Congestion and Noise

(a) Values Used to Analyze the Proposal

As explained in the proposal, changes in vehicle use affect the levels and economic costs of traffic congestion and highway noise associated with motor vehicle use.[2070] Congestion and noise costs are "external" to the vehicle owners whose decisions about how much, where, and when to drive more—or less—in response to changes in fuel economy result in these costs. Therefore, unlike changes in the costs incurred by drivers for fuel consumption or safety risks they willingly assume, changes in congestion and noise costs are not offset by corresponding changes in the travel benefits drivers experience.[2071]

Congestion costs are limited to road users; however, since road users include a significant fraction of the U.S. population, changes in congestion costs are treated as part of the rule's economic impact on the broader U.S. economy instead of as a cost or benefit to private parties. Costs resulting from road and highway noise are even more widely dispersed, because they are borne partly by surrounding residents, pedestrians, and other non-road users, and for this reason are also considered as a cost to the U.S. economy as a whole.

To estimate the economic costs associated with changes in congestion and noise caused by differences in miles driven, the analysis supporting the NPRM used estimates of per-mile congestion and noise costs from increased automobile and light truck use that were originally developed by FHWA as part of its 1997 Highway Cost Allocation Study.[2072] The agencies previously employed these same cost estimates in the 2010, 2011, and 2012 final rules.

The marginal congestion cost estimates reported in the 1997 FHWA study were intended to measure the costs of increased congestion resulting from incremental growth in travel by

[2070] The proposal estimated changes in congestion and noise costs associated with the overall change in vehicle use, which included changes in the use of new cars and light trucks associated with the fuel economy rebound effect as well as with changes in the use of older vehicles resulting from the effect of CAFE and CO_2 standards on turnover in the car and light truck fleets. As discussed in more detail elsewhere in this final rule, the current analysis assumes that total vehicle use (VMT) differs between the baseline and regulatory alternatives only because of changes in the use of cars and light trucks produced during the model years affected by this rule that occur in response to the fuel economy rebound effect.
[2071] The potential contribution of increased vehicle use to the costs of injuries and property damage caused by motor vehicle crashes may also be partly external to drivers who elect to travel more in response to the fuel economy rebound effect. However, these costs are dealt with directly and in more detail than the external costs of congestion and noise, in section VI.C.2. below.
[2072] Federal Highway Administration, 1997 Highway Cost Allocation Study, Chapter V, Tables V-22 and V-23, available at https://www.fhwa.dot.gov/policy/hcas/final/five.cfm.

different types of vehicles (including autos and light trucks), and the delays it causes to drivers, passengers, and freight shipments. As explained in the 1997 FHWA study, the distinction between marginal and average costs is extremely important in considering congestion costs on a per-vehicle-mile basis. Average congestion costs on a section of highway are calculated as the total congestion costs experienced by all vehicles, divided by total vehicle miles. In contrast, marginal congestion costs are calculated as the *increase* in congestion costs resulting from an incremental increase in vehicle miles.

Marginal congestion costs are significantly higher than average congestion costs because each additional vehicle that enters a crowded roadway slows travel speeds only slightly, thus adding only modestly to the *average* travel time of vehicles already on the road. During congested conditions, however, this modest increase is experienced by a very large number of vehicles, so the resulting increase in *total* delay experienced by all travelers using the road can be extremely large. As a consequence, the increases in total delay and congestion costs associated with additional driving are *more than* proportional to changes in VMT that cause them.[2073]

The FHWA study's estimates of marginal noise costs reflected the variation in noise levels resulting from incremental changes in travel by autos, light trucks, and other vehicles, and the annoyance and other adverse impacts caused by noise. These included adverse impacts on pedestrians and residents of the surrounding area, as well as on vehicle occupants themselves.

To calculate the incremental costs of congestion and noise, the agencies multiplied FHWA's "middle" estimates of marginal congestion and noise costs per mile of auto and light truck travel in urban and rural areas by the annual increases in driving attributable to the standards to yield increases in total congestion and noise externality costs. Because the proposal, and other alternatives that were considered, reduced the stringency of CAFE and CO_2 standards for model years 2021-2026, resulting in lower fuel economy for new cars and light trucks produced during those years, the fuel economy rebound effect resulted in *fewer* miles driven relative to the baseline, thus generating savings in congestion and noise costs relative to their levels under the baseline. Similarly, each of those alternatives also reduced the total amount of travel by the used vehicle fleet, generating additional savings in these costs.

(b) Comments on the NPRM Values

The agencies received few comments on the estimates of congestion and noise costs they used to analyze the economic impacts of the proposal. Almost all of these comments focused on the appropriateness of the estimated magnitude of the fuel economy rebound effect they used to estimate the change in use of new cars and light trucks or the plausibility of the reduction in driving by used vehicles, rather than to the unit costs estimates themselves. These included comments from ICCT and CARB.[2074]

[2073] Such "non-linearity" is a common feature of complex systems, such as computing or juggling. Each additional element added to a computation, or ball to a cascade, makes performing the task more difficult than the last addition.
[2074] ICCT, Comment, NHTSA-2018-0067-11741 at 121; CARB, Comment, NHTSA-2018-0067-11873 at 316.

One individual commenter did suggest that recent growth in traffic levels, resulting in part from increased use of home delivery services for online purchases, has increased congestion and resulting delays.[2075] Although this commenter is correct, traffic growth is not strictly a recent phenomenon, and longer-term growth in vehicle use—combined with comparatively modest increases in road and highway capacity—has contributed to increasing congestion levels. Because congestion increases more than proportionately to growing traffic volumes, this suggests that FHWA's estimates of congestion costs—now more than two decades old—are likely to understate the contribution of continuing increases in vehicle use to congestion, resulting delays to vehicle occupants and freight shipments, and their associated costs. Because noise levels also increase non-linearly with the volume of traffic using roads and highways, FHWA's 1997 estimates of marginal noise costs may also understate current values.

(c) Values Used to Analyze the Final Rule

The agencies are retaining the same methodology employed in the NPRM to estimate congestion and noise costs for the final rule. Like other nominal estimates used throughout the analysis, the agencies have updated the FHWA estimates to account for current economic and highway conditions. The major determinants of marginal congestion costs imposed by additional travel include baseline traffic volumes, which determine current travel speeds and how they would change in response to further increases in travel, together with vehicle occupancy and the value of occupants' travel time. These last two factors interact to determine the average hourly value of delays to vehicles, which is by far the largest component of the total cost of delays that occur under congested travel conditions.[2076] Because travel speeds measure the duration of congestion-related delays, while the value of vehicle occupants' time determines their hourly cost, the effects of changes in these variables on overall congestion costs is approximately additive, as long as changes in the two are relatively modest.

The agencies approximated the effect of growth in traffic volumes on travel speeds and congestion-related delays by increasing congestion costs in proportion to the increase in annual vehicle-miles of travel per lane-mile on major U.S. highways that occurred between 1997 and 2017.[2077] Next, they estimated the increase in the value of travel time per vehicle-hour over that same period by combining growth in the value of travel time per person-hour—estimated in accordance with DOT guidance[2078]—with the increase in average vehicle occupancy by persons 16 years of age and older (the same measure of occupancy used to estimate the value of refueling

---

[2075] Richard Carriere, NHTSA-2018-0067-12216.

[2076] Fuel consumption and other operating costs can also increase during travel in congested conditions, but their relationships to the frequent changes in speed that typically occur in congested travel is less well understood, and in any case, they vary by far smaller amounts than the value of vehicle occupants' travel time.

[2077] Traffic volumes, as measured by the annual number of vehicle-miles traveled per lane-mile of roads and highways nationwide, rose by 53 percent between 1997 and 2017. Calculated from FHWA, Highway Statistics, 1998 and 2018, Tables VM-1 and HM-48, available at https://www.fhwa.dot.gov/policyinformation/statistics.cfm.

[2078] *See* U.S. Department of Transportation, "Revised Departmental Guidance for the Valuation of Travel Time in Economic Analysis," 2016, at 5-6 and Table 1 at 13.

time elsewhere in this analysis).[2079] The agencies applied the increases in congestion-related delays and the hourly value of travel time to FHWA's 1997 estimates of marginal congestion costs to update those original values to reflect current conditions. The updated values of external congestion costs are $0.154 per vehicle-mile of increased travel by cars and $0.138 per vehicle-mile for light trucks (expressed in constant 2018 dollars), and these values are assumed to remain constant throughout the analysis period.

Similarly, the agencies revised the FHWA estimate of marginal noise costs by adjusting for inflation—since the 1994 base year used to express values in the FHWA study. Because marginal noise costs are so small—less than $0.001 per mile of travel for both cars and light trucks—this change did not have a significant impact on the agencies' estimates of benefits and costs from the final rule.

(14) Labor Utilization Assumptions

In previous joint CAFE/CO_2 rulemakings, the agencies considered employment impacts on the automobile manufacturing industry, but many of the considerations were qualitative. In the NPRM, the agencies presented and took comment on a methodology to quantify roughly the direct labor utilization impacts. The agencies recognize there is significant uncertainty in any forward-looking characterization of labor utilization, including effects resulting from CAFE/CO_2 rulemakings. Changes to other policies such as trade policies and tariff policies are likely substantially to alter underlying assumptions presented in the analysis for the rulemaking, and these changes could dwarf any differences between policy alternatives presented. In this section the agencies discuss the assumptions made in the NPRM analysis, summarize comments received on that work, and respond to these comments.

(a) Labor Utilization Baseline (Including Multiplier Effect) and Data Description

In prior CAFE/CO_2 rulemakings, the agencies considered an analysis of employment impacts in some form in setting both CAFE and tailpipe CO_2 emissions standards; NHTSA conducted an employment analysis in part to determine whether the standards the agency set were economically practicable, that is, whether the standards were "within the financial capability of the industry, but not so stringent as to" lead to "adverse economic consequences, such as a significant loss of jobs or unreasonable elimination of consumer choice."[2080] EPA similarly conducted an employment analysis under the authority granted to the agency under the

[2079] The average hourly value of travel time increased by 82 percent between 1997 and 2017; *see* U.S. Department of Transportation, "Departmental Guidance for the Valuation of Travel Time in Economic Analysis," April 9, 1997, Table 4, and U.S. Department of Transportation, "Benefit-Cost Analysis Guidance for Discretionary Grant Programs," December 2018, Table A-3. From 1995 to 2017, the average number of light-duty vehicle occupants 16 years of age and older increased by 18 percent; values were tabulated from FHWA, Nationwide Personal Transportation Survey, 2005 and 2017, using online table designer available at https://nhts.ornl.gov/ and https://nhts.ornl.gov/index9.shtml.
[2080] 67 FR 77015, 77021 (Dec. 16, 2002).

Clean Air Act.[2081] Both agencies recognized the uncertainties inherent in estimating employment impacts; in fact, both agencies dedicated a substantial amount of discussion to uncertainty in employment analyses in the 2012 final rule for MYs 2017 and beyond.[2082] Notwithstanding these uncertainties, by imposing costs on new light duty vehicles, CAFE and CO_2 standards can have an impact on the demand for labor. Providing the best analysis practicable better informs stakeholders and the public about the standards' impact than would omitting any estimates of potential labor impacts.

The NPRM quantified many of the effects that were previously qualitatively identified, but not considered. For instance, in the PRIA for the 2017-2025 rule EPA identified "demand effects," "cost effects," and "factor shift effects" as important considerations for labor, but the analysis did not attempt to quantify each of these effects.[2083]

The NPRM analysis considered direct labor effects on the automotive sector. The NPRM evaluated how labor utilization in different facets of the automobile manufacturing industry may be affected by the rule, including (1) dealership labor related to new light-duty vehicle unit sales; (2) assembly labor for vehicles, for engines and for transmissions related to new vehicle unit sales; and (3) labor related to mandated additional fuel savings technologies, accounting for new vehicle unit sales. Importantly, this analysis did not consider whether price reductions and regulatory savings associated with different standards would, because price reductions would allow consumers to save or spend that money on other things of value, increase the consumption of other vehicle technologies or, more generally, generate growth in other sectors of the overall economy. This means that the analysis is inherently and artificially narrow in its focus, and does not represent an attempt to quantify the overall labor or economic effects of this rulemaking. All labor effects were estimated and reported at a national level, in person-years, assuming 2,000 hours of labor per person-year.[2084]

The NPRM analysis estimated labor effects from the forecasted CAFE model technology costs and from review of automotive labor for the MY 2016 fleet. For each vehicle in the CAFE model analysis, the locations for vehicle assembly, engine assembly, and transmission assembly and estimated labor in MY 2016 were recorded. The percent of U.S. content for each vehicle was also recorded.[2085] The analysis also took into account the portion of parts that are made in the U.S. by holding constant the percent of U.S. content for each vehicle as manufacturers add fuel-savings technologies. The analysis further assumes that the U.S. labor added would be

[2083] U.S. EPA, "Regulatory Impact Analysis: Final Rulemaking for 2017-2025 Light-Duty Vehicle Greenhouse Gas Emission Standards and Corporate Average Fuel Economy Standards," at 8-24 to 8-32 (Aug. 2012).
[2084] The agencies recognize a few local production facilities may contribute meaningfully to local economies, but the analysis reported only on national effects.
[2085] NHTSA provides reports under 49 CFR Part 583, "American Automobile Labeling Act Reports" with information NHTSA received from vehicle manufacturers about the U.S./Canadian content (by percentage value) of the equipment (parts) used to assemble passenger motor vehicles. *See* https://www.nhtsa.gov/part-583-american-automobile-labeling-act-reports.

proportional to U.S. content, which means that the analysis assumes that U.S. labor inputs would remain constant over time, but this does not reflect a prediction that U.S. labor inputs actually will remain constant.[2086] From this foundation, the analysis forecasted automotive labor effects as the CAFE model added fuel economy technology and adjusted future sales for each vehicle.

The NPRM analysis also accounted for sales projections in response to the different regulatory alternatives; the labor analysis considers changes in new vehicle prices and new vehicle sales (for further discussion of the sales model, see Section VI.D.1.b(2)). As vehicle prices rise, the analysis expected consumers to purchase fewer vehicles than they would have at lower prices.[2087] As manufacturers sell fewer vehicles, the manufacturers may need less labor to produce the vehicles and dealers may need less labor to sell the vehicles. However, as manufacturers add equipment to each new vehicle, the industry will require labor resources to develop, sell, and produce additional fuel-saving technologies. The analysis also accounted for the possibility that new standards could shift the relative shares of passenger cars and light trucks in the overall fleet (see Section VI.D.1.b(2)); insofar as different vehicles involved different amounts of labor, this shifting impacts the quantity of estimated labor. The labor analysis took into account the anticipated reduction in vehicle sales, shifts in the mix of passenger cars and light trucks, and addition of fuel-savings technologies that result from the regulation—and, subsequently, the anticipated increase in sales and reduction of fuel-savings technologies that are expected to result from a reduction in stringency.

For the NPRM analysis, the agencies assumed that some observations about the production of MY 2016 vehicles would carry forward, unchanged into the future. For instance, assembly plants would remain the same as MY 2016 for all products now, and in the future. The analysis assumed the percent of U.S. content would remain constant, even as manufacturers updated vehicles and introduced new fuel-saving technologies. The analysis further assumed that assembly labor hours per unit would remain at estimated MY 2016 levels for vehicles, engines, and transmissions, and the factor between direct assembly labor and parts production labors would remain the same. When considering shifts from one technology to another, the analysis assumed revenue per employee at suppliers and original equipment manufacturers would remain in line with MY 2016 levels, even as manufacturers added fuel-saving technologies and realized cost reductions from learning.

The NPRM analysis focused on automotive labor because adjacent employment factors and consumer spending factors for other goods and services are uncertain and difficult to predict. The analysis did not consider how direct labor changes may affect the macro economy and possibly change employment in adjacent industries. For instance, the analysis did not consider possible labor changes in vehicle maintenance and repair, nor did it consider changes in labor at retail gas stations. The analysis did not consider possible labor changes due to raw material production, such as production of aluminum, steel, copper, and lithium, nor did the agencies consider possible labor impacts due to changes in production of oil and gas, ethanol, and

---

[2086] This is a key assumption that should be revisited as trade deals and tax or tariff policies materially change.
[2087] Many commenters contend that higher prices for more efficient goods will have no effect on unit sales and hence necessary production resources and employment. The sales aspect of labor utilization is addressed in the sales section. NHTSA-2018-0067-12000-35, Center for Biological Diversity, et al.

electricity. The analysis did not analyze potential labor effects arising from consumption of other products that would not have occurred but for improved fuel economy, nor did the analysis assess the effects arising from reduced consumption of other products that results from more expensive fuel savings technologies at the time of purchase. The effects of increased usage of car-sharing, ride-sharing, and automated vehicles were not analyzed. The analysis did not estimate how changes in labor from any of these industries could affect gross domestic product and possibly affect other industries as a result.

Many commenters voiced concerns that the NPRM analysis only included automotive direct employment, and did not explicitly consider other important factors, and that these factors would be better addressed with a macroeconomic model. For instance, the International Council on Clean Transportation contended that the dollars saved at the pump as a result of fuel saving technologies would be spent elsewhere in the economy, creating jobs.[2088] The Association of Global Automakers also referenced macroeconomic studies that project long-term job gains due to savings at the pump, but also highlight short-term setbacks for jobs as money spent to purchase additional fuel saving technologies on new vehicles is not spent in other job creating sectors of the U.S. economy, which were not considered in an analysis that only addresses direct automotive employment.[2089] The Union of Concerned Scientists and Environmental Defense Fund argued that the modeling of short-term job losses in the macroeconomic models is incorrect, and that purchasing a new vehicle, especially if financed, should *increase* disposable income, because monthly savings at the pump outpace the monthly financed cost of the fuel saving equipment, but also that consumers will not choose this equipment unless a stringent standard is chosen.[2090] The Institute for Policy Integrity commented that an analysis looking only at direct employment is incomplete, and encouraged the agencies to include long-term and economy-wide effects in scope on employment discussions.[2091]

The agencies have not quantified employment effects outside of automotive sector direct employment for this final rule. The agencies agree with commenters that the reductions in production costs of new vehicles will free up resources for other productive pursuits. Some producers may shift resources away from the development and production of fuel saving technologies and into the development and production of other vehicle attributes. In this case, there would be a transfer of labor resources within a firm. Other producers may instead pass along the reduction in production costs to consumers in the form of price reductions or avoided price increases, allowing those consumers to allocate those new funds between expenditure in other consumption categories or savings. The increased expenditure in other consumption categories would more efficiently create new employment in sectors expanding to cover new market-based (as opposed to regulatory-based) demand. Increased savings also creates additional investment in new productive capital, which will generate employment opportunities in the future. However, the extent and nature of these effects are all highly uncertain, and the

agencies have therefore not quantified the effect of the rule on economy-wide employment in the final rule analysis.

Many commenters expressed concern that America would cede leadership in development and production of fuel saving technologies, and fuel-saving technology investment would be gutted if augural standards were not kept in place. For instance, the Mayor of the City of Chillicothe, and Mayors of other Ohio cities, pointed out that many light duty vehicles are built in Ohio and neighboring geographies, and that workers designing and producing fuel economy equipment make an average annual salary of $61,500, expressing concern that if standards are lowered, some of these jobs may no longer be necessary.[2092] The BlueGreen Alliance pointed out that over the last twenty years, manufacturers have invested billions of dollars into fuel saving technologies, and that multinational companies may shift jobs to other countries if the standards do not require continued, strong, additional investment in even more fuel saving technologies.[2093]

The agencies recognize that development of fuel saving technologies can be capital intensive. However, high fuel economy standards do not, per se, guarantee multinational companies will invest in American research and development or production. For example, the larger percent U.S. content in the MY 2017 light truck vs. the MY 2017 passenger car new vehicle fleet may be tied to the so-called "Chicken Tax," a long-established tariff on the import of light duty trucks.[2094] On average, a light truck in the MY 2017 fleet contained 47.8 percent U.S. content, while a passenger car contained 36.0 percent U.S. content. To the extent that other policies encourage multi-national corporations to build and invest in U.S. production facilities, these organizations will need access to capital to do so. Notably, as part of the sales module, as fuel economy of the fleet improves, the agencies assume customers increasingly choose light trucks, meaning that a shift towards light-trucks is already considered in the CAFE model under the augural standards.

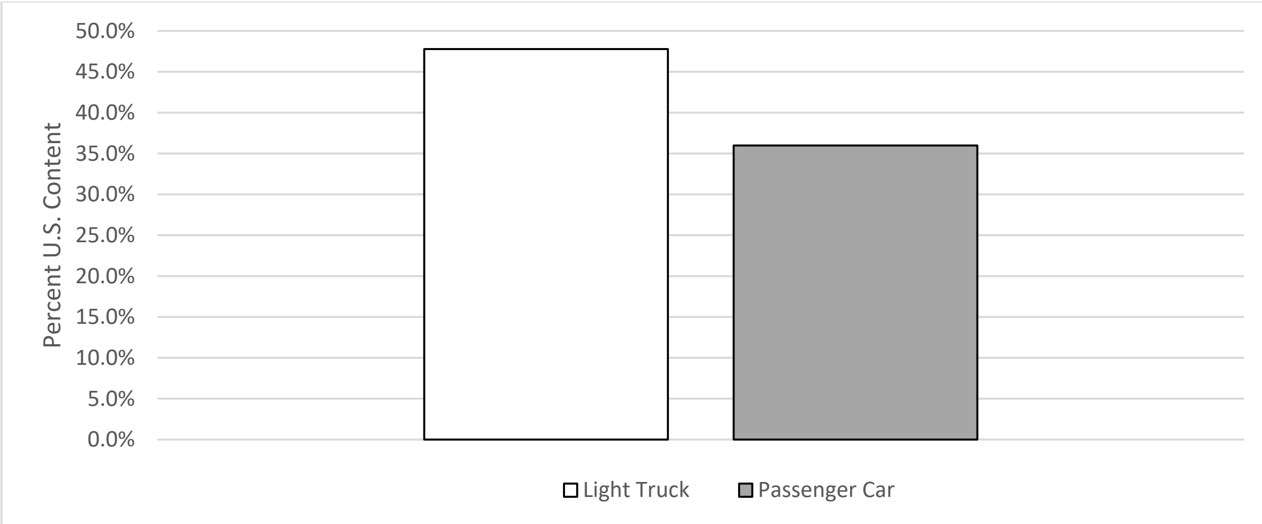

Figure VI-143 – MY 2017 Sales Weighted Percent U.S. Parts Content by Regulatory Class

Finally, no assumptions were made about part-time-level of employment in the broader economy and the availability of human resources to fill positions. When the economy is at full employment, a fuel economy regulation is unlikely to have much impact on net overall U.S. employment; instead, labor would primarily be shifted from one sector to another. These shifts in employment impose an opportunity cost on society, as regulation diverts workers from other market-based activities in the economy. In this situation, any effects on net employment are likely to be transitory as workers change jobs (e.g., some workers may need to be retrained or require time to search for new jobs, while short-term labor shortages in some sectors or regions could result in firms bidding up wages to attract workers). On the other hand, if a regulation comes into effect during a period of less-than-full employment, a change in labor demand due to regulation would affect net overall U.S. employment because the labor market is not in equilibrium. Schmalensee and Stavins point out that net positive employment effects are possible in the near term when the economy is at less than full employment due to the potential hiring of idle labor resources by the regulated sector to meet new requirements (e.g., to install new equipment) and new economic activity in sectors related to the regulated sector longer run.[2095] However, the net effect on employment in the long run is more difficult to predict and will depend on the way in which the related industries respond to regulatory requirements. For that reason, this analysis does not include multiplier effects but instead focuses on labor impacts in the most directly affected industries, which would face the most concentrated labor impacts.

[2095] Schmalensee, Richard, and Robert N. Stavins. "A Guide to Economic and Policy Analysis of EPA's Transport Rule." White paper commissioned by Excelon Corporation, March 2011 (Docket EPA-HQ-OAR-2010-0799-0676).

(b) Estimating Labor for Fuel Economy Technologies, Vehicle Components, Final Assembly, and Retailers

The following sections discuss the approaches to estimating factors related to dealership labor, final assembly labor and parts production, and fuel economy technology labor.

(i) Dealership Labor

The NPRM analysis evaluated dealership labor related to new light-duty vehicle sales, and estimated the labor hours per new vehicle sold at dealerships, including labor from sales, finance, insurance, and management. The effect of new car sales on the maintenance, repair, and parts department labor is expected to be limited, as this need is based on the vehicle miles traveled of the total fleet. To estimate the labor hours at dealerships per new vehicle sold, the agencies referenced the National Automobile Dealers Association 2016 Annual Report, which provides franchise dealer employment by department and function.[2096] The analysis estimated that slightly less than 20 percent of dealership employees' work relates to new car sales (versus approximately 80 percent in service, parts, and used car sales), and that on average dealership employees working on new vehicle sales labor for 27.8 hours per new vehicle sold. The analysis presented today retains assumptions about dealership labor hours per vehicle sold.

(ii) Final Assembly Labor and Parts Production

As new vehicle sales increase or decrease, the amount of labor required to assemble parts and vehicles changes accordingly. The NPRM evaluated how the quantity of assembly labor and parts production labor for MY 2016 vehicles would increase or decrease in the future as new vehicle unit sales increased or decreased. Specific assembly locations for final vehicle assembly, engine assembly, and transmission assembly for each MY 2016 vehicle were identified. In some cases, manufacturers assembled products in more than one location, and the analysis identified such products and considered parallel production in the labor analysis.

The analysis estimated average direct assembly labor per vehicle (30 hours), per engine (four hours), and per transmission (five hours) based on a sample of U.S. assembly plant employment and production statistics and other publicly available information. The analysis used the assembly locations and averages for labor per unit to estimate U.S. assembly labor hours for each vehicle. U.S. assembly labor hours per vehicle ranged from as high as 39 hours if the manufacturer assembled the vehicle, engine, and transmission at U.S. plants, to as low as zero hours if the manufacturer imported the vehicle, engine, and transmission.

The analysis also considered labor for parts production. The agencies surveyed motor vehicle and equipment manufacturing labor statistics from the U.S. Census Bureau, the Bureau of Labor Statistics, and other publicly available sources. The agencies found that the historical average ratio of vehicle assembly manufacturing employment to employment for total motor

---

[2096] *NADA Data 2016: Annual Financial Profile of America's Franchised New-Car Dealerships*, National Automobile Dealers Association, https://www.nada.org/2016NADAdata/ (last visited December 20, 2019).

vehicle and equipment manufacturing for new vehicles was roughly constant over the period from 2001 through 2013, at a ratio of 5.26.[2097] Observations from 2001-2013 included many combinations of technologies and technology trends, and many economic conditions, yet the ratio remained about the same over time. Accordingly, the analysis scaled up estimated U.S. assembly labor hours by a factor of 5.26 to consider U.S. parts production labor in addition to assembly labor for each vehicle. The estimates for vehicle assembly labor and parts production labor for each vehicle scaled up or down as unit sales scaled up or down over time in the CAFE model.

The analysis presented today retains assumptions about coefficients for final assembly labor and parts production, and updates production and final assembly locations for the MY 2017 fleet. As discussed in Section VI.D.1.b(2), today's analysis also applies updated methods for estimating the extent to which changes in CAFE and CO_2 standards might lead to changes in quantities of new vehicles sold each year. These estimated changes in sales lead to changes in estimated changes in domestic employment.

(iii) Fuel Economy Technology Labor

As manufacturers spend additional dollars on fuel-saving technologies, parts suppliers and manufacturers require labor to bring those technologies to market. Manufacturers may add, shift, or replace employees in ways that are difficult for the agencies to predict; however, it is expected that the revenue per labor hour at original equipment manufacturers (OEMs) and suppliers will remain about the same as in MY 2016 even as manufacturers include additional fuel-saving technology. To estimate the average revenue per labor hour at OEMs and suppliers, the analysis looked at financial reports from publicly traded automotive businesses.[2098] Based on recent figures, it was estimated that OEMs would add one labor year per each $633,066 increment in revenue and that suppliers would add one labor year per $247,648 in revenue.[2099] These global estimates are applied to all revenues, and U.S. content is applied as a later adjustment. In today's analysis, the agencies assume these ratios would remain constant for all technologies rather than that the increased labor costs would be shifted toward foreign countries. There are some reasons to believe that this may be a conservative assumption. For instance, domestic manufacturers may react to increased labor costs by searching for lower-cost labor in other countries.

The analysis presented today retains assumptions about coefficients for fuel economy technology labor, and updates the percent of U.S. content for the MY 2017 fleet.

[2097] NAICS Code 3361, 3363.

[2098] The analysis considered suppliers that won the Automotive News "PACE Award" from 2013-2017, covering more than 40 suppliers, more than 30 of which are publicly traded companies. Automotive News gives "PACE Awards" to innovative manufacturers, with most recent winners earning awards for new fuel-savings technologies.

[2099] The analysis assumed incremental OEM revenue as the retail price equivalent for technologies, adjusting for changes in sales volume. The analysis assumed incremental supplier revenue as the technology cost for technologies before retail price equivalent mark-up, adjusting for changes in sales volume.

(iv) Labor Calculations

The agencies estimated the total labor effect as the sum of three components: changes to dealership hours, final assembly and parts production, and labor for fuel-economy technologies (at OEMs and suppliers) that are due to the final rule. The CAFE model calculated additional labor hours for each vehicle, based on current vehicle manufacturing locations and simulation outputs for additional technologies, and sales changes. The analysis applied some constants to all vehicles.[2100] Other constants were vehicle specific, for all years considered in the analysis.[2101] Still, other constants were year-specific for a vehicle.[2102] While a multiplier effect of all U.S. automotive related labor on non-auto related U.S. jobs was not considered for the final rule's analysis, the analysis did incorporate a "global multiplier" that can be used to scale up or scale down the total labor hours. This parameter exists in the parameters file, and for the final rule's analysis the analysis set the value at 1.00. The results of this analysis can be found in Table VI-236 below.

Table VI-236 – Work Loss Days through MY 2029

	Alternative						
Model Years	1	2	3	4	5	6	7
	2021-2026	2021-2026	2021-2026	2021-2026	2022-2026	2021-2026	2022-2026
Annual Rate of Stringency Increase	0.0%/Year PC 0.0%/Year LT	0.5%/Year PC 0.5%/Year LT	1.5%/Year PC 1.5%/Year LT	1.0%/Year PC 2.0%/Year LT	1.0%/Year PC 2.0%/Year LT	2.0%/Year PC 3.0%/Year LT	2.0%/Year PC 3.0%/Year LT
Work Loss Days (thousand instances) through MY2029	89.61	87.55	45.36	36.38	19.91	-12.46	3.58

Results of this analysis can be found in Section VII. Considering that, all else equal, increases in new vehicle sales lead to increases in domestic employment while decreases in technology outlays lead to decreases in domestic employment, the agencies estimate that less stringent standards could slightly reduce domestic employment. It is important to note, however, that the reduction in person-years described in this table merely reflects the fact that, when compared to the standards set in 2012, fewer jobs will be specifically created to meet regulatory requirements that, for other reasons, are not economically practicable. It is also important to note that avoided outlays for technology can be invested by manufacturers into other areas, or passed on to consumers. Moreover, consumers can either take those cost savings in the form of a reduced vehicle price, or used toward the purchase of specific automotive features that they

---

[2100] The analysis applied the same assumptions to all manufacturers for annual labor hours per employee, dealership hours per unit sold, OEM revenue per employee, supplier revenue per employee, and factor for the jobs multiplier.
[2101] The analysis made vehicle-specific assumptions about percent of U.S. content and U.S. assembly employment hours.
[2102] The analysis estimated technology cost for each vehicle, for each year based on the technology content applied in the CAFE model, year-by-year.

desire (potentially including a more-efficient vehicle), which would increase employment among suppliers and manufacturers.

2. Simulating Safety Impacts of Regulatory Alternatives

The primary objectives of CAFE and CO_2 standards are to achieve maximum feasible fuel economy and reduce CO_2 emissions, respectively, from the light-duty vehicle fleet. In setting standards to achieve these intended effects, the potential of the standards to affect vehicle safety is also considered. As a safety agency, NHTSA has long considered the potential for adverse safety consequences when establishing CAFE standards, and under the CAA, EPA considers factors related to public health and human welfare, including safety, in regulating emissions of air pollutants from mobile sources.

Safety trade-offs associated with increases in fuel economy standards have occurred in the past—particularly before CAFE standards became attribute-based—because manufacturers chose to comply with stricter standards by building smaller and lighter vehicles. In cases where fuel economy improvements were achieved through reductions in vehicle size and mass, the smaller, lighter vehicles did not protect their occupants as effectively in crashes as larger, heavier vehicles, on average. Although the agencies now use attribute-based standards, in part to reduce the incentive to downsize vehicles to comply with CAFE and CO_2 standards, the agencies must continue to be mindful of the possibility of safety-related trade-offs.

Although prior analyses acknowledged that CAFE and CO_2 standards could influence factors that affect safety other than vehicle mass, those impacts were not estimated quantitatively.[2103] Instead, the agencies focused exclusively on the safety impacts of changes in vehicle mass. In the proposal, the safety analysis was expanded to include a broader and more comprehensive measure of safety impacts. The final rule retains this comprehensive approach and analyzes the safety impact of three factors:

1) **Changes in Vehicle Mass.** Similar to previous analyses, the agencies calculate the safety impact of changes in vehicle mass made to reduce fuel consumption and comply with the standards. The agencies' statistical analysis of historical crash data indicates reducing mass in heavier vehicles generally improves safety, while reducing mass in lighter vehicles generally reduces safety. NHTSA's crash simulation modeling of vehicle design concepts for reducing mass revealed similar effects.

2) **Impacts of Vehicle Prices.** Vehicles have become safer over time through a combination of new safety regulations and voluntary safety improvements. The agencies expect this trend to continue as emerging technologies, such as advanced driver assistance systems, are incorporated into new vehicles. Safety improvements

[2103] The agencies included a quantification of rebound-associated safety impacts in its Draft TAR analysis, but because the scrappage model is new for this rulemaking, did not include safety impacts associated with the effect of standards on new vehicle prices and thus on fleet turnover. The fact that the scrappage model did not exist prior to this rulemaking does not mean that the effects that it aims to show were not important considerations, simply that the agencies were unable to account for them quantitatively prior to the current rulemaking.

will likely continue regardless of changes to CAFE standards. However, the pace of such improvements may be modified if manufacturers choose to delay or forgo investments in safety technology because of the demands that complying with stricter CAFE and CO_2 standards impose on scarce research, development, and manufacturing resources.

As discussed in Section VI.D.1.b), technologies added to comply with fuel economy standards have an impact on vehicle prices, and, by extension, on the affordability of newer, safer vehicles, and therefore on the rates at which newer vehicles are acquired and older, less safe vehicles are retired from use. The delays in fleet turnover caused by the effect of new vehicle prices on sales and scrappage rates affect safety, by slowing the penetration of new safety technologies into the fleet.
The standards also influence the composition of the light-duty fleet. As the safety provided by light trucks, SUVs and passenger cars responds differently to technology that manufacturers employ to meet the standards—particularly mass reduction—fleets with different compositions of body styles will have varying numbers of fatalities, so changing the share of each type of light-duty vehicle in the projected future fleet impacts safety outcomes.

3) **Increased driving because of better fuel economy.** The "rebound effect" predicts consumers will drive more when the cost of driving declines. More stringent standards reduce vehicle operating costs, and in response, some consumers may choose to drive more. Additional driving increases exposure to risks associated with motor vehicle travel, and this added exposure translates into higher fatalities and injuries.

The impact of these factors is measured as differences in fatalities across the alternatives. Fatalities are calculated by deriving a fleet-wide fatality rate (fatalities per vehicle mile of travel) incorporating the different factors and multiplying it by the alternative's expected VMT. Fatalities are converted into a societal cost by multiplying fatalities with the DOT-recommended value of a statistical life (VSL). As with the NPRM, traffic injuries and property damage are not modeled directly;[2104] rather, traffic injuries and property damage continue to be estimated using adjustment factors that reflect the observed relationship between societal costs of fatalities and costs of injuries and property damage.

All three factors influence predicted fatalities, but only two of them—changes in vehicle mass and in the composition of the light-duty fleet in response to changes in vehicle prices—impose increased risks on drivers and passengers that are not compensated for by accompanying benefits. In contrast, increased driving associated with the rebound effect is a consumer choice that reveals the benefit of additional travel. Consumers who choose to drive more have apparently concluded that the utility of additional driving exceeds the additional costs for doing so—including the crash risk that they perceive additional driving involves. As discussed in

[2104] The agencies noted in the NPRM that traffic injuries and property damage are not directly modeled because of insufficient data. *See* PRIA at 43108.

Impact of Rebound Effect on Fatalities, the benefits of rebound driving are accounted for by offsetting a portion of the added safety costs.

Some commenters argued that the agencies should be measuring the change in the fatality rate rather than the change in the number of fatalities. For example, EDF argued that changes in fatalities was a measurement of VMT and number of passengers rather than safety, and that "NHTSA's job is to decrease the fatality rate per mile, not to decrease the number of miles people drive."[2105] EDF also commented that the agencies were required to report the "fatality rate data for the overall safety impacts." The agencies disagree with EDF. The agencies are responsible for measuring the impacts of fuel economy and CO_2 standards, including changes to VMT. While other NHTSA safety rules have minimal impacts upon aggregate VMT, CAFE standards have a large impact on VMT and VMT-related costs, including fatalities.

Although NHTSA often uses changes in fatality rates as a metric to evaluate the impact of regulations on safety, these rates are just a tool utilized to derive the relevant safety impact—namely the estimated change in fatalities. Furthermore, as part of the cost-benefit analysis required by Executive Order 12866 and specified in OMB Circular A-4, the agencies must quantify and value safety impacts to compare them to the costs of the regulation. The fundamental metric for valuing loss of life is the VSL. To apply this metric, the agencies must first produce estimates of any change in the number of fatalities that results from the regulatory action. Fatalities prevented, as well as other safety impacts such as non-fatal injuries prevented and property damage crashes avoided, are appropriate measures of rules that affect motor vehicle safety.

The safety component of CAFE analysis has evolved over time. In the 2012 final rule and 2016 Draft Technical Assessment Report, the agencies accounted for the change in projected fatalities attributable to mass reduction of new vehicles, however inputs to the analysis were adjusted to achieve a safety neutral outcome. The model assumed that manufacturers would choose limit mass reduction as a compliance method across vehicle classes such that the net effect of mass reduction on fatalities was zero. However, in the 2016 draft Technical Assessment Report, DOT made two consequential changes to the analysis of fatalities associated with the CAFE standards. In particular, first, the modelling assumed that mass reduction technology was available to all vehicles, regardless of net safety impact, and second, it accounted for the incremental safety costs associated with additional miles traveled due to the rebound effect. The proposal for this rulemaking made several additional changes to the analysis that continue to be used for the final rule. In particular, mass reduction is no longer limited to ensure a safety neutral outcome. Instead, mass reduction is available to all vehicles and is applied without manipulation based on its cost-effectiveness, and regardless of net safety impact. It also extends the analysis to report incremental fatality impacts associated with additional miles traveled due to the rebound effect, and identifies the increase in fatalities associated with additional driving separately from changes in fatalities attributable to other sources.[2106] The

---

[2105] EDF, Appendix A, NHTSA-2018-0067-12108, at 7-9.

[2106] Drivers who travel additional miles are assumed to experience benefits that at least offset the costs they incur in doing so, including the increased safety risks they face. Thus, while the number of additional fatalities resulting from increased driving is reported, the associated costs are offset to reflect drivers' internalization of safety risk.

NPRM and current analysis adds another element: the effect that higher new vehicle prices have on new vehicle sales and on used vehicle scrappage, which influences total expected fatalities because older vehicle vintages are associated with higher rates of involvement in fatal crashes than newer vehicles.

a) Impact of Weight Reduction on Safety

Vehicle mass reduction can be one of the more cost-effective means of increasing fuel economy and reducing CO_2 emissions to meet standards—particularly for makes and models not already built with much high strength steel or aluminum closures or low mass components. Manufacturers have stated that they will continue to reduce vehicle mass to meet more stringent standards, and therefore, this expectation is incorporated into the modeling analysis supporting the standards. Safety trade-offs associated with mass-reduction have occurred in the past, particularly before CAFE standards were attribute-based; past safety trade-offs may have occurred because manufacturers chose at the time, in response to CAFE standards, to build smaller and lighter vehicles. In cases where fuel economy improvements were achieved through reductions in vehicle size and mass, the smaller, lighter vehicles did not fare as well in crashes as larger, heavier vehicles, on average. Although the agencies now use attribute-based standards, in part to reduce or eliminate the incentive to downsize vehicles to comply with CAFE and CO_2 standards,[2107] the agencies must be mindful of the possibility of related safety trade-offs.

Historically, as shown in FARS data analyzed by the agencies, mass reduction concentrated among the heaviest vehicles (chiefly, the largest LTVs, CUVs and minivans) is estimated to reduce overall fatalities, while mass reduction concentrated among the lightest vehicles (chiefly, smaller passenger cars) is estimated to increase overall fatalities. Mass reduction in heavier vehicles is more beneficial to the occupants of lighter vehicles than it is harmful to the occupants of the heavier vehicles. Mass reduction in lighter vehicles is more harmful to the occupants of lighter vehicles than it is beneficial to the occupants of the heavier vehicles. In response to questions of whether designs and materials of more recent model year vehicles may have weakened the historical statistical relationships between mass, size, and safety, NHTSA updated its public database for statistical analysis consisting of crash data. The analysis considered the full range of real-world crash types.

The methodology used for the statistical analysis of historical crash data has evolved over many years. The methodology used for the NPRM and unchanged for the final rule reflects learnings and refinements from: NHTSA studies in 2003, 2010, 2011, 2012, and 2016; independent peer review of 23 studies by the University of Michigan Transportation Research

---

[2107] CAFE and CO_2 standards are "footprint-based," with footprint being defined as a measure of a vehicle's size, roughly equal to the wheelbase times the average of the front and rear track widths. Footprint-based standards create a disincentive for manufacturers to produce smaller-footprint vehicles. This is because, as footprint decreases, the corresponding fuel economy/CO_2 emission target becomes more stringent. We also believe that the shape of the footprint curves themselves is such that the curves should neither encourage manufacturers to increase nor decrease the footprint of their fleets.

Institute;[2108] two public workshops hosted by NHTSA;[2109] interagency collaboration among NHTSA, DOE and EPA; and comments to CAFE and CO_2 rulemakings in 2010, 2012, the 2016 Draft TAR, and the 2018 NPRM. As explained in greater detail below, the methodology used for the statistical analysis of historical crash data for the NPRM and final rule is the best and most up to date available.

Additionally, to assess whether future vehicle designs may impact the relationship of vehicle mass reduction on safety, NHTSA sponsored a fleet crash simulation study using future mass reduction vehicle design concepts (see Section 11.1.5 below). The results of the simulation research showed that future mass reduction techniques continue to exhibit impacts on safety and were consistent with the statistical analysis of FARS crash data. The agencies considered the findings of the study and concluded it was reasonable and appropriate to continue to consider the impact of mass reduction on safety for future vehicles because the data indicate the relationship between mass and safety will continue in the future.

For the rulemaking analysis, the CAFE Model tracks the amount of mass reduction applied to each vehicle model, and then applies estimated changes in societal fatality risk per 100 pounds of mass reduction determined through the statistical analysis of FARS crash data. This process allows the CAFE Model to tally changes in fatalities attributed to mass reduction across all of the analyzed future model years. In turn, the CAFE Model is able to provide an overall impact of the final standards and alternatives on fatalities attributed to mass reduction.

A number of comments were received on technical aspects of the mass-safety analysis in the NPRM. The agencies carefully considered all comments. Where warranted, the agencies conducted additional analyses to determine whether commenters' suggestions would improve the analysis. The agencies found that the methodology employed by the proposal, which was developed over many years, subject to extensive review and feedback, remains the most rigorous methodology. The agencies found the alternative approaches raised in comments would provide less likely estimates, were statistically problematic, or, in some cases, advocated discarding or ignoring the most likely estimates altogether. The agencies' assessments of comments are discussed in detail in the subsections below.

Overall, consistent with prior analyses, the data show that mass reduction concentrated in heavier vehicles is generally beneficial to overall safety, and mass reduction concentrated in lighter vehicles is harmful.

Available at http://www.umtri.umich.edu/our-results/publications/independent-review-statistical-analyses-relationship-between-vehicle-curb.

[2109] The workshops were held on February 25, 2011 and May 13-14, 2013. Video, transcripts, and presentations are available on the NHTSA website (recommended search terms include "workshop", "mass", "safety", and the dates of the workshops).

(1) Crash Data

The agencies use real-world crash data as the basis for projecting the future safety implications for regulatory changes. To support the 2012 rulemaking, NHTSA created a common, updated database for statistical analysis consisting of crash data. The initial iteration contained crash data for model years 2000-2007 vehicles in calendar years 2002-2008. NHTSA made the preliminary version of the new database, which was the basis for NHTSA's 2011 preliminary report (*hereinafter* 2011 Kahane report),[2110] available to the public in May 2011, and an updated version in April 2012 (used in NHTSA's 2012 final report, *hereinafter* 2012 Kahane report),[2111] enabling other researchers to analyze the same data and, hopefully, minimize discrepancies in results caused by reporting inconsistencies across databases.[2112] NHTSA updated the crash and exposure databases for the 2016 Draft TAR analysis.

For the proposed rule and unchanged for today's final rule, the crash and exposure databases were updated again. The databases are the most up-to-date possible (MY 2004-2011 vehicles in CY 2006-2012), given the processing time for crash data and the need for enough crash cases to permit statistically meaningful analyses. As in previous analyses, NHTSA has made the new databases available to the public on its website.[2113]

(2) Methodology

The relationship between a vehicle's mass, size, and fatality risk is complex, and it varies in different types of crashes. NHTSA has been examining this relationship for more than two decades. The basic analytical method used to analyze the impacts of weight reduction on safety for the proposal, and unchanged for this final rulemaking, is the same as in 2016 Puckett and Kindelberger report.[2114] NHTSA released the 2016 Puckett and Kindelberger report as a preliminary report on the relationship between fatality risk, mass, and footprint in June 2016 in advance of the Draft TAR. The 2016 Puckett and Kindelberger report covered the same scope as previous NHTSA reports,[2115] offering a detailed description of the crash and exposure databases, modeling approach, and analytical results on relationships among vehicle size, mass, and fatalities that informed the Draft TAR. The modeling approach described in the 2016 Puckett and Kindelberger report was developed with the collaborative input of NHTSA, EPA and DOE,

and subject to extensive public review, scrutiny in two NHTSA-sponsored workshops, and a thorough peer review that compared it with the methodologies used in other studies.[2116]

In computing the impact of changes in mass on safety, the agencies are faced with competing challenges. Research has consistently shown that mass reduction affects "lighter" and "heavier" vehicles differently across crash types. The 2016 Puckett and Kindelberger report found mass reduction concentrated amongst the heaviest vehicles is likely to have a beneficial effect on overall societal fatalities, while mass reduction concentrated among the lightest vehicles is likely to have a detrimental effect on fatalities.[2117] To accurately capture the differing effect on lighter and heavier vehicles, the agencies must split vehicles into lighter and heavier vehicle classifications in the analysis.[2118] However, this poses a challenge of creating statistically-meaningful results. There is limited relevant crash data to use for the analysis. Each partition of the data reduces the number of observations per vehicle classification and crash type, and thus reduces the statistical robustness of the results. The methodology employed by the agencies was designed to balance these competing forces as an optimal trade-off to accurately capture the impact of mass-reduction across vehicle curb weights and crash types while preserving the potential to identify robust estimates.

For the proposal and the final rule, the agencies employed the modeling technique developed in the 2016 Puckett and Kindelberger report to analyze the updated crash and exposure data by examining the cross sections of the societal fatality rate per billion vehicle miles of travel (VMT) by mass and footprint, while controlling for driver age, gender, and other factors, in separate logistic regressions for five vehicle groups and nine crash types. "Societal" fatality rates include fatalities to occupants of all the vehicles involved in the collisions, plus any pedestrians, cyclists, or occupants of other conveyances (e.g., motorcyclists). The agencies utilize the relationships between weight and safety from this analysis, expressed as percentage increases in fatalities per 100-pound weight reduction, to examine the weight impacts applied in this CAFE analysis. The effects of mass reduction on safety were estimated relative to (incremental to) the regulatory baseline (augural standards) in the CAFE analysis, across all vehicles for MYs 2018 and beyond.

As in the 2012 Kahane report, 2016 Puckett and Kindelberger report, and the Draft TAR, the vehicles are grouped into three classes: passenger cars (including both two-door and four-

---

[2116] Previous reports from which the 2016 Puckett and Kindelberger report was derived from, were also subject to extensive peer reviews. Farmer, Green, and Lie, who reviewed the 2010 Kahane report, also peer-reviewed the 2011 Kahane report. In preparing his 2012 report (along with the 2016 Puckett and Kindelberger report and Draft TAR), Kahane also took into account Wenzel's assessment of the preliminary report and its peer reviews, DRI's analyses published early in 2012, and public comments such as the International Council on Clean Transportation's comments submitted on NHTSA and EPA's 2010 notice of joint rulemaking. These comments prompted supplementary analyses, especially sensitivity tests, discussed at the end of this section.

[2117] The findings of the 2016 Puckett and Kindelberger report are consistent with the results of the 2012 Kahane report and Draft TAR.

[2118] If lighter and heavier vehicles are left undistinguished, the agencies analysis would be restricted to identifying a single effect of mass reduction for passenger cars and a single effect of mass reduction for truck-based LTVs. As discussed below, distinct effects have been estimated historically for lighter versus heavier vehicles for cars and LTVs, confirming the validity of distinguishing by curb weight where feasible.

door cars); CUVs and minivans; and truck-based LTVs. The curb weight of passenger cars is formulated, as in the 2012 Kahane report, 2016 Puckett and Kindelberger report, and Draft TAR, as a two-piece linear variable to estimate one effect of mass reduction in the lighter cars and another effect in the heavier cars. The boundary between "lighter" and "heavier" cars is 3,201 pounds (which is the median mass of MY 2004-2011 cars in fatal crashes in CY 2006-2012, up from 3,106 pounds for MY 2000-2007 cars in CY 2002-2008 in the 2012 NHTSA safety database, and up from 3,197 pounds for MY 2003-2010 cars in CY 2005-2011 in the 2016 NHTSA safety database). Likewise, for truck-based LTVs, curb weight is a two-piece linear variable with the boundary at 5,014 pounds (again, the MY 2004-2011 median, higher than the median of 4,594 pounds for MY 2000-2007 LTVs in CY 2002-2008 and the median of 4,947 pounds for MY 2003-2010 LTVs in CY 2005-2011). CUVs and minivans are grouped together in a single group covering all curb weights of those vehicles; as a result, curb weight is formulated as a simple linear variable for CUVs and minivans. Historically, CUVs and minivans have accounted for a relatively small share of new-vehicle sales over the range of the data, resulting in less crash data available than for cars or truck-based LTVs. In sum, vehicles are distributed into five groups by class and curb weights: passenger cars < 3,201 pounds; passenger cars 3,201 pounds or greater; truck-based LTVs < 5,014 pounds; truck-based LTVs 5,014 pounds or greater; and all CUVs and minivans.

There are nine types of crashes specified in the analysis for each vehicle group: three types of single-vehicle crashes, five types of two-vehicle crashes; and one classification of all other crashes. Single-vehicle crashes include first-event rollovers, collisions with fixed objects, and collisions with pedestrians, bicycles and motorcycles. Two-vehicle crashes include collisions with: heavy-duty vehicles; cars, CUVs, or minivans < 3,187 pounds (the median curb weight of other, non-case, cars, CUVs and minivans in fatal crashes in the database); cars, CUVs, or minivans ≥ 3,187 pounds; truck-based LTVs < 4,360 pounds (the median curb weight of other truck-based LTVs in fatal crashes in the database); and truck-based LTVs ≥ 4,360 pounds. Grouping partner-vehicle CUVs and minivans with cars rather than LTVs is more appropriate because their front-end profile and rigidity more closely resemble a car than a typical truck-based LTV. An additional crash type includes all other fatal crash types (e.g., collisions involving more than two vehicles, animals, or trains). Splitting the vehicles from this crash type involved in crashes involving two light-duty vehicles into a lighter and a heavier group permits more accurate analyses of the mass effect in collisions of two vehicles.

For a given vehicle class and weight range (if applicable), regression coefficients for mass (while holding footprint constant) in the nine types of crashes are averaged, weighted by the number of baseline fatalities that would have occurred for the subgroup MY 2008-2011 vehicles in CY 2008-2012 if these vehicles had all been equipped with electronic stability control (ESC). The adjustment for ESC, a feature of the analysis added in 2012, takes into account results will be used to analyze effects of mass reduction in future vehicles, which will all be ESC-equipped, as required by NHTSA's safety regulations.

The agencies received multiple comments on how they distribute vehicles into classifications. IPI, quoting a study by Tom Wenzel, commented that sorting vehicles into footprint deciles shows positive impacts from mass reduction for the majority of the footprint deciles.[2119] CARB commented that the agencies should have used the curb weight of all vehicles to calculate the thresholds for "lighter" and "heavier" vehicle types rather than just the curb weights of vehicles involved in fatal crashes.[2120] CARB also commented that pickup trucks and SUVs that are not subject to CAFE regulation (i.e., Class 2b and Class 3 vehicles, such as ¾-ton and one-ton pick-up trucks, vans and related SUVs) should not be included in the assessment of the impact of mass on safety and doing so raises the median weight of trucks.[2121] CARB also commented that the median weights are static values representing the historical fleet, but the median weights and proportions of crash types involving given vehicle weight categories should change with median weight of the fleet modeled by the CAFE Model.[2122] Commenters generally believed that the agencies' approach "results in inappropriate apportioning of cars and trucks into the corresponding lighter or heavier bins," which in turn causes the agencies to overestimate the fatalities associated with mass reduction.[2123]

Dividing vehicles into footprint deciles and excluding Class 2b and 3 vehicles pose sample size and data coverage issues. If vehicles were grouped into footprint deciles, the sample sizes in each decile would be approximately one-fifth as large as the corresponding sample sizes in each of the agencies' four passenger car and LTV vehicle classes (and one-tenth as large as the sample size for CUVs and minivans). Smaller parameter estimates require correspondingly smaller standard errors (i.e., relatively precise estimates) to achieve statistical significance, but splitting the limited data into deciles yields larger standard errors, restricting the ability to identify statistically-significant estimates. Likewise, by extending the footprint-curb weight-fatality data to include Class 2b and 3 trucks that are functionally and structurally similar to corresponding ½-ton models that are subject to CAFE regulation,[2124] the sample size and ranges

[2124] Class 2b and 3 pick-up trucks, vans and SUVs have physical characteristics and usage profiles that are substantially similar to their Class 2a counterparts. For example, the Class 2a version of the Ford F-150 has similar physical characteristics to and has a similar usage profile to the Class 2b Ford F150. Same for the Class 2a Ford F150 relative to the Class 2b and 3 Ford F250, and for the GMC Yukon relative to the Yukon XL. The Class 2b and 3 pickup trucks in the sample generally have gross vehicle weight ratings of 10,000 pounds or less, and thus are subject to the same Federal motor vehicle safety standards as their light-duty counterparts. Likewise, these vehicles generally have similar physical dimensions (e.g., ground clearance, width) as related light-duty vehicles. Key differentiating factors among these vehicles are height, payload, and towing capacity. There are likely to be unobserved differences in how these vehicles are driven relative to light-duty alternatives; however, the crash data include a census of fatal crashes involving case vehicles and the Class 2b and 3 vehicles included in the analysis, in turn representing the relative risk of differences in curb weight in crashes involving Class 2b and 3 vehicles. Despite being regulated by different fuel economy and emissions regulation as they become heavier, the vehicles may continue to be used in similar ways over time; in turn, the safety implications of the presence of these vehicles may continue to be similar. In contrast, other types of heavy-duty vehicles, such as box trucks, buses, refuse trucks, fire trucks, and other heavy-duty commercial vehicles are substantially different from light duty vehicles in their physical characteristics and usage profiles, and it would not be appropriate to include them in the statistical analysis to determine the impact of mass on crash fatalities.

of curb weights and footprint are improved. Sample size is a challenge for estimating relationships between curb weight and fatality risk for individual crash types in the main analysis; dividing the sample further or removing observations makes it exceedingly difficult to identify meaningful estimates and the relationships that are present in the data.

Compounding the issue is the fact the analysis focuses on societal fatality risk (i.e., all fatalities, including crash partners and people outside of vehicles, such as pedestrians, cyclists, and motorcyclists) rather than merely in-vehicle fatality risk, which yields estimates that are smaller in magnitude (and thus more difficult to identify meaningful differences from zero) than estimates representing changes in in-vehicle fatality risk. That is, compared to an analysis of in-vehicle fatality risk (which would tend to yield relatively large estimated effects of mass reduction), the focus on societal fatalities tends to yield relatively small (net) effects of mass reduction on fatality risk.

Including Class 2b and 3 vehicles in the analysis to determine the relationship of vehicle mass on safety has the added benefit of improving correlation constraints. Notably, curb weight increases faster than footprint for large light trucks and Class 2b and 3 pickup trucks and SUVs, in part because the widths of vehicles are constrained more tightly (i.e., due to lane widths) than their curb weights. Including data from Class 2b and 3 pick-up truck and SUV fatal crashes provides data over a wider range of vehicle weights, which improves the ability to estimate the mass-crash fatality relationship. The agencies believe the decision of whether to include Class 2b and 3 vehicles in the analysis should be made based on whether the additional data improves the estimate of the safety impact of mass reduction in light trucks, and that the fatality data should not be simplistically excluded because the vehicles are not regulated under the CAFE and CO_2 emissions programs. Ultimately, the agencies find that: (1) the fundamental objective is to capture the strongest, meaningful signal regarding societal fatality risk as a function of the mass of light trucks; (2) that incorporating information on fatal incidents involving Class 2b and 3 trucks improves the quality of the signal the agencies can capture, and (3) including the vehicles provides the best estimate of the impacts of mass on societal fatalities.

In assessing whether to calculate the median curb weight threshold from all vehicles involved in accidents or on the road, the agencies weighed changing the process used to establish the thresholds and the potential impact on the robustness of the statistical analysis. From a statistical perspective, using thresholds that allocate a similar number of fatal crash cases to both the lower vehicle weight group and the higher vehicle weight group for a given vehicle type will minimize the average standard errors of estimates for both groups, which provides the best estimates for each group. Because reducing average standard errors strengthens the statistical analysis, the agencies conclude using only the curb weight of vehicles involved in fatal crashes to calculate the median curb weight threshold produces the best estimate. This conclusion is the same that was reached previously when considering the same issue for the 2011 Kahane, 2012 Kahane, and 2016 Puckett and Kindelberger analyses.

On a related note, the regression models are estimated based on with respect to the total number of fatalities associated within each vehicle weight group classification (referred to as vehicle group below, for brevity). Shifting the threshold would change the estimated incremental impact of changes in curb weight in each vehicle group, but the net effects would offset each other across vehicle groups, resulting in the same overall estimated effect of changes in vehicle mass on societal fatality risk. For example, if one restricted the "lightest" group for a vehicle type to include only the bottom ten percentiles of vehicle weight, one would expect to identify a very strong detrimental effect (or weakest beneficial effect) of mass reduction for that group. However, the estimated effect of mass reduction in that group has minimal implications for the fleet (i.e., because there are fewer vehicles in the group), and the corresponding estimated effect of mass reduction for other groups would also mute the impact (i.e., because there are many vehicles in the group that vary in mass to a much larger degree than in the "lighter" group). Ultimately, the mean effect of mass reduction across the lighter and heavier groups would be the same as when using the median as the threshold (or at least, similar, subject to limitations in statistical optimization), but with a different point of reference when comparing the groups. Thus, the agencies believe the selection of curb weight threshold has a minimal impact on the estimated effects of mass reduction across all vehicle types.

Full consideration of CARB's comment on mass thresholds, and whether they should change as the median weight of the fleet modeled by the CAFE Model changes, requires a deeper look at each of the crash types considered in the analysis. That is, the point estimates presented in Table VI-237 represent weighted averages across nine separate, mutually-exclusive and exhaustive crash models (analyzed separately for cars, LTVs, and CUVs and minivans). For example, an individual model for first-event rollovers yields estimates of the percentage change in societal fatality risk per 100-pound mass reduction for lighter and heavier (or, in the case of CUVs and minivans, all) vehicles in the target vehicle class. The final, overall point estimate for a given vehicle type is found by: (1) multiplying the estimate associated with an individual crash type by the estimated share of societal fatalities involving the vehicle class (adjusting for two-vehicle collisions that span vehicle classes to avoid double-counting); and (2) summing the values estimated in (1) across all crash types. In its comments, CARB noted that if the distribution of vehicles in terms of curb weight changes through lightweighting, the shares of (fatal) two-vehicle crashes involving a given pair of vehicles as defined by weight class (e.g., car below a given threshold colliding with a LTV above a given threshold) would change. In turn, the appropriate weighting across the crash types modeled in the analysis would likewise be different (involving an increasing share of vehicles below a given curb weight threshold). Due to these potential limitations, CARB questioned the stability of the summary point estimates relative to changes in the shares of fatalities within each crash type in the analysis.[2125]

To evaluate CARB's concerns regarding future crash mixes and definitions of vehicle weight classes, the agencies performed an exploratory analysis examining the scope and impacts of potential model changes. In doing so, the agencies examined the degree of change in the median vehicle fleet weight in the NPRM analysis relative to the fixed mass threshold values, and also how sensitive the curb weight safety point estimates are to assumptions about the distribution of curb weights in future vehicle fleets. The agencies also considered the feasibility of changing the shares of fatalities by crash type as a function of forthcoming or developing vehicle safety technologies. This information would help inform adjustments to fatality rate impacts for each vehicle type, because the likelihood of observing individual fatal crash types could change in different ways across vehicle types in the analysis as the vehicle mix changes.

[2125] CARB, Detailed Comments, Docket No. NHTSA-2018-0067-11873, at 278-79.

However, the agencies identified no studies on the effectiveness of forthcoming or developing vehicle safety technologies that could inform projections of shares of fatalities across crash types, nor did the commenters reference any such studies. Likewise, commenters provided no data that would enable projections of these factors. Thus, for a given vehicle mix, the agencies have no information available to justify changing the shares of fatalities across crash types over time. Therefore, the agencies decided to keep the distribution of fatality shares constant for: first-event rollovers; fixed-object collisions; collisions with pedestrians, bicyclists, and motorcycles; collisions with heavy vehicles; collisions with one other light-duty vehicle (i.e., a constant share across the sum of these crashes, but not constant for any given type of crash partner); and all other crashes.

The agencies had sufficient information to evaluate the effects of changes in the fatal crash mix for cases involving two light-duty vehicles. The agencies agreed that it was internally consistent to adjust fatality shares by crash type proportionally to the distribution of vehicle types and curb weight classes for a given focal MY. An important technical question associated with this approach is the level of disaggregation. The agencies considered an alternative in which the agencies would estimate and apply unique curb weight point estimates for each calendar year in the analysis for each regulatory alternative. This alternative would account for changes in the distribution of crash types associated with changes in both vehicle type shares (i.e., shifts from passenger cars to CUVs and LTVs) and vehicle mass shares (i.e., shifts from vehicles above the curb weight thresholds to vehicles below the thresholds). As in the status quo analysis of curb weight and fatality risk, the resulting point estimates would be weighted averages across the individual crash type models as presented in the NPRM, but re-weighted to reflect projected changes to the fleet.

The agencies investigated this alternative and identified several concerns. A key functional constraint is that the curb weight safety point estimates are applied in the CAFE Model as a lump-sum, lifetime effect to a given vehicle. This characteristic of the model limits the ability to apply calendar-year-specific effects of changes in curb weight and vehicle type distributions when evaluating safety impacts of changes in curb weights. The safety point estimates also represent net effects of changes in curb weights over the lifetime of a given vehicle in the CAFE Model; any changes in the calculation of safety point estimates would need to preserve this characteristic. More broadly, the vehicle fleet is not static over a vehicle's lifetime (i.e., the distributions of curb weight and vehicle type change each year), so the effective probabilities of each crash type over a given vehicle's lifetime are a function of many calendar-year-level curb weight and vehicle type distributions. To capture any effects of changes in vehicle mass distributions over time within the current CAFE Model structure, the agencies would need to enact a method that: (1) identifies defensible changes in fatality risk associated with vehicle mass as the distribution of vehicle mass changes (e.g., accounting for changes in the likelihood of observing particular fatal crash types that reflect projected changes in the distribution of vehicle types and curb weights across vehicles); and (2) allocates calendar-year-specific impacts of curb weight on fatality risk to each vehicle in the fleet across the analysis horizon. Identifying how best to achieve this would be complex, and would require the development of an alternative analytical approach that would be outside the scope of this rulemaking.

With these concerns in mind, the agencies explored an alternative approach to test the sensitivity of the safety point estimates to distributions of vehicles by curb weight and vehicle type. The starting point for the alternative approach is maintaining the understanding that the nine crash type models that are present in the curb weight safety analysis represent the best statistical alternatives for evaluating the crash data in the database (i.e., optimal statistical precision conditional on the coverage of the data). Furthermore, the nine crash type models are defined in terms of physical relationships (i.e., crashes involving vehicles of particular curb weight ranges and vehicle types) that are invariant to changes in the distributions of vehicles for those same characteristics. That is, the estimated changes in societal fatality risk as curb weights change for a focal vehicle (i.e., of a particular type and weight range) that is involved in a particular type of crash apply equally to any scenario involving such vehicle, regardless of changes in the probability of observing such a scenario. For example, it is reasonable to expect that the societal fatality risk for a crash involving a passenger car lighter than 3,201 pounds colliding with a LTV heavier than 4,360 pounds to be the same regardless of how many such collisions take place. Thus, the net effect of a given change in curb weight for a given vehicle type in a given crash type would be expected to scale proportionally with the probability of such crashes occurring. Put simply, if there are half as many potential crash partners of a given type in a future year compared to a base year, a given curb weight reduction would be expected to have half as large of a net effect on fatalities in the future year relative to the base year. In the extreme, curb weight changes would have no net effect on fatalities at all for a given crash type if such crashes had a zero percent probability of occurring (i.e., if there are no potential crash partner vehicles).

Based on this maintained hypothesis, the agencies examined test curb weight safety point estimates under alternative scenarios, in which fatality shares by crash type were proportional to the distribution of vehicle types and curb weight classes across a range of outcomes reflecting different model years and policy alternatives represented in the NPRM. The sensitivities of the safety point estimates to changes in the distributions of vehicle curb weights and vehicle types were tested by adjusting fatality shares across the relevant crash types in the analysis (i.e., involving two light-duty vehicles) in a manner consistent with potential changes in the vehicle fleet, while holding the outputs of the individual crash type models the same as in the NPRM.

For example, compare the safety point estimate for LTVs lighter than 5,014 pounds in the NPRM with an alternative point estimate for an extreme hypothetical future year where 80 percent of the LTV fleet is lighter than the median curb weight for crash partners (4,360 pounds):

Table VI-237 – Calculation of Example Alternative Safety Point Estimate (LTVs Lighter than 5,014 Pounds)

Crash Type	**Share of Fatalities**		**Change in Fatality Risk per 100-Pound Mass Reduction for Crash Type (%)**	**Change in Fatalities per 100-Pound Mass Reduction for Crash Type (Baseline = 1,782)**	
	NPRM	**Example**		**NPRM**	**Example**
First-Event Rollover	0.03	0.03	0.65	0.3	0.3
Hit Fixed Object	0.11	0.11	-0.53	-1.0	-1.0

Crash Type	Share of Fatalities		Change in Fatality Risk per 100-Pound Mass Reduction for Crash Type (%)	Change in Fatalities per 100-Pound Mass Reduction for Crash Type (Baseline = 1,782)	
	NPRM	**Example**		**NPRM**	**Example**
Hit Pedestrian/Bicycle/ Motorcycle	0.22	0.22	0.78	3.0	3.0
Hit Heavy Vehicle	0.06	0.06	2.10	2.3	2.3
Hit Car/CUV/Minivan < 3,187 Lbs.	0.12	0.12	0.48	1.0	1.0
Hit Car/CUV/Minivan 3,187+ Lbs.	0.12	0.12	-0.46	-1.0	-1.0
Hit Truck-Based LTV < 4,360 Lbs.	0.05	*0.08*	0.54	0.5	0.7
Hit Truck-Based LTV 4,360+ Lbs.	0.04	*0.02*	1.91	1.5	0.7
All Other	0.25	0.25	-0.93	-1.0	-4.1
Total	**1.00**	**1.00**	**NPRM: 0.31** **Example: 0.28**	**5.5**	**4.9**

The estimated net societal effect of a 100-pound mass reduction is equal to: (1) the sum of the estimated net effects across all crash types, divided by (2) the baseline estimate of annual fatalities involving the vehicle class (adjusted to avoid double-counting) for the most recent four MYs in the database (MYs 2008-2011), or 1,782 fatalities per year. In the NPRM, the estimated net societal effect of a 100-pound mass reduction for lighter LTVs was a 5.5 fatality increase, or a 0.31 percent increase relative to a baseline of 1,782 fatalities. Changing the share of crash fatalities involving heavier LTVs to be consistent with a fleet with only 20 percent of LTVs above the curb weight threshold yields: (1) an increase in incremental fatalities in crashes involving lighter LTVs (from 0.5 fatality to 0.7 fatality); and (2) a decrease in incremental fatalities in crashes involving heavier LTVs (from 1.5 fatalities to 0.7 fatality); for a total net increment of 4.9 fatalities compared to the NPRM's estimate of 5.5 fatalities. Thus, it is estimated that, in a future year where the fleet differs from the baseline by having an extreme case of 80 percent of LTVs below the crash-partner curb weight threshold, the net societal effect of a 100-pound mass reduction in LTVs lighter than 5,014 pounds would be 4.9 divided by 1,782, or 0.28 percent, versus 0.31 percent in the baseline.

This simple example confirms that the estimates do indeed change as the distribution of curb weights changes. In this case, the change is intuitive: As the LTV fleet becomes lighter, mass reduction among LTVs below 5,014 pounds becomes less detrimental to society. However, the incremental effect is estimated to be quite small: Shifting from an even mix of LTVs above and below the threshold to an extreme 20%/80% split only changes the estimated net societal effect by 0.03 percent in absolute terms. Thus, the model results for lighter LTVs appear relatively insensitive to the LTV curb weight distribution. Indeed, in the limit, where all LTVs are below the crash-partner curb weight threshold (and thus there are no fatality impacts for crashes involving heavier LTVs), the estimated net societal effect of a 100-pound mass reduction for LTVs below 5,014 pounds (i.e., all LTVs in this case) is 0.25 percent, a difference of 0.06 percent in absolute terms compared to the baseline. This result is driven by the dominating effects of crash types involving either: (1) no crash partner (e.g., first-event rollovers); (2) one crash partner from a group not associated with a given change in a curb weight distribution (e.g., heavy vehicles, bicyclists, passenger cars); or (3) multiple crash partners (an element of "all other crashes"). That is, even extreme changes in the distribution of curb weights for a given vehicle type will not change the role that vehicle mass plays in crashes for a focal vehicle when that vehicle does not collide with another vehicle from the distribution in question. In the above example involving lighter LTVs, 90 percent of fatalities involve incidents that do not include a single LTV crash partner, and 66 percent of fatalities involve incidents that do not include a single light-duty crash partner.

Continuing with this example scenario, the point estimate for LTVs heavier than 5,014 pounds becomes larger in magnitude (i.e., more societally beneficial mass reduction) to a similar degree as the reduction in magnitude for lighter LTVs when moving to an extreme 20%/80% split of crash partner LTVs above (versus below in the case above) the curb weight threshold:

Table VI-238 – Calculation of Example Alternative Safety Point Estimate (LTVs 5,014 Pounds or Heavier)

Crash Type	Share of Fatalities		Change in Fatality Risk per 100-Pound Mass Reduction for Crash Type (%)	Change in Fatalities per 100-Pound Mass Reduction for Crash Type (Baseline = 3,304)	
	NPRM	Example		NPRM	Example
First-Event Rollover	0.02	0.02	0.76	0.6	0.6
Hit Fixed Object	0.09	0.09	0.99	3.1	3.1
Hit Pedestrian/Bicycle/Motorcycle	0.19	0.19	0.02	0.1	0.1
Hit Heavy Vehicle	0.06	0.06	0.79	1.6	1.6
Hit Car/CUV/Minivan < 3,187 Lbs.	0.14	0.14	-2.56	-12.0	-12.0
Hit Car/CUV/Minivan 3,187+ Lbs.	0.13	0.13	-0.36	-1.5	-1.5
Hit Truck-Based LTV < 4,360 Lbs.	0.07	0.10	-1.81	-4.0	-6.1
Hit Truck-Based LTV 4,360+ Lbs.	0.06	0.03	0.81	1.6	0.7
All Other	0.24	0.24	-1.20	-9.5	-9.5
Total	**1.00**	**1.00**	**NPRM: -0.61** **Example: -0.69**	**-20.0**	**-22.9**

In the NPRM and this analysis, the estimated net societal effect of a 100-pound mass reduction for lighter LTVs was a 20.0 fatality decrease, or a 0.61 percent decrease relative to a baseline of 3,304 fatalities. Changing the share of crash fatalities involving heavier LTVs to be consistent with a fleet with only 20 percent of LTVs above the curb weight threshold yields: (1) a larger reduction in fatalities in crashes involving lighter LTVs per 100-pound mass reduction (from 4.0 fatalities to 6.1 fatalities); and (2) a decrease in incremental fatalities in crashes involving heavier LTVs (from 1.6 fatalities to 0.7 fatality); for a total net change of -22.9 fatalities compared to a baseline of -20.0 fatalities. Thus, in a future year where the fleet differs from the baseline by having 80 percent of LTVs below the crash-partner curb weight threshold, it is estimated that the net societal effect of a 100-pound mass reduction in LTVs 5,014 pounds or heavier would be -22.9 divided by 3,304, or -0.69 percent, versus -0.61 percent in the baseline. Consistent with the test results for lighter LTVs, the model results for heavier LTVs appear relatively insensitive to the LTV curb weight distribution. In the limit, where all LTVs (except for one remaining heavier LTV in consideration) are below the crash-partner curb weight threshold (and thus there are no effective fatality impacts for crashes involving heavier LTVs), the estimated net societal effect of a 100-pound mass reduction for the remaining LTV above 5,014 pounds is -0.76 percent, a difference of 0.15 percent in absolute terms compared to the baseline.

Expanding the analysis to account for changes in the relative sales shares of each vehicle type dampens the net effects further. As the fleet share of passenger cars decreases, the net effects of mass reduction among LTVs become less societally beneficial. That is, as there are fewer relatively vulnerable passenger cars in the fleet, there become fewer opportunities to reduce fatalities in collisions between LTVs and passenger cars through mass reduction. In some scenarios considered in the exploratory analysis, the effects of sales shifts from passenger cars to LTVs at least fully offset the estimated improvements in net fatalities associated with mass reduction summarized above as the LTV fleet becomes lighter.

Ultimately, the exploratory analysis using extreme example cases confirmed that the baseline safety point estimates are very reasonable for the feasible ranges of mixes of vehicle types and curb weights across the model years in the CAFE Model analysis. The sensitivities of the point estimates are relatively low across relative shares of lighter versus heavier LTVs (especially relative to the uncertainty in the baseline estimates), and similarly low and offsetting across decreasing fleet shares for passenger cars. Because shifts in mass in the rulemaking analysis would have insignificant impacts on the safety estimated values and therefore rulemaking decision making, the agencies conclude no changes are warranted for this final rule analysis.

(3) Mass Safety Results

Table VI-239 presents the estimated percent increase in U.S. societal fatality risk per 10 billion VMT for each 100-pound reduction in vehicle mass, while holding footprint constant, for each of the five vehicle classes:

Table VI-239 – Fatality Increase (Percent) per 100-Pound Mass Reduction While Holding Footprint Constant: MY 2004-2011, CY 2006-2012

	Central Estimate	**95% Confidence Bounds**
Cars < 3,201 pounds	1.20	-.35 to +2.75
Cars > 3,201 pounds	0.42	-.67 to +1.50
CUVs and minivans	-0.25	-1.55 to +1.04
Truck-based LTVs < 5,014 pounds	0.31	- .51 to +1.13
Truck-based LTVs > 5,014 pounds	-0.61	-1.46 to +.25

Techniques developed in the 2011 (preliminary) and 2012 (final) Kahane reports have been retained to test statistical significance and to estimate 95-percent confidence bounds (sampling error) for mass effects and to estimate the combined annual effect of removing 100 pounds of mass from every vehicle (or of removing different amounts of mass from the various classes of vehicles), while holding footprint constant.

None of the estimated effects has 95-percent confidence bounds that exclude zero, and thus are not statistically significant at the 95-percent confidence level. The NPRM reported that two estimated effects are statistically significant at the 85-percent level. Societal fatality risk is estimated to: (1) increase by 1.2 percent if mass is reduced by 100 pounds in the lighter cars; and (2) decrease by 0.61 percent if mass is reduced by 100 pounds in the heavier truck-based LTVs. The estimated increases in societal fatality risk for mass reduction in the heavier cars and the lighter truck-based LTVs, and the estimated decrease in societal fatality risk for mass reduction in CUVs and minivans are not significant, even at the 85-percent confidence level. Although 85-percent statistical significance is not a traditional metric of meaningful differences to zero, this result confirms that the estimated effects for vehicles with curb weights most dissimilar to the median vehicle are the most likely to be significantly different to zero.

The agencies judge the central value estimates are the best and most up-to-date estimates available; the estimates offer a stronger statistical representation of relationships among vehicle curb weight, footprint and fatality risk than an assumption of no correlation whatsoever. The agencies appropriately present the statistical uncertainty. For example, the central values for the highest vehicle weight group (LTVs 5,014 pounds or heavier) and the lowest vehicle weight group (passenger cars lighter than 3,201 pounds) (which, based on fundamental physics, are expected to have the greatest impact of mass reduction on safety) are economically significant[2126], and are in line with the prior analyses used in past NHTSA CAFE and EPA CO_2 rulemakings. As shown in Table VI-240, the estimated coefficients have trended to lower numerical values in successive studies, but remain positive for lighter cars and negative for heavier LTVs. The 85-percent confidence level was reported only to show the scope of uncertainty at the first rounded (to five percent) threshold where the coefficient estimates were significantly different to zero for the two vehicle groups at the extremes of the curb weight distribution. No preference was suggested for an 85-percent confidence bound. Rather, the agencies found value in reporting confidence intervals for all five coefficients at the threshold where the estimates for the two extremes of the curb weight distribution were significantly different to zero. The agencies determined it was better to include the estimates, despite the slightly lower confidence level, than knowingly omitting economically significant results.

[2126] The agencies use "economically significant results" to mean values that have an important, practical implication, but may be derived from estimates that do not meet traditional levels of statistical significance. For example, if the projected economic benefit of a project equaled $100 billion, the agencies would consider the impact economically significant, even if the estimates used to derive the impact were not statistically significant at the 95-percent confidence level. Conversely, if the projected economic benefit of a project equaled $1, the agencies would not consider the impact economically significant, even if the estimates used to derive the impact were statistically significant at the 99.99-percent confidence level. In the case above, the results associated with the lightest and heaviest vehicle types were considered to be economically significant because the associated safety costs were large and the estimates had magnitudes meaningfully different from zero and were statistical significant at the 85-percent confidence level.

The regression results are constructed to project the effect of changes in mass, independent of all other factors, including footprint. With each additional change from the current environment (e.g., the scale of mass change, presence and prevalence of safety features, demographic characteristics), the results may become less representative. That is, although safety features and demographic factors are accounted for separately, the estimated effects of mass are identified under the specific mix of vehicles and drivers in the data. NHTSA notes that the analysis accounts for safety features that are optional but available across all MYs in the sample (most notably electronic stability control, which was not yet mandatory for all model years in the sample), and calibrates historical safety data to account for future fleets with full ESC penetration to reflect the mandate.

The agencies considered the near multicollinearity of mass and footprint to be a major issue in the 2010 Kahane report and voiced concern about inaccurately estimated regression coefficients. High correlations between mass and footprint and variance inflation factors (VIF) have persisted from MY 1991-1999 to MY 2004-2011; large footprint vehicles continued to be, on the average, heavier than small footprint vehicles to the same extent as in the previous decade.

Nevertheless, multicollinearity appears to have become less of a problem in the 2012 Kahane, 2016 Puckett and Kindelberger/Draft TAR, and current analyses. Ultimately, only three of the 27 core models of fatality risk by vehicle type in the current analysis indicate the potential presence of effects of multicollinearity, with estimated effects of mass and footprint reduction greater than two percent per 100-pound mass reduction and one-square-foot footprint reduction, respectively; these three models include passenger cars and CUVs in first-event rollovers, and CUVs in collisions with LTVs greater than 4,360 pounds. This result is consistent with the 2016 Puckett and Kindelberger report, which also found only three cases out of 27 models with estimated effects of mass and footprint reduction greater than two percent per 100-pound mass reduction and one-square-foot footprint reduction.

For comparison, Table VI-240 shows the fatality coefficients from the 2012 Kahane report (MY 2000-2007 vehicles in CY 2002-2008) and the 2016 Puckett and Kindelberger report and Draft TAR (MY 2003-2010 vehicles in CY 2005-2011).

Table VI-240 – Fatality Increase (%) per 100-Pound Mass Reduction While Holding Footprint Constant

Vehicle Class[2127]	2012 Report Point Estimate	2016 Report/Draft TAR Point Estimate	2012 Report 95% Confidence Bounds	2016 Report 95% Confidence Bounds
Lighter Passenger Cars	1.56	1.49	+.39 to +2.73	-.30 to +3.27
Heavier Passenger Cars	.51	.50	-.59 to 1.60	-.59 to +1.60

[2127] Median curb weights in the 2012 Kahane report: 3,106 pounds for cars, 4,594 pounds for truck-based LTVs. Median curb weights in the 2016 Puckett and Kindelberger report: 3,197 pounds for cars, 4,947 pounds for truck-based LTVs.

CUVs and minivans	-.37	-.99	-1.55 to +.81	-2.17 to +.19
Lighter Truck-based LTVs	.52	-.10	-.45 to +1.48	-1.08 to +.88
Heavier Truck-based LTVs	-.34	-.72	-.97 to + .30	-1.45 to +.02

The new results are directionally the same as in 2012; in the 2016 analysis, the estimate for lighter LTVs was of opposite sign (but small magnitude). Consistent with the 2012 Kahane and 2016 Puckett and Kindelberger reports, mass reductions in lighter cars are estimated to lead to increases in fatalities, and mass reductions in heavier LTVs are estimated to lead to decreases in fatalities.

The estimated mass effect for heavier truck-based LTVs is stronger in this analysis and in the 2016 Puckett and Kindelberger report than in the 2012 Kahane report; both estimates are statistically significant at the 85-percent confidence level, unlike the corresponding estimate in the 2012 Kahane report. The estimated mass effect for lighter truck-based LTVs is insignificant and positive in this analysis and the 2012 Kahane report, while the corresponding estimate in the 2016 Puckett and Kindelberger report was insignificant and negative.

Multiple commenters, including the South Coast Air Quality Management District and States and Cities, challenged the practical value of using estimates with statistical significance at the 85-percent level, arguing that below 95 (or 90) percent are insufficiently reliable.[2128] For example, CARB stated, "[d]ue to the lack of statistical significance, NHTSA should not be attributing any increase in fatalities due to mass reduction" and argues that the "effect of mass reduction on fatality risk should be set to zero since the estimates are not statistically different to zero."[2129]

The agencies believe the updated analysis that was presented in the NPRM represents the most up to date and best estimate of the impacts of mass reduction on crash fatalities; and, that it is appropriate for the analysis to use the best and most likely estimates for safety, even if the estimates are not statistically significant at the 95-percent confidence level. Significance at the 85-percent confidence level is important evidence that the relevant point estimates are meaningfully different to zero (e.g., approximately five to six times more likely to be non-zero than zero). The agencies believe it would be misleading to ignore these data or to use values of zero for the rulemaking analysis, as doing so would not properly inform decision makers on the safety impacts of the regulatory alternatives and final standards. Similar to past analyses, the NPRM and this final rule analysis use the best available estimates. The agencies feel it is inappropriate to ignore likely impacts of the standards simply because the best available estimates have confidence levels below 95 percent; uniform estimates of zero are statistically weaker than the estimates identified in the analysis, and thus are not the best available. Because the point estimates are derived from the best-fitting estimates for each crash type (all of which

[2129] CARB, Detailed Comments, Docket No. NHTSA-2018-0067-11873, at 269.

are non-zero), the confidence bounds around an overall estimate of zero would necessarily be larger than the corresponding confidence bounds around the point estimates presented here.

The sensitivity analysis in Section VII.E provides an evaluation of extreme cases in which all of the estimated net fatality rate impacts of mass reduction are either at their fifth- or 95th-percentile values. The range of net impacts in the sensitivity analysis not only covers the relatively more likely case that uncertain, yet generally offsetting, effects are distinct from the central estimates considered here (e.g., in a plausible case where mass reduction in the heaviest LTVs is less beneficial than indicated by the central estimates, it would also be relatively likely that mass reduction in the lightest passenger cars would be less harmful, yielding a similar net impact), but also covers the relatively unlikely case that all of the estimates are uncertain in the same direction.

At a broader level, multiple commenters asserted that the role of safety-related estimates should be restricted because of what they claim is a weak historical relationship between fuel economy and vehicle safety. For example, the Green Energy Institute at Lewis & Clark Law School commented, "[o]ver the past 40 years, per-capita vehicle fatalities decreased by 50%, while average fuel economy doubled."[2130] However, this statistic is misleading because it does not account for vehicle safety factors and changes in driving behavior external to fuel economy (e.g., FMVSS and other safe design advances, reductions in drunk driving, increases in seat belt use). That is, fatality rates have decreased due to a range of factors that are unrelated to fuel economy efforts. The methodology in the 2012 Kahane report, the 2016 Puckett and Kindelberger, the Draft TAR, the 2018 NPRM analysis and today's final rule analysis addresses these other changes in order to isolate the impacts of mass reduction alone. The role of the safety analysis outlined in this document is to isolate incremental effects on safety outcomes that are related to changes in fuel economy.

Multiple commenters disagreed with the results in Table VI-239, maintaining that mass reduction need not reduce societal safety. EDF cited a Michigan Manufacturing Technology Center (MMTC) review as supporting that widespread lightweighting would decrease crash severity through reduced kinetic energy in multiple-vehicle crashes. Similarly, the Aluminum Association commented, "[v]ehicle size, not weight, has been shown to be the leading safety determinant."[2131] Other commenters cited Anderson and Auffhammer (2014), which finds that the safety effects of mass reduction in one vehicle are offset by the safety effects in the crash partner vehicle.[2132] The South Coast Air Quality Management District asserted that NHTSA and EPA appear to argue "that fuel-efficient vehicles are lighter than other vehicles, and therefore, less safe." The North Carolina Department of Environmental Quality asserted that a takeaway from the preferred alternative is that larger vehicles are safer than smaller vehicles. The agencies' conclusion is that, at the societal level, it is the distribution of changes in vehicle mass

that matter (i.e., mitigating mass reduction in the lightest vehicles is societally beneficial, while mitigating mass reduction in the heaviest vehicles is societally harmful).

The 2012 Kahane report, the 2016 Puckett and Kindelberger, the Draft TAR, the 2018 NPRM analysis and today's final rule analysis all have shown that both mass and vehicle size impact societal safety. Across recent rulemakings, the analyses have confirmed a protective effect of vehicle size (i.e., societal fatality risk decreases as footprint increases). As mentioned previously, the agencies believe vehicle footprint-based standards help to discourage vehicle manufacturers from downsizing their vehicles, and therefore assume changes in CAFE and CO_2 standards will not impact vehicle size and size-related safety impacts. On the other hand, mass reduction is a cost-effective technology for increasing fuel economy and reducing CO_2 emissions. Therefore, the agencies do include the assessment of safety impacts related to mass reduction. As discussed throughout this mass-safety subsection, comprehensive consideration of the various studies and workshops on the impact of vehicle mass on safety is presented, and conclude there is in fact a relationship. The fleet simulation study, discussed in the next subsection, further supports the existence of this relationship and that this relationship will continue to exist in future vehicle designs.

The principal difference between heavier vehicles, especially truck-based LTVs, and lighter vehicles, especially passenger cars, is that mass reduction has a different effect in collisions with another car, LTV, or other object such as a lamp post. When two vehicles of unequal mass collide, the change in velocity (delta-V) is greater in the lighter vehicle. Through conservation of momentum, the degree to which the delta-V in the lighter vehicle is greater than in the heavier vehicle is proportional to the ratio of mass in the heavier vehicle to mass in the lighter vehicle:

$$\Delta v_1 = \frac{m_2}{m_1}\Delta v_2$$

Where:

Δv_1 is the delta-V for a focal vehicle,

$\boldsymbol{\Delta v_2}$ is the delta-V for a partner vehicle, and

$\frac{m_2}{m_1}$ is the mass of the partner vehicle divided by the mass of the focal vehicle.

Because fatality risk is a positive function of delta-V, the fatality risk in the lighter vehicle in two-vehicle collisions is also higher. Vehicle design can reduce the magnitude of delta-V to some degree (e.g., changing the stiffness of a vehicle's structure could dampen delta-V for both crash partners). These considerations drive the overall result: mass reduction is associated with an increase in fatality risk in lighter cars, a decrease in fatality risk in heavier LTVs, CUVs, and minivans, and has smaller effects in the intermediate groups. Mass reduction may also be harmful in a crash with a movable object such as a small tree, which may break if hit by a high mass vehicle resulting in a lower delta-V than may occur if hit by a lower mass vehicle which does not break the tree and therefore has a higher delta-V. However, in some types of crashes not involving collisions between cars and LTVs, especially first-event rollovers and impacts with fixed objects, mass reduction may not be harmful and may even be beneficial.

Ultimately, delta-V is a direct function of relative vehicle mass for given vehicle structures. Removing some mass from the heavier vehicle involved in an accident with a lighter vehicle reduces the delta-V in the lighter vehicle, where fatality risk is higher, resulting in a large benefit to the passengers of the lighter vehicle. This is partially offset by a small increase in the delta-V in the heavy vehicle; however, the fatality risk is lower in the heavier vehicle and remains relatively low despite the increase in delta-V. In sum, the change in mass and delta-V from mass reduction in heavier vehicles results in a net societal benefit.

Multiple commenters claimed that the agencies' analysis does not allow for the likely outcome that mass reduction would be concentrated among relatively heavy vehicles.[2133] For example, Global Automakers commented that the agencies should not include weight reduction in their safety analysis because "very few vehicles [have] implemented lightweight material substitution strategies."[2134]

Neither CAFE standards nor this analysis mandate mass reduction, or mandate mass reduction occur in any specific manner. However, mass reduction is a highly cost-effective technology for improving fuel economy and CO_2 emissions. The steel, aluminum, plastics, composite, and other material industries are developing new materials and manufacturing equipment and facilities to produce those materials. In addition, suppliers and manufacturers are optimizing designs to maintain or improve functional performance with lower mass. Manufacturers have stated that they will continue to reduce vehicle mass to meet more stringent standards, and therefore, this expectation is incorporated into the modeling analysis supporting the standards to: (1) determine capabilities of manufacturers; and (2) to predict costs and fuel consumption effects of CAFE standards. The CAFE and CO_2 rulemakings in 2012, the Draft TAR and EPA Preliminary Determination, imposed an artificial constraint on vehicle mass reduction to achieve a desired safety-neutral outcome. For the current rulemaking, this artificial constraint is eliminated so the analysis reflects manufacturers applying the most cost-effective technologies to achieve compliance with the regulatory alternatives and the final standards; this approach allows mass reduction to be applied across the fleet. This is consistent with industry trends.[2135] To the extent that mass reduction is only cost-effective for the heaviest vehicles, the CAFE Model would create the outcome predicted by commenters. In reality, however, mass reduction is a cost-effective means of improving fuel economy and does take place across vehicles of all sizes and weights. Accordingly, the model reflects that manufacturers may reduce vehicle mass—regardless of vehicle class—when doing so is cost-effective.

[2134] Association of Global Automakers, Attachment A, Docket No. NHTSA-2018-0067-12032, at A-32.
[2135] The baseline MY 2016 (for the NPRM) and MY 2017 (for this final rule analysis) vehicle fleet data show manufacturers have in fact implemented mass reduction technology across vehicle types and sizes– including smaller and lighter vehicles.

The National Tribal Air Association claimed the 2015 NAS study found "evidence suggest[ing] that the [2012] standards will lead the nation's light-duty vehicle fleet to become lighter but not less safe."[2136] The agencies note the NAS quote is one phrase from the press release that accompanied the NHTSA sponsored 2015 NAS study,[2137] and the agencies do not believe the phrase in isolation reflects the findings of the NAS Committee, which are discussed in over 3 pages of the report.[2138] The 2015 NAS report supported the analytical methodology used for the 2012 NHTSA CAFE and EPA CO_2 rulemaking and found it reasonable. As discussed in the subsections further above, a nearly identical methodology was used for the NPRM analysis and for this final rule.

The agencies received several comments about the relationship between mass and crash avoidance. The NRDC commented that the analysis should account for the expected result that mass reduction makes it easier to avoid crashes.[2139] Conversely, IPI quoted a finding by LNL that "found that mass reductions may increase the number of accidents but that each crash results in fewer fatalities."[2140]

The phenomenon touched upon by IPI and NRDC has been identified in past rulemakings as well, and highlights that the relationship between mass reduction and societal fatality risk include two partially-offsetting components (i.e., increased exposure to crashes is offset partially by decreased risk in some vehicles conditional on a crash occurring). The agencies note that this relationship, while not reported separately, is in fact embedded within the analysis detailed in this document, as the extent to which some vehicles are more maneuverable and faster braking, the crash data reflect those characteristics through lower observed fatality rates. However, when considering the purposes of estimating effects of mass reduction on fatalities, it is immaterial what share of the effect is comprised of crash avoidance factors and crashworthiness factors, the ultimate effect is present within the data evaluated in the analysis. The mass-safety impacts estimated by the statistical analysis of crash data are based on the safety technologies and mass levels present among the vehicle fleets for the calendar and model years in the data. As discussed below in this section, the analysis separately accounts for the effects of future safety technologies.

(4) Sensitivity Analysis

Table VI-241 shows the principal findings and includes sampling-error confidence bounds for the five parameters used in the CAFE Model. The confidence bounds represent the statistical uncertainty that is a consequence of having less than a census of data. NHTSA's 2011, 2012, and 2016 reports acknowledged another source of uncertainty: The central (baseline) statistical model can be varied by choosing different control variables or redefining the vehicle classes or crash types, which for example, could produce different point estimates.

Beginning with the 2012 Kahane report, NHTSA has provided results of 11 plausible alternative models that serve as sensitivity tests of the baseline model. Each alternative model was tested or proposed by: Farmer (IIHS) or Green (UMTRI) in their peer reviews; Van Auken (DRI) in his public comments; or Wenzel in his parallel research for DOE. The 2012 Kahane and 2016 Puckett and Kindelberger reports provide further discussion of the models and the rationales behind them.

Alternative models use NHTSA's databases and regression-analysis approach but differ from the central model in one or more explanatory variables, assumptions, or data restrictions. NHTSA applied the 11 techniques to the latest databases to generate alternative CAFE Model coefficients. The range of estimates produced by the sensitivity tests offers insight to the uncertainty inherent in the formulation of the models, subject to the caveat that these 11 tests are, of course, not an exhaustive list of conceivable alternatives.

The central and alternative results follow, ordered from the lowest to the highest estimated increase in societal risk per 100-pound reduction for cars weighing less than 3,201 pounds:

Table VI-241 – Fatality Increase (%) Per 100-Pound Mass Reduction While Holding Footprint* Constant

		Cars < 3,201	**Cars ≥ 3,201**	**CUVs & Minivans**	**LTVs† < 5,014**	**LTVs† ≥ 5,014**
Central Estimate		1.20	0.42	-0.25	0.31	-0.61
95% Confidence Interval (sampling error)	Lower:	-0.35	-0.67	-1.55	-0.51	-1.46
	Upper:	2.75	1.50	1.04	1.13	0.25
11 Alternative Models						
1. Without CY control variables		0.26	-0.07	-0.58	0.35	-0.16
2. By track width & wheelbase		0.66	0.54	-0.48	-0.44	-0.90
3. Track width/wheelbase w. stopped veh data		0.73	-0.02	-0.18	-0.77	-1.91
4. Without non-significant control variables		0.98	0.26	0.14	0.36	-0.50
5. CUVs/minivans weighted by 2010 sales		1.20	0.42	-0.07	0.31	-0.61
6. With stopped-vehicle State data		1.32	-0.17	-0.08	0.21	-1.55
7. Including muscle/police/AWD cars/big vans		1.56	1.01	-0.25	0.87	0.43
8. Limited to drivers with BAC=0		1.83	1.47	-0.05	0.40	-0.80

10. Limited to good drivers‡	2.15	1.80	-0.33	0.4	-0.45
11. Control for vehicle manufacturer/nameplate	2.26	2.70	-0.48	1.12	0.50

*While holding track width and wheelbase constant (rather than footprint) in alternative model nos. 2 and 3.

†Excluding CUVs and minivans.

‡BAC=0, no drugs, valid license, at most one crash and one violation during the past three years.
For example, in cars weighing less than 3,201 pounds, the baseline estimate associates 100- pound mass reduction, while holding footprint constant, with a 1.56 percent increase in societal fatality risk. The corresponding estimates for the 11 sensitivity tests range from a 0.26 to a 2.15 percent increase.

The sensitivity tests illustrate both the fragility and the robustness of central estimates. On the one hand, the variation among the coefficients is quite large relative to the central estimate: in the preceding example of cars < 3,201 pounds, the estimated coefficients range from almost zero to almost double the central estimate. This result underscores the key relationship that the societal effect of mass reduction is small. In other words, varying how to model some of these other vehicle, driver, and crash factors, which is exactly what sensitivity tests do, can appreciably change the estimate of the societal effect of mass reduction.

On the other hand, variations are not particularly large in absolute terms. The ranges of alternative estimates are generally in line with the sampling-error confidence bounds for the central estimates. Generally, in alternative models as in the central model, mass reduction tends to be relatively more harmful in the lighter vehicles and more beneficial in the heavier vehicles, just as they are in the central analysis. In all models, the point estimate of the coefficient is positive for the lightest vehicle class, cars < 3,201 pounds. In 10 out of 11 models, the point estimate is negative for CUVs and minivans, and in nine out of 11 models the point estimate is negative for LTVs ≥ 5,014 pounds. NHTSA believes the central case uses the most rigorous methodology, as discussed further above, and provides the best estimates of the impacts of mass reduction on safety.

Tom Wenzel commented confirming a preference for the alternative model with footprint separated into track width and wheelbase, and with the induced exposure data limited to stopped vehicle cases.[2141] Wenzel asserts that splitting footprint into its components reduces multicollinearity with curb weight, and that limiting induced exposure cases to stopped vehicles mitigates bias against driver-vehicle pairs that are less likely to be involved in crashes. Based on this feedback and the intuitiveness of the approach, NHTSA further considered the alternative model with footprint split into track width and wheelbase. Consistent with previous analyses and assessments, there are problems with splitting footprint into its components within the mass-size-safety models because of strong correlations among curb weight, track width and wheelbase. For all vehicle classes in the analysis, curb weight is correlated either nearly as high or higher with track width as with footprint. Track width and wheelbase are also highly correlated with one another (ranging from around 0.64 to 0.80, with the exceptions of smaller correlations for large pickups and minivans). Viewed from another angle, wheelbase is almost perfectly correlated with footprint (with correlations ranging from around 0.95 to 0.97).

[2141] Wenzel, T., Lawrence Berkeley National Laboratories, Docket No. EPA-HQ-OAR-2018-0283-4118.

Considered in concert, the track width and wheelbase model not only essentially incorporates the full correlation issues from the baseline model (curb weight highly correlated with another independent variable), but also adds a further correlation issue (the variable that is highly correlated with curb weight is also highly correlated with a separate independent variable). NHTSA examined supplementary means of confirming the relative methodological merit of the footprint-based model and the track-width-wheelbase-based alternative. The supplementary analysis centered on the *condition index,* which quantifies the invertibility of the matrix of independent variables in a given model through its measure, the *condition number*.[2142] A model with a low condition number has relatively low correlations among its independent variables, and thus its invertibility and the corresponding model outputs are robust to variations in model input values. A model with a high condition number has relatively high correlations among its independent variables, and thus its invertibility and model outputs are not robust to variations in model input values. That is, a model with a high condition number is likely to be subject to the problems associated with multicollinearity. Although there is no strict threshold condition number value to indicate multicollinearity, higher values indicate greater likelihood that the independent variables are correlated to a problematic degree.

The condition index offers an alternative means of capturing the same forces as the variance inflation factor (VIF), which the agencies have used historically (including in this rulemaking) as a diagnostic of multicollinearity. However, the condition index offers some advantages relative to the VIF. Notably, the condition index applies regardless of the econometric form of the model (i.e., the decomposition of the independent variables is the same regardless of how the variables are applied in the model). This is distinct from the VIF, which is limited to a linear diagnostic of the data that may not map well to non-linear econometric models, including the logistic regression models that form the core of the curb weight-fatality risk analysis. The condition index estimates the incremental effects of individual variables, which is helpful in an analysis of which independent variables are the most problematic. Conversely, the diagnostic values from the VIF are not necessarily sensitive to incremental correlated variables, as the VIF value (1/(1-R^2) does not necessarily change much once correlations are relatively high (i.e., when R^2 is already high, the inclusion of one or more highly correlated variables may not change R^2, and in turn, the VIF, by much.

An incremental comparison of VIF estimates for the data confirmed the potential weakness of the VIF in this case. For the CUV-minivan model data, the VIF decreases from 9.4 to 6.7 when: (1) substituting either track width or footprint for footprint that has an identical correlation with curb weight as footprint; and (2) adding the other component of footprint. This result is counterintuitive (i.e., the simpler model should necessarily have fewer issues of multicollinearity), and may be an artifact of differences in model fit (e.g., a higher R^2 in the simpler model could indicate better model fit rather than anything problematic in terms of

correlation structure). This result led the agencies to question how well the VIF identifies relative impacts of multicollinearity across related models, especially in non-linear applications.

The calculated condition numbers for the curb weight-footprint models and their corresponding curb weight-wheelbase-track width alternatives were consistent with expectations regarding multicollinearity, however. The condition numbers for the curb weight-wheelbase-track width models are approximately two to three times higher than the condition numbers for the curb weight-footprint models. This indicates that the level of imprecision in model estimates using track width and wheelbase would be expected to be between approximately two to three times higher than in the baseline models using footprint. Unlike the VIF, the condition index supports a hypothesis that multicollinearity would not be mitigated in an alternative with disaggregated variables that are highly correlated with both the variable of interest and the variable they are replacing. Considering these results, the agencies that using footprint to represent vehicle size in the safety models provides a more reliable estimate of safety impacts than splitting footprint into track width and wheelbase.

The agencies also considered the use of stopped-vehicle data as an alternative. The primary problem with this approach is that the agencies do not observe as large of a share of cases on roads with higher travel speeds (e.g., interstate highways) when including only stopped vehicles; this relationship influences the extent to which the induced exposure data reflect the distributions of driver attributes and contextual effects across national VMT. Based on this assessment, the agencies believe the methodology used for the analysis in the proposal provides a more reliable and representative estimate of safety impacts, and thus is not changing the methodology for today's final rule.

In a related comment, Wenzel proposes that future analyses should directly account for differences in curb weight between vehicles in two-vehicle crashes. The agencies believe that would require the development of a model that directly accounts for the relative weights of vehicles in two-vehicle crashes, and that such a model would require peer review. Key alternatives to test would vary in terms of the functional form of the mass disparity between two crash partners (e.g., a relative mass ratio consistent with the delta-V calculation presented above, linear mass difference, non-linear mass difference). The agencies will consider initiating work to explore such a model in the future.

DRI requested the agencies clarify whether the analysis accounts for all road users (i.e., including pedestrians, bicyclists, motorcyclists, and other crash partners), while the Pennsylvania Department of Environmental Protection commented, "[i]t is inadequate for the agencies' analysis for this Proposed Rule to only focus on frontal crashes while omitting near-frontal collisions, side-impact collisions, rear-end collisions, rollover accidents, impacts with stationary objects and accidents involving pedestrians."[2143] The agencies confirm that the analysis presented in this section continues to apply the methodology developed by Kahane, which incorporates all road users, without double-counting, to identify societal fatality rate impacts. Because every fatal crash (across crash types) is included in the analysis, not just frontal crashes,

[2143] Pennsylvania Department of Environmental Protection, Detailed Comments, Docket No. NHTSA-2018-0067-11956, at 9.

the agencies find this comment lacks a basis. The commenter's confusion may stem from the use of front-to-back crashes to generate estimates of the proportions of all driving for each vehicle model associated with particular characteristics of drivers (e.g., age, gender) and crashes (e.g., urban/rural, day/night). These crashes represent the best available trade-off among sample size, representativeness of overall vehicle and driver exposure, and mitigating bias in a sample that is intended to be effectively random (i.e., the probability of being struck from behind by an at-fault driver is assumed to be a function of characteristics of other drivers and travel demand, but not of the struck driver or the struck vehicle).

(5) Fleet Simulation Study

Commenters to recent CAFE rulemakings, including some vehicle manufacturers, have suggested designs and materials of more recent model year vehicles may have weakened the historical statistical relationships between mass, size, and safety. NHTSA and EPA agreed that the statistical analysis would be improved by using an updated crash and exposure database reflecting more recent safety technologies, vehicle designs and materials, and reflecting changes in the vehicle fleet. As mentioned above, a new crash and exposure database was created with the intention of capturing modern vehicle engineering and has been employed for assessing safety effects for CAFE rules since 2012.

The agencies have traditionally relied solely on real-world crash data as the basis for projecting the future safety implications for regulatory changes. The agencies are required to consider relevant data in setting standards.[2144] Every fleet regulated by the agencies' standards differs from the fleet used to establish said standard, and as such, the light-duty vehicle fleet in the MY 2021-2026 timeframe will be different from the MY 2004-2011 fleet analyzed above. This is not a new or unique phenomenon, but instead is an inherent challenge in regulating an industry reliant on continual innovation. This is the agencies' sixth evaluation of effects of mass reduction and/or downsizing,[2145] comprising databases ranging from MYs 1985 to 2011. Despite continual claims that modern lightweight engineering will render current data obsolete, results of the six studies, while not identical, have been generally consistent in showing a small, negative

[2144] *See* Center for Biological Diversity v. NHTSA, 538 F.3d 1172, 1203 (9th Cir. 2008).

[2145] As outlined throughout this section, NHTSA's six related studies include the new analysis supporting this rulemaking, and: Kahane, C. J. *Vehicle Weight, Fatality Risk and Crash Compatibility of Model Year 1991-99 Passenger Cars and Light Trucks*, National Highway Traffic Safety Administration (Oct. 2003), available at https://crashstats.nhtsa.dot.gov/Api/Public/ViewPublication/809662; Kahane, C. J. *Relationships Between Fatality Risk, Mass, and Footprint in Model Year 2000-2007 Passenger Cars and LTVs: Final Report, NHTSA Technical Report.* Washington, D.C.: NHTSA, Report No. DOT-HS-811-665; and Puckett, S. M., & Kindelberger, J. C. *Relationships between Fatality Risk, Mass, and Footprint in Model Year 2003-2010 Passenger Cars and LTVs – Preliminary Report*, National Highway Traffic Safety Administration (June 2016), available at https://www.nhtsa.gov/sites/nhtsa.dot.gov/files/2016-prelim-relationship-fatalityrisk-mass-footprint-2003-10.pdf.

impact related to mass reduction. The agencies strongly believe that real-world crash data remains the best, relevant data to measure the effect of mass reduction on safety.

However, because lightweight vehicle designs introduce fundamental changes to the structure of the vehicle, there remains a persistent question of whether historical safety trends will apply. To address this concern and to verify that real-world crash data remain an appropriate source of data for projecting mass-safety relationships in the future fleet, in 2014, NHTSA sponsored research to develop an approach to utilize experimental lightweight vehicle designs to evaluate safety in a broader range of real-world representative crashes.[2146] NHTSA contracted with George Washington University to perform a fleet simulation model to study the impact and relationship of light-weighted vehicle design with injuries and fatalities.[2147] The study involved simulating crashes on eight test vehicles, five of which were equipped with lightweight materials and advanced designs not yet incorporated into the U.S. fleet. The study assessed a range of frontal crashes, including crashes with fixed objects and other vehicles, across wide range of vehicle speeds, and with mid-size male and mid-size female dummies.[2148] In all, more than 440 vehicle crashes with 1,520 dummy passengers were simulated for a range of crash speeds and crash configurations. Results from the fleet simulation study showed the trend of increased societal injury risk for light-weighted vehicle designs occurs for both single vehicle and two-vehicle crashes. Results are listed in Table VI-242.[2149]

Table VI-242 – Overall Societal Risk Calculation Results for Model Runs, with Base Vehicle Restraint and Airbag Settings Being the same for All Vehicles, in Frontal Crash Only

Target Vehicle	**Passenger Car Baseline**	**Passenger Car LW**	**CUV Baseline**	**CUV Low Option**	**CUV High Option**

Methodology for evaluating fleet protection of new vehicle designs - Application to lightweight vehicle designs. Report No. DOT HS 812 051A, Washington, DC - National Highway Traffic Safety Administration.
2148 Regulatory and consumer information crash safety tests are performed at high speeds, and the dummy occupant is generally a mid-size male. In the real world, crashes occur at various impact velocities and configurations; with various impact partners (e.g., rigid obstacles, lighter or heavier vehicles); and involve occupants of various sizes and ages.
2149 This fleet simulation study does not provide information that can be used to modify coefficients derived for the NPRM regression analysis because of the restricted types of crashes and vehicle designs. Additionally, the fleet simulation study assumed restraint equipment to be as in the baseline model, in which restraints/airbags are not redesigned to be optimal with light-weighting.

Delta Increase		0.14%		0.06%	0.16%
Societal Risk IIP	1.44%	1.59%			
Delta Increase		0.15%			
Societal Risk I - Target + Partner Combined AIS3+ risk of Head, Neck, Chest & Femur Societal Risk II - Target + Partner Combined AIS3+ risk of Head, Neck, and Chest Societal Risk IIP - Target + Partner Combined AIS3+ risk of Head, Neck, and Chest with A-Pillar Intrusion Penalty					

The change in the safety risk from the fleet simulation study was directionally consistent with results for passenger cars from the 2012 Kahane report,[2150] the 2016 Puckett and Kindelberger report, and the analysis used for the proposal and today's final rule. As noted, fleet simulations were performed in frontal crash mode and did not consider other crash modes such as rollover crashes.[2151] The fleet simulation analysis confirmed that real-world crash data were still a reliable source for analyzing mass safety impacts.

Despite the results of the fleet simulation analysis, which was republished in the proposal, the agencies received additional comments questioning the assumption that relationships among vehicle mass, size, and fatality risk will continue in the future. For example, the Alliance for Vehicle Efficiency asserted that using lighter frame materials has no impact on safety, noting that any mass reduction strategies are applied to components that are unrelated to crash safety and crash ratings have not declined for vehicles over the past five years.[2152] CARB commented that the agencies did not account for new vehicle improvements and claimed the data used for the analysis was "not a good indicator of the safety performance of future purpose-designed lightweighted vehicles."[2153] Consumers Union offered a similar appraisal, indicating that the MYs in the sample are "unlikely to capture the current and future mass/fatality relationship of modern vehicles."[2154] While the Aluminum Association commented vehicle size, not mass, is the only physical feature that impacts safety.[2155] The American Chemistry Council, Hyundai, and Tesla commented that it is feasible to utilize design improvements and technologies to offset the incremental risk for vehicle occupants associated with mass reduction.[2156] EDF said the mass-safety analysis did not agree with conclusions from a study by

2150 The 2012 Kahane study considered only fatalities, whereas, the fleet simulation study considered severe (AIS 3+) injuries and fatalities (DOT HS 811 665).

[2151] The risk assessment for CUV in the regression model combined CUVs and minivans in all crash modes and included belted and unbelted occupants.

the Michigan Manufacturing Technology Center.[2157] Comments from States and Cities, American Honda, ICCT, and NRDC shared these sentiments.[2158]

These comments and the MMTC study ignored the results of the fleet simulation study and seem premised on the notion that a vehicles' performance on NHTSA FMVSS, NHTSA voluntary NCAP, and IIHS voluntary safety tests is the only measure for assessing societal safety impacts for mass reduction. The regulatory and consumer information tests are representative of real-world, single-vehicle crash configurations. However, the tests are performed at constant speeds, and the dummy occupant is generally a mid-size male. In the real world, crashes occur at various impact velocities and configurations; with various impact partners (e.g., rigid obstacles, lighter or heavier vehicles); and involve occupants of various sizes and ages. The fleet simulation study, summarized above, assessed additional types of frontal crashes, including crashes with fixed objects and other vehicles at a wide range of vehicle speeds, and with mid-size male and mid-size female dummies. The fleet simulation study was more comprehensive and focused on the need to assess overall societal safety impacts. The fleet simulation study found that vehicle mass does impact safety with future lightweight vehicle designs that perform well on regulatory and consumer information tests.

The agencies received one comment regarding the fleet simulation analysis. CARB commented that the analysis tested too few vehicles and crash types, should have optimized restraints in the lightweighted models to simulate future safety improvements instead of using modern restraints, and lacked credibility because the results of the fleet simulation analysis did not reproduce the same results of other studies.[2159] CARB's comments demonstrate a general misunderstanding of the fleet simulation analysis; the analysis was not intended to serve as a prediction of how the future vehicle fleet will perform, but rather was an exploration of whether expected lightweighting techniques would alter the dynamic between mass reduction and safety. The analysis was not an attempt to model every potential vehicle construction or crash scenario. Attempting to simulate every future crash would be impractical and ineffective. The combination of vehicles and crash simulations were purposely selected to provide the strongest insight into the effective of lightweighting techniques. For passenger cars and light trucks, frontal crashes account for 58 percent of fatal crashes;[2160] it is appropriate to focus research on understanding the effects of mass reduction where the largest issue exists. For the study, the use of generic restraint systems as the foundations for the models was intentional so that the models would be more representative of a vehicle class rather than a specific vehicle. The models of the

Report No. DOT HS 812 051A, Washington, DC - National Highway Traffic Safety Administration.

restraint systems represented designs currently in production at time of the study in terms of pretensioners, load limiters and air bag inflators. It is worth noting that in general, driver air bags are similar in most vehicles. And finally, the analysis was not an attempt to reproduce the 2012 Kahane report or any other study. The fact that the fleet simulation analysis showed mass-reduction to be detrimental in more types of vehicles than in the FARS data only further highlights the need to consider how today's standards may impact mass-safety. While in the future there may be resources and opportunity to expand the fleet simulation approach to other crash scenarios and, if they become available, to include additional vehicle mass reduction concepts, the lack of potential future data does not justify ignoring the data that currently exist.

From a higher perspective, the comments, and in particular CARB's comment, identify the problem with abandoning real-world crash data: there is no alternate methodology or data that can account for the full diversity of crash scenarios that occur in the real world. Real-world crash data is the only data type that can achieve that. Therefore, the agencies have determined that, while simulations can prove helpful to understanding potential effects of key crash scenarios and as a check on the agencies' preferred analysis, real-world data still is still the best, most relevant data available for assessing safety.

(6) Summary of Mass Safety Impacts

Table VI-243 through Table VI-248 show results of NHTSA's vehicle mass-size-safety analysis over the cumulative lifetime of MY 1977-2029 vehicles, for both the CAFE and CO_2 programs, based on the MY 2017 baseline fleet, accounting for the projected safety baselines. Results are driven extensively by the degree to which mass is reduced in relatively light passenger cars and in relatively heavy vehicles because their coefficients in the logistic regression analysis have the most significant values. It is assumed that any impact on fatalities will occur over the lifetime of the vehicle, and the chance of a fatality occurring in any particular year is directly related to the weighted vehicle miles traveled in that year.

As shown in the tables above, all of the alternatives are estimated to lead to a decrease in the number of mass-related fatalities over the cumulative lifetime of MY 1977-2029 vehicles. The effects of mass changes on fatalities range from a combined decrease (relative to the augural standards, the baseline) of 126 fatalities for Alternative #7 to a combined decrease of 253 fatalities for Alternatives #1 and #2. The difference in results by alternative depends upon how much weight reduction is used in that alternative and the types and sizes of vehicles to which the weight reduction applies. The decreases in fatalities are driven by impacts within passenger cars (decreases of between 146 and 33 fatalities) and are offset by impacts within light trucks (increases of between 8 and 81 fatalities).

Changes in vehicle mass are estimated to decrease social safety costs over the lifetime of the nine model years by between $2.2 billion (for Alternative #7) and $4.5 billion (for Alternatives #1 and #2) relative to the augural standards at a three-percent discount rate and by between $1.3 billion and $2.7 billion at a seven-percent discount rate. The estimated decreases in social safety costs are driven by estimated decreases in costs associated with passenger cars, ranging from $2.6 billion (for Alternative #7) to $5.9 billion (for Alternatives #1 and #2) relative to the Augural standards at a three-percent discount rate and by between $1.6 billion and $3.5 billion at a seven-percent discount rate. The estimated decreases in costs associated with passenger cars are offset partially by estimated increases in costs associated with light trucks, ranging from $0.1 billion (for Alternative #5) to $1.4 billion (for Alternatives #1 and #2) relative to the Augural standards at a three-percent discount rate and by between $0.1 billion and $0.8 billion at a seven-percent discount rate.

In this analysis, the profile of mass reduction across vehicle models leads to a small, but beneficial effect on fatalities as fuel economy standards are tightened. Table VI-249 through Table VI-254 present average annual estimated safety effects of vehicle mass changes, for CYs 2035-2045. The CY-level values offer a complementary view of the impacts of fuel economy standards on mass-related fatalities relative to model-year-level results. Effects by CY over the interval selected (2036-2045) enable a summary view of (a flow of) annual fatality impacts during a period where vehicles subjected to the standards have not only fully entered the fleet, but also interact with both older and newer vehicles. Conversely, the MY-level values offer a summary view of (a stock of) the impacts of fuel economy standards for the lifetime of a given MY:

For all light-duty vehicles, mass changes are estimated to lead to an average annual decrease in fatalities in all alternatives evaluated for CYs 2035-2045. The effects of mass changes on fatalities range from a combined decrease (relative to the augural standards) of 17 fatalities per year for Alternative #7 to a combined decrease of 34 fatalities per year for Alternative #4. The difference in the results by alternative depends upon how much weight reduction is used in that alternative and the types and sizes of vehicles to which the weight reduction applies. The decreases in fatalities are generally driven by impacts within passenger cars (decreases of between 19 and 44 fatalities per year relative to the augural standards) and are offset by impacts within light trucks (increases of between 2 and 11 fatalities per year).

Changes in vehicle mass are estimated to decrease average annual social safety costs in CY 2035-2045 by between $0.2 billion (for Alternative #7) and $0.5 billion (for Alternative #4) at a three-percent discount rate relative to the augural standards (decrease of between $0.1 and $0.2 billion at a seven-percent discount rate). Average annual social safety costs associated with passenger cars in CY 2035-2045 are estimated to decrease by between $0.3 billion and $0.6 billion at a three-percent discount rate (decrease of between $0.1 billion and $0.3 billion at a seven-percent discount rate), but this effect is partially offset by a corresponding increase in costs associated with light trucks (increase of $0.1 billion or less across alternatives at three-percent and seven-percent discount rates).

To help illuminate effects at the model year level, Table VI-255 presents the lifetime fatality impacts associated with vehicle mass changes for passenger cars, light trucks, and all light-duty vehicles by model year under the preferred alternative, relative to the Augural standards for the CAFE Program. Table VI-256 presents an analogous table for the CO_2 Program.

Table VI-255 – Comparison of Lifetime Vehicle-Mass-Related Fatality Impacts by Model Year for CAFE Program under Preferred Alternative, Relative to Augural Standards, Fatalities Undiscounted

	MY 1977-2016	MY 2017	MY 2018	MY 2019	MY 2020	MY 2021	MY 2022	MY 2023	MY 2024	MY 2025	MY 2026	MY 2027	MY 2028	MY 2029	TOTAL
Passenger Cars	0	0	-5	-5	-8	-10	-16	-22	-25	-36	-47	-52	-53	-52	**-331**

Under the preferred alternative, passenger car fatalities associated with mass changes are estimated to decrease relative to the augural standards steadily from MYs 2018-19 (decrease of 4 fatalities) through MYs 2028-29 (decrease of 46 fatalities). Conversely, light truck fatalities associated with mass changes under the preferred alternative are estimated to increase relative to the augural standards from MY 2019 (increase of 1 fatality) through MY 2029 (increase of 8 fatalities).

Table VI-257 and Table VI-258 present estimates of monetized lifetime social safety costs associated with mass changes by model year at three-percent and seven-percent discount rates, respectively for the CAFE Program.

Table VI-259 and Table VI-260 show comparable tables from the perspective of the CO_2 Program.

Lifetime social safety costs associated with mass change in passenger cars are estimated to decrease by between $0.1 billion (for MYs 2020-23) and $0.3 billion (for MYs 2026-29) at a three-percent discount rate. At a seven-percent discount rate, lifetime social safety costs associated with mass change in passenger cars are estimated to decrease by between $0.1 billion and $0.2 billion from MY 2022 through MY 2029. Lifetime social safety costs associated with mass change in light trucks are estimated to increase by less than $0.1 billion for all MYs at three-percent and seven-percent discount rates.

b) Impact of Vehicle Scrappage and Sales Response on Fatalities

The sales and scrappage responses discussed in Section VI have important safety consequences and influence safety outcomes through the same basic mechanism, fleet turnover. In the case of the scrappage response, delaying fleet turnover keeps drivers in older vehicles which are less safe than newer vehicles[2161]. Similarly, the sales response slows the rate at which newer vehicles, and their associated safety improvements, enter the on-road population. The sales response also influences the mix of vehicles on the road–with more stringent CAFE standards leading to a higher share of light trucks sold in the new vehicle market, assuming all else is equal. Light trucks have higher rates of fatal crashes when interacting with passenger cars and, as earlier sections discussed, different directional responses to mass reduction technology based on the existing mass and body style of the vehicle.

With an integrated fleet model now part of the analytical framework for CAFE analysis, any effects on fleet turnover (either from delayed vehicle retirement or deferred sales of new vehicles) will affect the distribution of both ages and model years present in the on-road fleet. Because each of these vintages carries with it inherent rates of fatal crashes, and newer vintages are generally safer than older ones, changing that distribution will change the total number of on-road fatalities under each regulatory alternative. Similarly, the dynamic fleet share model captures the changes in the fleet's composition of cars and trucks. As cars and trucks have different fatality rates, differences in fleet composition across the alternatives will affect fatalities.

At the highest level, the agencies calculate the impact of the sales and scrappage effects by multiplying the VMT of a vehicle by the fatality risk of that vehicle. For this analysis, calculating VMT is rather simple: the agencies use the distribution of miles calculated in Section VI. The trickier aspect of the analysis is creating fatality rate coefficients. The fatality risk measures the likelihood that a vehicle will be involved in fatal accident per mile driven. As explained below, the agencies' methodology changed from the proposal to this final rule in response to comments, but the basic analytical framework remains the same. The agencies calculate the fatality risk of a vehicle based on the vehicle's model year, age, and style, while

[2161] *See* Passenger Vehicle Occupant Injury Severity by Vehicle Age and Model Year in Fatal Crashes, Traffic Safety Facts Research Note, DOT-HS-812-528, National Highway Traffic Safety Administration, April, 2018, and The Relationship Between Passenger Vehicle Occupant Injury Outcomes and Vehicle Age or Model Year in Police-Reported Crashes, Traffic Safety Facts Research Note, DOT-HS-812-937, National Highway Traffic Safety Administration, March, 2020.

controlling for factors which are independent of the intrinsic nature of the vehicle, such as behavioral characteristics.

(7) NPRM Safety Model

The analysis supporting the joint MYs 2017 and beyond rule did not account for differences in exposure or inherent safety risk as vehicles aged throughout their useful lives. However, the relationship between vehicle age and fatality risk is an important one. In a 2013 Research Note,[2162] NHTSA's National Center for Statistics and Analysis (NCSA) concluded a driver of a vehicle that is 4-7 years old is 10% more likely to be killed in a crash than the driver of a vehicle 0 – 3 years old, accounting for the other factors related to the crash. This trend continued for older vehicles more generally, with a driver of a vehicle 18 years or older being 71% more likely to be killed in a crash than a driver in a new vehicle. While there are more registered vehicles that are 0-3 years old than there are 20 years or older (nearly three times as many) because most of the vehicles in earlier vintages are retired sooner, the average age of vehicles in the United States is 11.6 years old and has risen significantly in the past decade.[2163] This relationship reflects a general trend visible in the Fatality Analysis Reporting System (FARS) when looking at a series of calendar years—newer vintages are safer than older vintages, over time, at each age. This is likely because of advancements in safety technology, like side-impact airbags, electronic stability control, and (more recently) sophisticated crash avoidance systems starting to work their way into the vehicle population. In fact, the 2013 Research Note indicated that the percentage of occupants fatally injured in fatal crashes increased with vehicle age—from 27 percent for vehicles three or fewer years old, to 41 percent for vehicles 12-14 years old, to 50 percent for vehicles 18 or more years old.[2164]

To estimate the empirical relationship between vehicle age, model year vintage, and fatalities for the proposal, the agencies conducted a statistical analysis linking data from the FARS database, a time series of Polk registration data to represent the on-road vehicle population, and assumed per-vehicle mileage accumulation rates (the derivation of which is discussed in detail in Preamble Section VII). These data were used to construct per-mile fatality rates that varied by vehicle vintage, accounting for the influence of vehicle age. However, unlike the NCSA study referenced above, any attempt to account for this relationship in the CAFE analysis faced two challenges. The first challenge is the CAFE Model lacks the internal structure to account for other factors related to observed fatal crashes—for example, vehicle speed, seat belt use, drug use, or age of involved drivers or passengers. Vehicle interactions are simply not modeled at this level; the safety analysis in the CAFE Model is statistical, using aggregate values to represent the totality of fleet interactions over time. The second challenge is perhaps the more significant of the two—the CAFE analysis is inherently forward-looking. To implement a statistical model analogous to the one developed by NCSA, the CAFE Model would require forecasts of all factors considered in the NCSA model – about vehicle speeds in crashes, driver behavior, driver and passenger ages, vehicle vintages, and so on. In particular, the model would require distributions (joint distributions, in most cases) of these factors over a period of time spanning decades. Any such forecasts would be highly uncertain and would be likely to assume a continuation of current conditions.

Instead of trying to replicate the NCSA work at a similar level of detail, the agencies conducted a simpler statistical analysis to separate the safety impact of the two factors the CAFE Model explicitly accounts for - the distribution of vehicle ages in the fleet and the number of miles driven by those vehicles at each age. To accomplish this, the agencies used data from the FARS database at a lower level of resolution; rather than looking at each crash and the specific factors that contributed to its occurrence, the agencies looked at the total number of fatal crashes involving light-duty vehicles over time with a focus on the influence of vehicle *age* and vehicle *vintage*. When considering the number of fatalities relative to the number of registered vehicles for a given model year (without regard to the passenger car/light-truck distinction, which has evolved over time and can create inconsistent comparisons), a somewhat noisy pattern develops. Using data from calendar year 1996 through 2015, some consistent stories develop. The points in Figure VI-144 represent the number of fatalities per registered vehicle with darker circles associated with increasingly current calendar years.

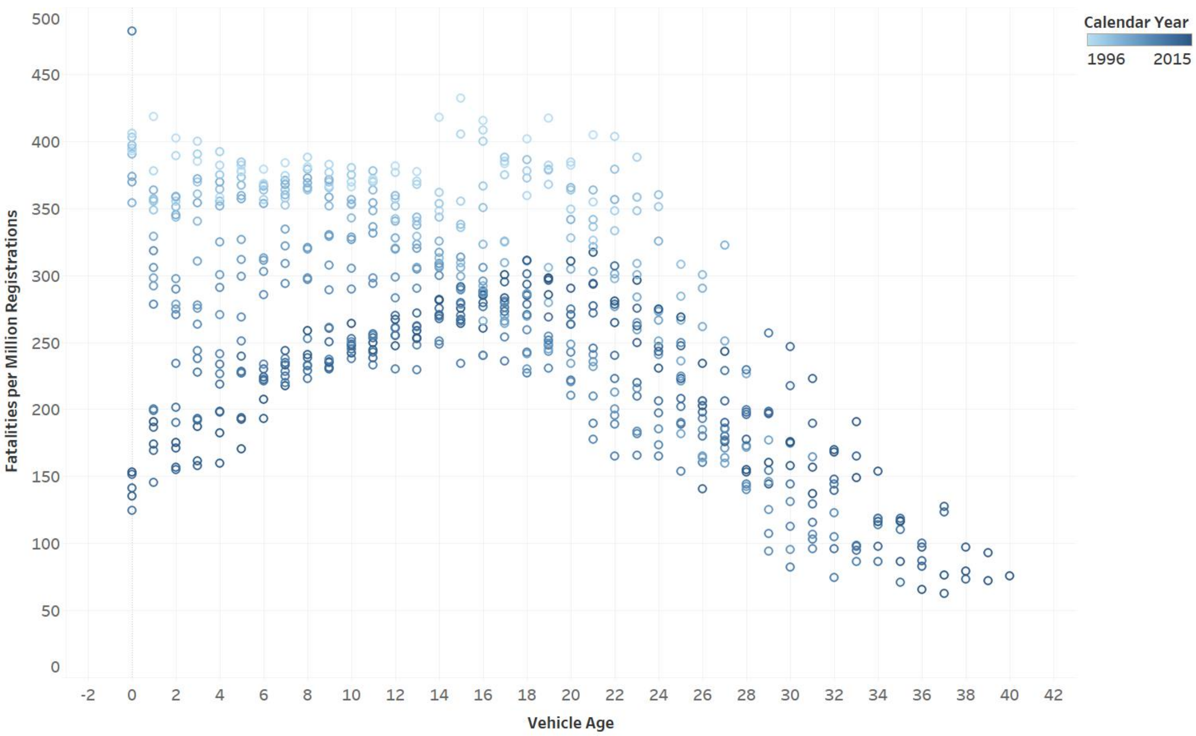

Figure VI-144 – Fatalities per million registered vehicles, 1996 -2015

As shown in Figure VI-144, fatalities per registered vehicle have generally declined over time across all vehicle ages (the darker points representing newer vintages being closer to the x-axis) and, across most recent calendar years, fatality rates (per registered vehicle) start out at a low point, rise through age 15 or so, then decline through age 30 (at which point little of the initial model year cohort is still registered). While this pattern is evident in the registration data, it is magnified by imposing a mileage accumulation schedule on the registered population and examining fatalities per billion miles of VMT.

The mileage accumulation schedule used in this analysis was developed using odometer readings of vehicles aged 0-15 years in calendar year 2015. The years spanned by the FARS database cover all model years from calendar year 1996 through 2015. Given that there is a significant number of years between the older vehicles in the 1996 CY data and the most recent model years in the odometer data the informed the mileage accumulation schedules, staff applied an elasticity of -0.20 to the change in the average cost per mile of vehicles over their lives. While the older vehicles had lower fuel economies, which would be associated with higher per-mile driving costs, they also (mostly) faced lower fuel prices. This adjustment increased the mileage accumulation for older vehicles, but not by large amounts. Because the NPRM model uses the mileage accumulation schedule and applies it to all vehicles in the fleet, it is necessary to use the same schedule to estimate per-mile fatality rates in the statistical analysis—even if the schedule is based on vehicles that look different than the oldest vehicles in the FARS dataset.

When the per-vehicle fatality rates are converted into per-mile fatality rates, the pattern observed in the registration comparison becomes clearer. As Figure VI-145 shows, the trend present in the fatality data on a per-registration basis, is even clearer on a per-mile basis - newer vintages are safer than older vintages, at each age, over time.

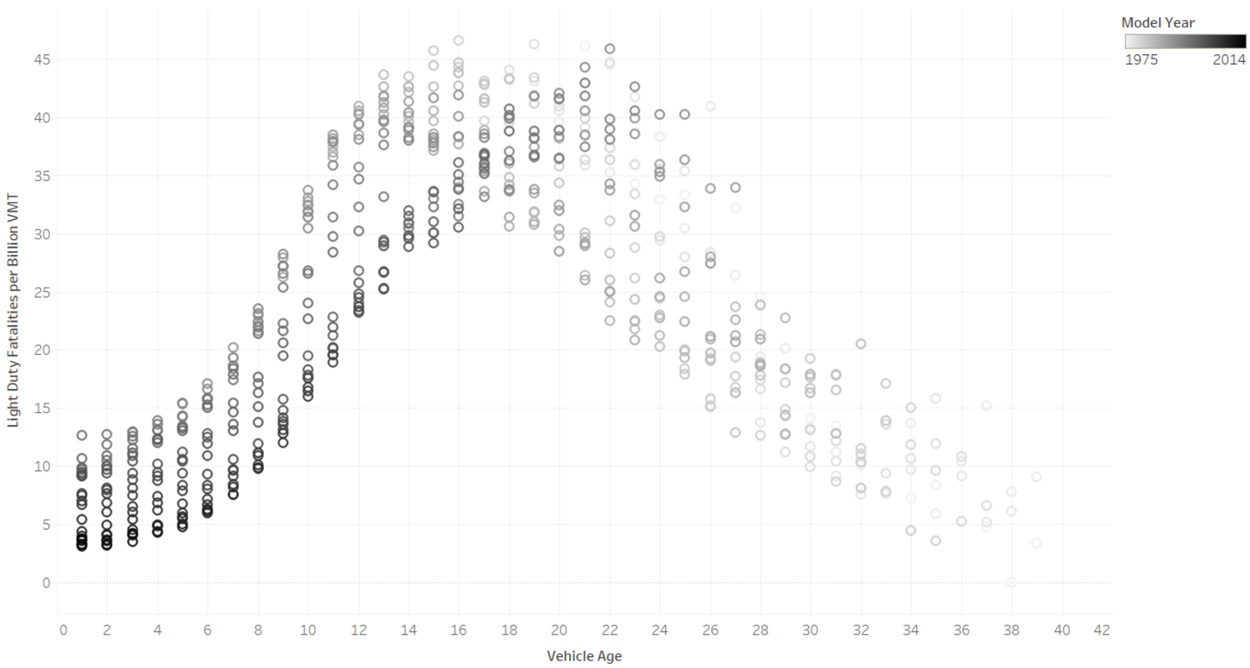

Figure VI-145 – Fatalities per billion VMT, 1996 - 2015

The shape of the curve in Figure VI-145 suggests a polynomial relationship between fatality rate and vehicle age, so agencies' statistical model for the NPRM was based on that structure. The NPRM model was a weighted quartic polynomial regression (by number of registered vehicles) on vehicle age with fixed effects for the model years present in the dataset:[2165]

Equation VI-15 - Fatalities per Billion Miles

Fatalities per billion miles = β_0 * Age + β_1 * Age^2 + β_2 * Age^3 + β_3 * Age^4 + $\sum \beta_i$ * MYi,

for i = {1976, 1977, …, 2014}.

The coefficient estimates and model summary are in Table VI-261.

This function was embedded in the NPRM model, so the combination of VMT per vehicle and the distribution of ages and model years present in the on-road fleet determined the number of fatalities in a given calendar year. The model reproduced the observed fatalities of a given model year, at each age, reasonably well with more recent model years (to which the VMT schedule is a better match) estimated with smaller errors.

(a) Predicting Future Safety Trends

The base NPRM model predicted a net increase in fatalities due primarily to slower adoption of safer vehicles and added driving because of less costly vehicle operating costs. In earlier calendar years, the improvement in safety of the on-road fleet produces a net reduction in fatalities, but from the mid-2020s forward, the baseline model predicts no further increase in safety, and the added risk from more VMT and older vehicles produces a net increase in fatalities. This model thus reflected a conservative limitation; it implicitly assumed the trend toward increasingly safe vehicles that has been apparent for the past 3 decades will flatten in the mid-2020s. The agencies did not assert that this is the most likely case. In fact, the agencies noted that the development of advanced crash avoidance technologies in recent years indicates some level of safety improvement is almost certain to occur. Moreover, autonomous vehicles offer the possibility of significantly reducing or eventually even eliminating the effect of human error in crash causation, a contributing factor in roughly 94% of all crashes. This conservative assumption may cause the today's analysis to understate the beneficial effect of the final standards on improving (reducing) the number of fatalities.

Advanced technologies that are currently deployed or in development include:

Forward Collision Warning (FCW) systems are intended to passively assist the driver in avoiding or mitigating the impact of rear-end collisions (i.e., a vehicle striking the rear portion of a vehicle traveling in the same direction directly in front of it). FCW uses forward-looking vehicle detection capability, such as RADAR, LIDAR (laser), camera, etc., to detect other vehicles ahead and use the information from these sensors to warn the driver and to prevent crashes. FCW systems provide an audible, visual, or haptic warning, or any combination thereof, to alert the driver of an FCW-equipped vehicle of a potential collision with another vehicle or vehicles in the anticipated forward pathway of the vehicle.

Crash Imminent Braking (CIB) systems are intended to actively assist the driver by mitigating the impact of rear-end collisions. These safety systems have forward-looking vehicle detection capability provided by sensing technologies such as RADAR, LIDAR, video camera, etc. CIB systems mitigate crash severity by automatically applying the vehicle's brakes shortly before the expected impact (i.e., without requiring the driver to apply force to the brake pedal).

Dynamic Brake Support (DBS) is a technology that actively increases the amount of braking provided to the driver during a rear-end crash avoidance maneuver. If the driver has applied force to the brake pedal, DBS uses forward-looking sensor data provided by technologies such as RADAR, LIDAR, video cameras, etc. to assess the potential for a rear-end crash. Should DBS ascertain a crash is likely (i.e., the sensor data indicate the driver has not applied enough braking to avoid the crash), DBS automatically intervenes. Although the manner in which DBS has been implemented differs among vehicle manufacturers, the objective of the interventions is largely the same - to supplement the driver's commanded brake input by increasing the output of the foundation brake system. In some situations, the increased braking provided by DBS may allow the driver to avoid a crash. In other cases, DBS interventions mitigate crash severity.

Pedestrian AEB (PAEB) systems provide automatic braking for vehicles when pedestrians are in the forward path of travel and the driver has taken insufficient action to avoid an imminent crash. Like CIB, PAEB safety systems use information from forward-looking sensors to automatically apply or supplement the brakes in certain driving situations in which the system determines a pedestrian is in imminent danger of being hit by the vehicle. Many PAEB systems use the same sensors and technologies used by CIB and DBS.

Rear Automatic Braking feature means installed vehicle equipment that has the ability to sense the presence of objects behind a reversing vehicle, alert the driver of the presence of the object(s) via auditory and visual alerts, and automatically engage the available braking system(s) to stop the vehicle.

Semi-automatic Headlamp Beam Switching device provides either automatic or manual control of headlamp beam switching at the option of the driver. When the control is automatic, headlamps switch from the upper beam to the lower beam when illuminated by headlamps on an approaching vehicle and switch back to the upper beam when the road ahead is dark. When the control is manual, the driver may obtain either beam manually regardless of the conditions ahead of the vehicle.

Rear Turn Signal Lamp Color Turn signal lamps are the signaling element of a turn signal system, which indicates the intention to turn or change direction by giving a flashing light on the side toward which the turn will be made. FMVSS No. 108 permits a rear turn signal lamp color of amber or red.

Lane Departure Warning (LDW) system is a driver assistance system that monitors lane markings on the road and alerts the driver when their vehicle is about to drift beyond a delineated edge line of their current travel lane.

Lane Keep Assist (LKA) systems utilize LDW sensors to monitor lane markings but in addition to warning the driver they will also provide gentle steering adjustments to prevent drivers from unintentionally drifting out of their lane.

Blind Spot Detection (BSD) systems uses digital camera imaging technology or radar sensor technology to detect one or more vehicles in either of the adjacent lanes that may not be apparent to the driver. The system warns the driver of an approaching vehicle's presence to help facilitate safe lane changes.

Lane Change Alert (LCA) systems use digital camera imaging technology or radar sensor technology to detect vehicles either in, or rapidly approaching in adjacent lanes, that may not be apparent to the driver. The system warns the driver of an approaching vehicle's presence to help facilitate safe lane changes.

These technologies are either under development or are currently being offered, typically in luxury vehicles, as either optional or standard equipment.

(b) NPRM/PRIA Safety Trends Methodology

For the PRIA, to estimate baseline fatality rates in future years, the agencies examined predicted results from a previous NCSA study that measured the effect of known safety regulations on fatality rates. This study relied on statistical evaluations of the effectiveness of motor vehicle safety technologies based on real world performance in the on-road vehicle fleet to determine the effectiveness of each safety technology. These effectiveness rates were applied to existing fatality target populations and adjusted for current technology penetration in the on-road fleet, taking into account the retirement of existing vehicles and the pace of future penetration required to meet statutory compliance requirements, as well as adjustments for overlapping target populations. Based on these factors, as well as assumptions regarding future VMT, the study predicted future fatality levels and rates. Because the safety impact in the NPRM model independently predicted future VMT, the VMT growth rate was removed from the NCSA study to develop a prediction of vehicle fatality trends based only on the penetration pace of new safety technologies into the on-road fleet. These data were then normalized into relative safety factors with CY 2015 as the baseline (to match the baseline fatality year used in this CAFE analysis). These factors were then converted into equivalent fatality rates/100 million VMT by anchoring them to the 2015 fatality rate/100 million VMT published by NHTSA. Figure VI-146 below illustrates the modelling output and projected fatality trend from the analysis of the NCSA study, prior to adjustment to fatality rates/100 million VMT.

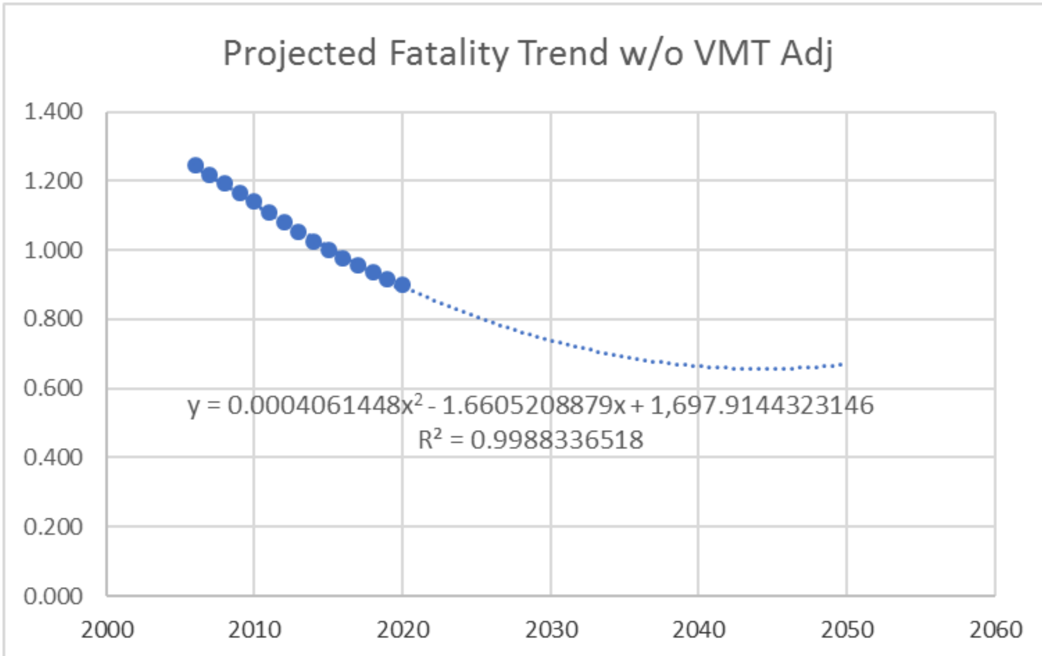

Figure VI-146 – Projected Fatality Trend without VMT Adjustment

This model was based on inputs representing the impact of technology improvement through CY 2020. Projecting this trend beyond 2020 can be justified based on the continued transformation of the on-road fleet to 100% inclusion of the known safety technologies. Based on projections in the NCSA study, significant further technology penetration can be expected in the on-road fleet for side impact improvements (FMVSSS 214), electronic stability control (FMVSS 126), upper interior head impact protection (FMVSS 301), tire pressure monitoring systems (FMVSS 138), ejection mitigation (FMVSS 226), and heavy truck stopping distance improvements (FMVSS 121). These technologies were estimated to be installed in only 40-70% of the on-road fleet as of CY 2020, implying further safety improvement well beyond the 2020 calendar year.

The NCSA study focused on projections to reflect known technology adaptation requirements, but it was conducted prior to the 2008 recession, which disrupted the economy and changed travel patterns throughout the country. Thus, while the relative trends it predicts seem reasonable, they cannot account for the real-world disruption and recovery that occurred in the 2008-2015 timeframe. In addition, the NCSA study did not attempt to adjust for safety impacts that may have resulted from changes in the vehicle sales mix (vehicle types and sizes creating different interactions in crashes), in commuting patterns, or in shopping or socializing habits associated with internet access and use. To address this, the actual change in the fatality rate as measured by fatality counts and VMT estimates were examined. Figure VI-147 below illustrates the actual fatality rates measured from 2000 through 2016 and the modeled fatality rate trend based on these historical data.

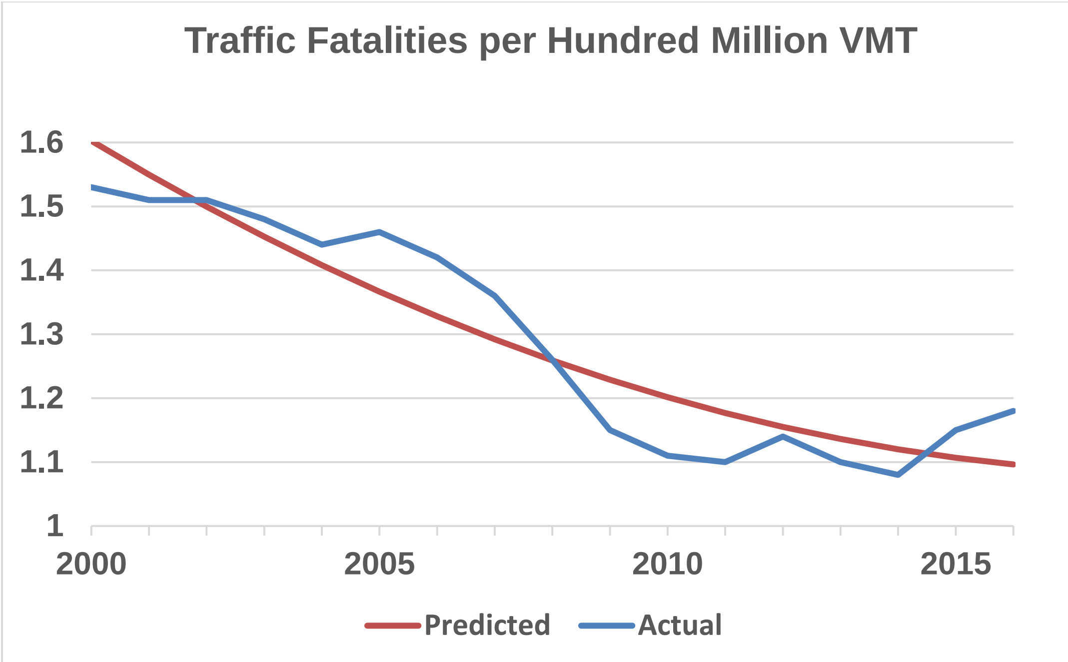

Figure VI-147 – Traffic Fatalities per Hundred Million VMT

The effect of the recession and subsequent recovery can be seen in chaotic shift in the fatality rate trend starting in 2008. The generally gradual decline that had been occurring over the previous decade was interrupted by a slowdown in the rate of change followed by subsequent upward and downward shifts. More recently, the rate has begun to increase. These shifts reflect some combination of factors not captured in the NCSA analysis mentioned above. The significance of this is that although there was a steady increase in the penetration of safety technologies into the on-road fleet between 2008 and 2015, other unknown factors offset their positive influence and eventually reversed the trend in vehicle safety rates. Because of the upward shift over the 2014-2015 period, this model, which does not reflect technology trend savings after 2015, will predict an upward shift of fatality rates after 2020.

Predicting future safety trends has significant uncertainty. Although further safety improvements are expected because of advanced safety technologies such as automatic braking and eventually, fully automated vehicles, the pace of development and extent of consumer acceptance of these improvements is uncertain. Thus, two imperfect models exist for predicting future safety trends. The NCSA model reflects the expected trend from required technologies and indicates continued improvement well beyond the 2020 timeframe, which is when the historical fatality rate based model breaks down. By contrast, the historical fatality rate model reflects shifts in safety not captured by the NCSA model, but gives arguably implausible results after 2020. It essentially represents a scenario in which economic, market, or behavioral factors minimize or offset much of the potential impact of future safety technology.

For the NPRM, the agencies examined a scenario projecting safety improvements beyond 2015 using a simple average of the NCSA and historical fatality rate models, accepting each as an illustration of different and conflicting possible future scenarios. As both models eventually curve up because of their quadratic form, each models' results are flattened at the point where they begin to trend upward. This occurs in 2045 for the NCSA model and in 2021 for the historical model. The results are shown in Figure VI-148 below. The results indicate roughly a 19% reduction in fatality rates between 2015 and 2050. This is a slower pace than what has historically occurred over the past several decades, but the biggest influence on historical rates was significant improvement in safety belt use, which was below 10% in 1960 and had risen to roughly 70% by 2000, and is now more than 90%. Because belt use is now above 90%, further such improvements are unlikely unless they come from new technologies.

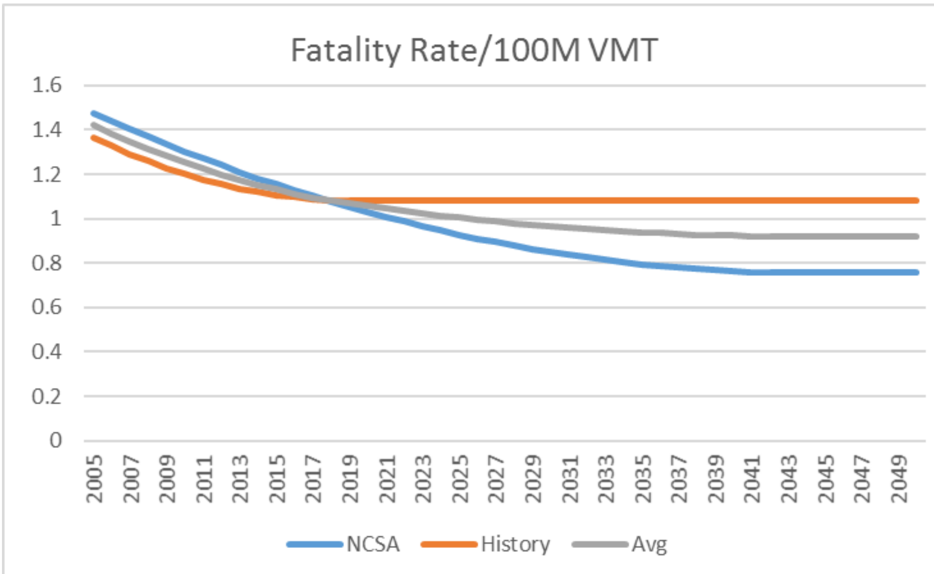

Figure VI-148 – Fatality Rate Per 100M Vehicle Mile Traveled

A difficulty with these trend models is they are based on calendar year predictions, which are derived from the full on-road vehicle fleet rather than the model year fleet, which is the basis for calculations in the NPRM model. As such they are useful primarily as indicators that vehicle safety has steadily improved over the past several decades, and given the advanced safety technologies under current development, some continuation of improvement in MY vehicle safety is expected over the near and mid-term future. To account for this, a model year safety trend continuing through about 2035 (Figure VI-149) was approximated. For this trend, actual data from FARS was used to calculate the change in fatality rates through 2007. The recession, which struck our economy in 2008, distorted normal behavioral patterns and affected both VMT and the mix of drivers and type of driving to an extent that recession-era data may not give an accurate picture of the safety trends inherent in the vehicles themselves. Therefore, beginning in 2008, a trend for safety improvement through about MY 2035 was approximated to reflect the continued effect of improved safety technologies such as advanced automatic braking, which manufacturers have announced will be in all new vehicles by MY 2022.

Although the analysis projected vehicles would continue to become safer going forward to about 2035, corresponding cost information for technologies enabling this improvement is not available. In a standard elasticity model, sales impacts are a function of the percent change in vehicle price. Hypothetically, increasing the base price for added safety technologies would decrease the impact of higher prices due to impacts of CAFE standards on vehicle sales. The percentage change in baseline price would decrease, which would mean a lower elasticity effect, which would mean a lower impact on sales. The agencies did not have sufficient information regarding the long-term price impacts of future safety technologies to make this adjustment, but the agencies note that it may have a small impact on the sales estimates.

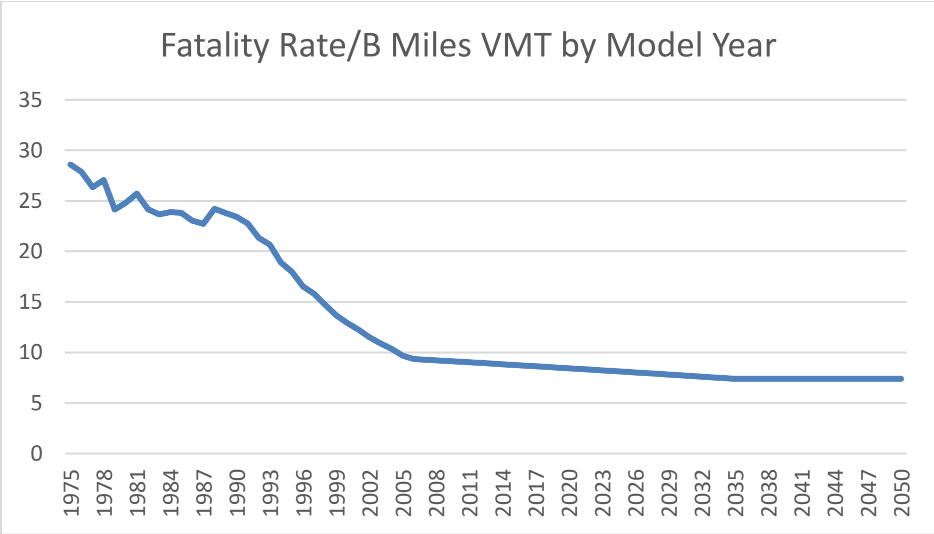

Figure VI-149 – Fatality Rate – B Miles VMT by Model Year

In the PRIA, the influence of delayed purchases of new vehicles was estimated to have the most significant effect on safety imposed by CAFE standards. Because of a combination of safety regulations and voluntary safety improvements, passenger vehicles have become safer over time. Compared to prior decades, fatality rates have declined significantly because of technological improvements, as well as behavioral shifts, such as increased seat belt use. As these safer vehicles replace older less safe vehicles in the fleet, the on-road fleet is replaced with vehicles reflecting the improved fatality rates of newer, safer vehicles. However, fatality rates associated with different model year vehicles are influenced by the vehicle itself and by driver behavior. Over time, used vehicles are purchased by drivers in different demographic circumstances who also tend to have different behavioral characteristics. Data from the Fatality Analysis Reporting System (FARS) indicate that drivers of older vehicles, on average, tend to have lower belt use rates, are more likely to drive inebriated, and are more likely to drive over the speed limit. Additionally, older vehicles are more likely to be driven on rural roadways, which typically have higher speeds and produce more serious crashes. Figure VI-150, Figure VI-151, Figure VI-152, and Figure VI-153 below illustrate these relationships.[2166]

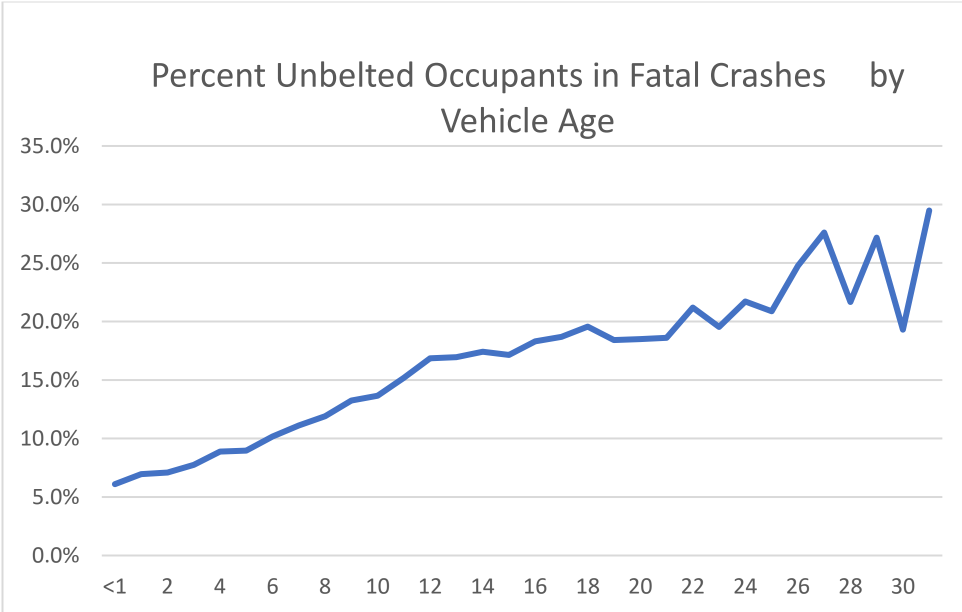

Figure VI-150 – Percent Unbelted Occupants in Fatal Crashes

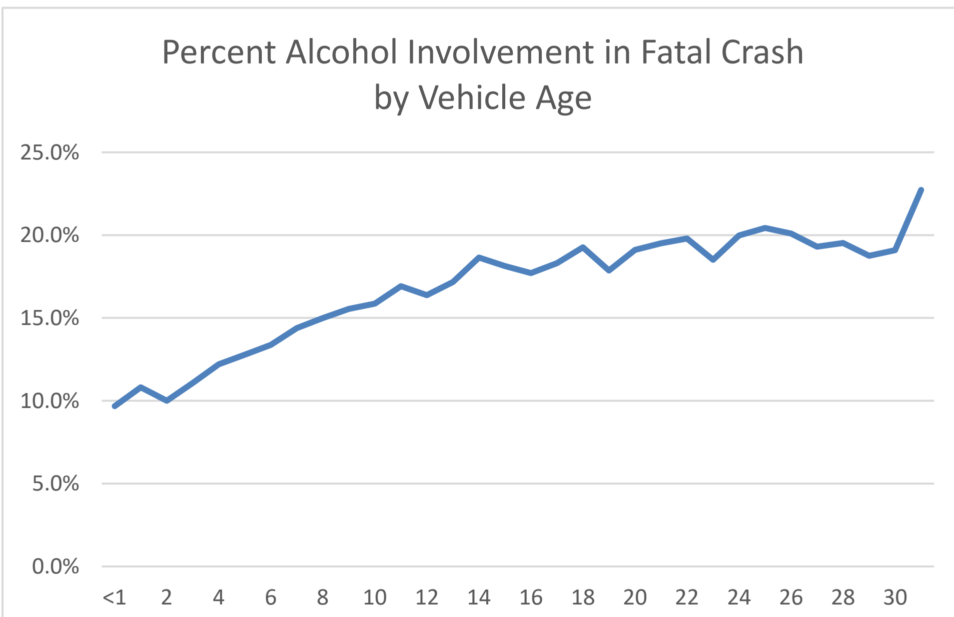

Figure VI-151 – Percent Alcohol Involvement in Fatal Crashes

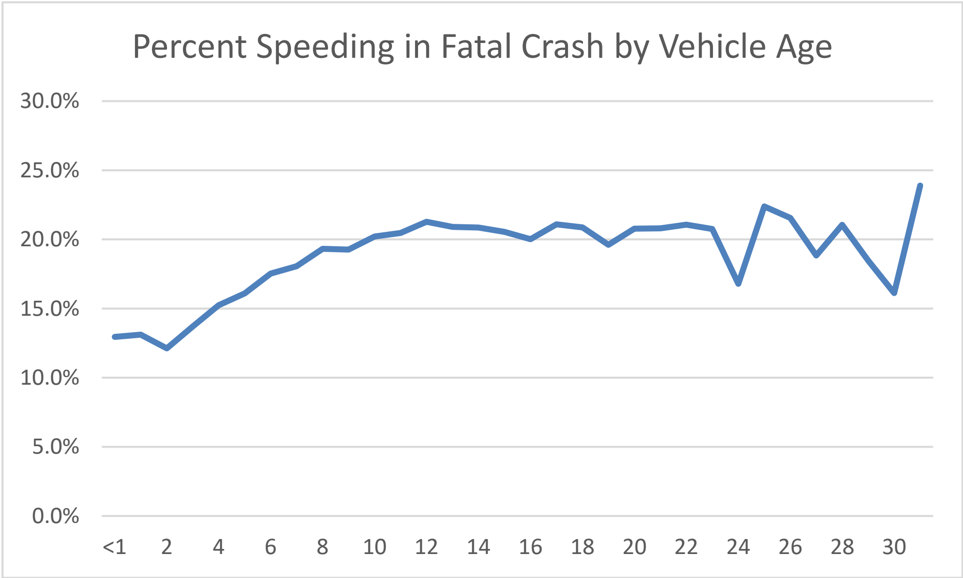

Figure VI-152 – Percent Speeding in Fatal Crash

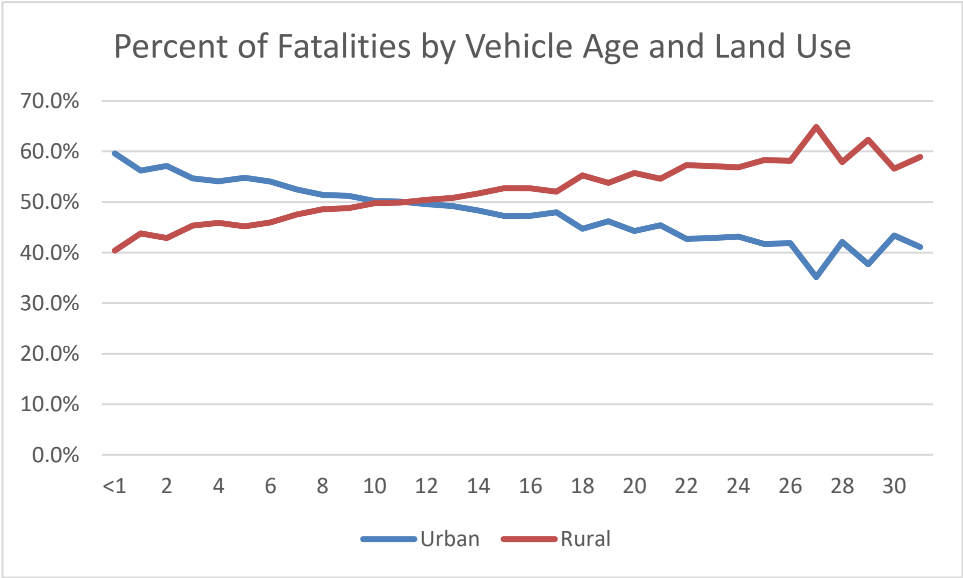

Figure VI-153 – Percent Fatalities by Vehicle Age and Land Use

The behavior being modelled and ascribed to CAFE involves decisions by drivers who are contemplating buying a new vehicle, and the purchase of a newer vehicle will not in itself cause those drivers to suddenly stop wearing seat belts, speed, drive under the influence, or shift driving to different land use areas. The goal of this analysis is to measure the effect of different vehicle designs that change by model year. The modelling process for estimating safety essentially involves substituting fatality rates of older MY vehicles for improved rates that would have been experienced with a newer vehicle. Therefore, it was important to control in the

NPRM for behavioral aspects associated with vehicle age so only vehicle design differences are reflected in the estimate of safety impacts. To address this, the CAFE safety model was run to control for vehicle age. That is, it did not reflect a decision to replace an older model year vehicle that is, for example, 10 years old with a new vehicle. Rather, it reflected the difference in the average fatality rate of each model year across its entire lifespan, which accounted for most of the difference because of vehicle age, but it may still have reflected a bias caused by the upward trend in societal seat belt use over time. Because of this secular trend, each subsequent model year's useful life will occur under increasingly higher average seat belt use rates. This could cause some level of behavioral safety improvement to be ascribed to the model year instead of the driver cohort. However, it is difficult to separate this effect from the belt use impacts of changing driver cohorts as vehicles age.

Glassbrenner[2167] analyzed the effect of improved safety in newer vehicles for model years 2001 through 2008. She developed several statistical regression models that specifically controlled for most behavioral factors to isolate model year vehicle characteristics. However, her study did not specifically report the change in MY fatality rates – rather, she reported total fatalities that could have been saved in a baseline year (2008) had all vehicles in the on-road fleet had the same safety features as the MY 2001 through MY 2008 vehicles. This study potentially provides a basis for comparison with results of the CAFE safety estimates. To make this comparison, the CY 2008 passenger car and light truck fatalities total from FARS were modified by subtracting the values found in Figure 7-17 of her study. This gives a stream of comparable hypothetical CY 2008 fatality totals under progressively less safe model year designs. Results indicated that had the 2008 on-road fleet been equipped with MY 2008 safety equipment and vehicle characteristics, total fatalities would have been reduced by 25% compared to vehicles that were actually on the road in 2008. Similar results were calculated for each model years' vehicle characteristics back to 2001.

For comparison, predicted MY fatality rates were derived from the NPRM model and applied to the CY 2008 VMT calculated by that model. This gives an estimate of CY 2008 fatalities under each model years' fatality rate, which, when compared to the predicted CY fatality total, gives a trendline comparable to the Glassbrenner trendline illustrating the change in MY fatality rates. Both models are sensitive to the initial 2008 baseline fatality total, and because the predicted CAFE total is somewhat lower than the actual total, the agency ran a third trendline to examine the influence of this difference. Results are shown in Figure VI-154.

Using the corrected fatality count, but retaining the predicted VMT changes the initial 2018 CY fatality rate to 12.62 (instead of 12.15) and produced the result shown in Figure VI-154. The NPRM model trendline shifted up, which narrowed the difference in early years but expanded it in later years. However, VMT and fatalities are linked in the CAFE Model, so the actual level of the MY safety predicted by the CAFE curve had uncertainty. Perhaps the most meaningful result from this comparison is the difference in slopes; the NPRM model predicted more rapid change through 2006, but in the last few years change decreased. This might have reflected the trend in societal belt use, which rose steadily through 2005 and levelled off. Later model years' fatality rates would benefit from this trend while earlier model years would suffer. This seemed consistent with using lifetime MY fatality rates to reflect MY change rather than first year MY fatality rates (although even first year rates would reflect this bias, but not as much).

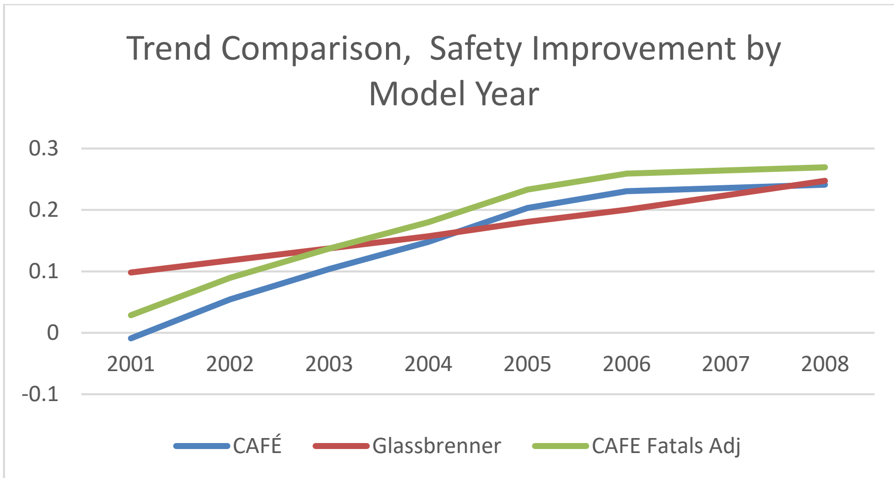

Figure VI-154 – Safety Improvement Trend by Model Year

To provide another perspective on safety impacts, the agencies accessed data from a comprehensive study of the effects of safety technologies on motor vehicle fatalities. Kahane (2015)[2168] examined all safety effects of vehicle safety technologies from 1960 through 2012 and found these technologies saved more than 600,000 lives during that time span. Kahane is currently working under contract for NHTSA to update this study through 2016. At NHTSA's request, Kahane accessed his database to provide a measure of relative MY vehicle design safety by controlling for seat belt use. The result was a MY safety index illustrating the progress in vehicle safety by model year which isolates vehicle design from the primary behavioral impact – seat belt usage. The Kahane's index to MY 1975 was normalized and did the same to the "fixed effects" currently used from the safety model to compare the trends in MY safety from the two methods. Results are shown in Figure VI-155.

Kahane, C.J., Lives Saved by Vehicle Safety Technologies and Associated Federal Motor Vehicle Safety Standards, 1960 to 2012 – Passenger Cars and LTVs, National Highway Traffic Safety Administration, Paper Number 15-0291.

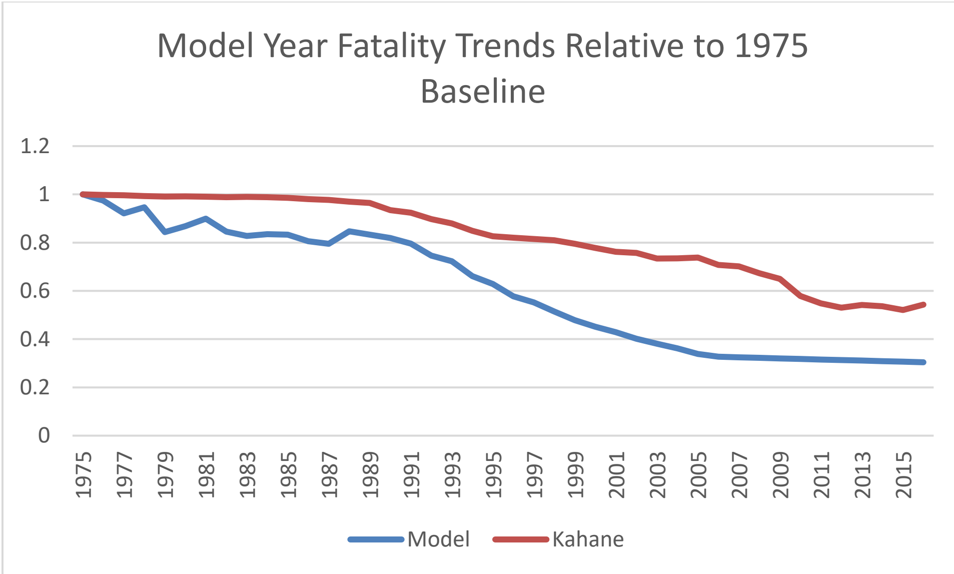

Figure VI-155 – Fatality Trends Relative to 1975

From Figure VI-155 both approaches showed similar long-term downward trends, but the NPRM model showed a steeper slope than Kahane's model. The two models involved completely different approaches, so some difference is to be expected. However, it is also possible this reflected different methods used to isolate vehicle design safety from behavioral impacts. As discussed previously, the agencies addressed this issue by removing vehicle age impacts from the NPRM model, whereas Kahane's model does it by controlling for belt use. As noted previously, aside from the age impact on belt use associated with the different demographics driving older vehicles, there is a secular trend toward more belt use reflecting the increase in societal awareness of belt use importance over time. This trend is illustrated in Figure VI-156 below.[2169] The NPRM approach removed the age trend in belt use, but it's not clear whether it accounted for the full impacts of the secular trend as well. If not, some portion of the gap between the two trendlines could reflect behavioral impacts rather than vehicle design.

These models (the NPRM safety model, Glassbrenner, and Kahane) involved differing approaches and assumptions contributing to uncertainty, and given this, their differences are not surprising. The agencies recognized predicting future fatality impacts, as well as sales impacts that cause them, is a difficult and imprecise task.

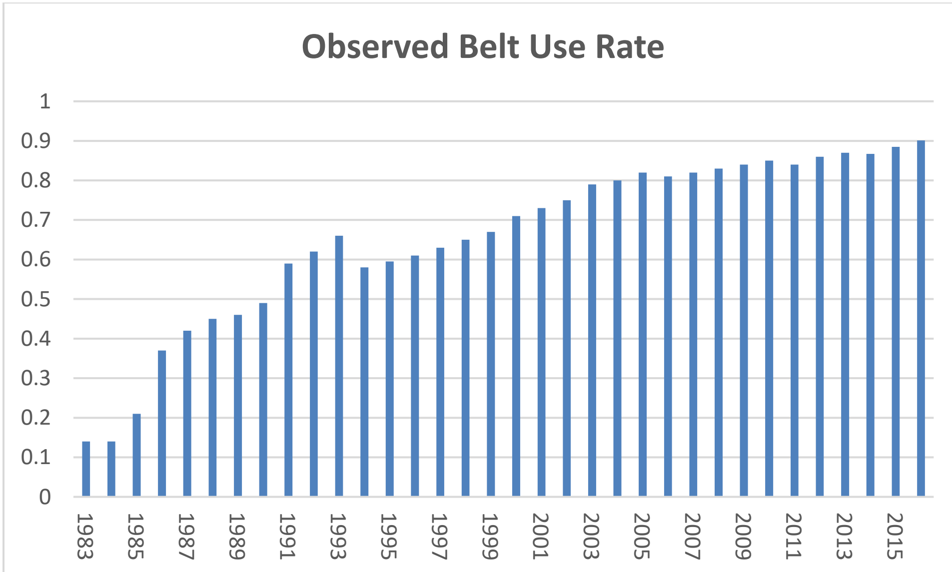

Figure VI-156 – Observed Seat Belt Use Rate

(8) Revised Sales-Scrappage Safety Model

In response to the comments, the agencies have taken several steps to revise the sales-scrappage safety model. First, the agencies developed a revised statistical model to explain historical improvements in the lifetime safety performance of each successive new vintage of cars and light trucks, and used the results of this improved model to project the future trend in the overall fatality rates. While the revised historical trend model itself is more complex than the one utilized in the proposal, the overall procedure is simpler; the agencies have collapsed the two piecemeal components discussed above into one model and eliminated the need to 'reconcile' differences between competing future projections. Next, the agencies applied detailed empirical estimates of the market uptake and improving effectiveness of crash avoidance technologies to estimate their effect on the fleet-wide fatality rate, including explicitly incorporating both the direct effect of those technologies on the crash involvement rates of new vehicles equipped with them, as well as the "spillover" effect of those technologies on improving the safety of occupants of vehicles that are not equipped with these technologies.

(c) Crash Avoidance

In the NPRM, the agencies took a very generalized approach to estimating the pace of future safety trends. For reasons discussed above, the agencies noted that there was uncertainty regarding actual trends in fatality rates. This issue was addressed by numerous commenters who took opposing positions. Among them, IPI stated that "[t]he agencies have not provided an adequate explanation for why past safety trends are likely to continue until the mid-2020s." IPI further noted that "crash avoidance technology may not be adopted as easily or readily as crash mitigation technologies have been."[2170] In response, the agencies note that the trend the agencies

[2170] IPI, Appendix, NHTSA-2018-0067-12213, at 98.

adopted for the NPRM was not a direct continuation of past trends. Rather, it was a simple average of several possible models the agencies had examined, accepting each as an illustration of different and conflicting possible future scenarios.

By contrast, States and Cities asserted that fatality rates may be lower in the future than the agencies estimated, noting that the NPRM analysis did not "account for safety benefits that new safety technologies in future vehicles will have on the agencies predicted outcome."[2171] While the agencies agree that the NPRM analysis did not analyze individual safety benefits of new technologies, the trends included in the NPRM were intended, in part, as a proxy estimate of the impact of these technologies. As discussed in the NPRM, these technologies were cited as a justification for assuming a continued downward trend in the fatality rate through roughly 2035.

Nonetheless, the agencies believe that further analysis of these potential trends can now be ascertained for several explicit technologies. In response to comments suggesting that the agencies account more directly for new safety technologies, the agencies augmented the sales-scrappage safety analysis for the final rule with recent research into the effectiveness of specific advanced crash avoidance safety technologies (also known as ADAS or advanced driver assistance systems) that are expected to drive future safety improvement to estimate the impacts of crash avoidance technologies. The analysis analyzes six crash avoidance technologies that are currently being produced and commercially deployed in the new vehicle fleet. These include Frontal Collision Warning (FCW), Automatic Emergency Braking (AEB), Lane Departure Warning (LDW), Lane Keep Assist (LKA), Blind Spot Detection (BSD), and Lane Change Alert (LCA).[2172] These are the principal technologies that are being developed and adopted in new vehicle fleets and will likely drive vehicle-based safety improvements for the coming decade. These technologies are being installed in more and more new vehicles; in fact, manufacturers recently reported that they voluntarily installed AEB systems in more than 70 percent of their new vehicles sold in the year ending August 31, 2019. [2173] The agencies note that the terminology and the detailed characteristics of these systems may differ across manufacturers, but the basic system functions are common across all.

These 6 technologies address three basic crash scenarios through warnings to the driver or alternately, through dynamic vehicle control:

1. Forward collisions, typically involving a crash into the rear of a stopped vehicle;
2. Lane departure crashes, typically involving inadvertent drifting across or into another traffic lane; and
3. Blind spot crashes, typically involving intentional lane changes into unseen vehicles driving in or approaching the driver's blind spot.

[2171] States and Cities, Detailed Comments, NHTSA-2018-0067-11735, at 80.
[2172] A full description of these technologies and several other technologies referenced below may be found in Section Summary of Safety Impacts.
[2173] NHTSA Announces Update to Historic AEB Commitment by 20 Automakers, NHTSA press release December 17, 2019. https://www.nhtsa.gov/press-releases/nhtsa-announces-update-historic-aeb-commitment-20-automakers

Unlike traditional safety features where the bulk of the safety improvements were attributable to improved protection when a crash occurs (crash worthiness), the impact of advanced crash avoidance technologies (ADAS or advanced driver assistance systems) will have on fatality and injury rates is a direct function of their effectiveness in preventing or reducing the severity of the crashes they are designed to mitigate. This effectiveness is typically measured using real world data comparing vehicles with these technologies to similar vehicles without them. While these technologies are actively being deployed in new vehicles, their penetration in the larger on-road vehicle fleet has been at a low, but growing level. This limits the precision of statistical regression analyses, at least until the technologies become more common in the on-road fleet.

The agencies' approach in the final rule is to derive effectiveness rates for these advanced crash-avoidance technologies from safety technology literature. The agencies then apply these effectiveness rates to specific crash target populations for which the crash avoidance technology is designed to mitigate and adjusted to reflect the current pace of adoption of the technology, including the public commitment by manufactures to install these technologies. The products of these factors, combined across all 6 advanced technologies, produce a fatality rate reduction percentage that is applied to the fatality rate trend model discussed below, which projects both vehicle and non-vehicle safety trends. The combined model produces a projection of impacts of changes in vehicle safety technology as well as behavioral and infrastructural trends.

(d) Technology Effectiveness Rates

(i) Forward Crash Collision Technologies

For forward collisions, manufacturers are currently equipping vehicles with FCW, which warns drivers of impending collisions, as well as AEB, which incorporates the sensor systems from FCW together with dynamic brake support (DBS) and crash imminent braking (CIB) to help avoid crashes or mitigate their severity. Manufacturers have committed voluntarily to install some form of AEB on all light vehicles by the 2023 model year (September 2022).[2174]

Table VI-262 summarizes studies which have measured effectiveness for various forms of FCW and AEB over the past 13 years. Most studies focused on crash reduction rather than injury reduction. This is a function of limited injury data in the on-road fleet, especially during the early years of deployment of these technologies. In addition, it reflects engineering limitations in the technologies themselves. Initial designs of AEB systems were basically incapable of detecting stationary objects at speeds higher than 30 mph, making them potentially ineffective in higher speed crashes that are more likely to result in fatalities or serious injury. For example, Wiacek et al. (2-15) conducted a review of rear-end crashes involving a fatal occupant in the 2003-2012 NASS-CDS data-bases to determine the factors that contribute to fatal rear-end crashes.[2175] They found that the speed of the striking vehicle was the primary factor in 71 percent of the cases they examined. The average Delta-V of the striking vehicle in

[2174] *See* https://www.nhtsa.gov/press-releases/nhtsa-iihs-announcement-aeb.

these cases was 46 km/h (28.5 mph), implying pre-crash travel speeds in excess of this speed. While Table VI-262 includes studies going back to 2005, the agencies focus discussion on more recent studies conducted after 2012 in order to reflect more current safety systems and vehicle designs.

Table VI-262 – Summary of AEB Technology Effectiveness Estimates

				Injury Reduction		
Authors	**AEB Type**	**Crashes**	**Fatalities**	**Serious**	**Minor**	**All Injuries**
Sugimoto & Sauer (2005)[2176]	CMBS	38%	44%

	AEB	7.70%	50%	50%		
Leslie et al. (2019)[2189]	FCW	21%				
	AEB	46%				

Doecke et al. (2012) created simulations of 103 real world crashes and applied AEB system models with differing specifications to determine the change in impact speed that various AEB interventions might produce. Their modeling found significant rear-end crash speed reductions with various AEB performance assumptions. In addition, they estimated a 29 percent reduction in rear-end crashes and that 25 percent of crashes over 10 km/h were reduced to 10 km/h or less.

Cicchino (2016) analyzed the effectiveness of a variety of forward collision mitigation systems including both FCW and AEB systems. Cicchino used a Poisson regression to compare rates of police-reported crashes per insured vehicle year between vehicles with these systems and the same models that did not elect to install them. The analysis was based on crashes occurring during 2010 to 2014 in 22 States and controlled for other factors that affected crash risk. Cicchino found that FCW reduced all rear-end striking crashes by 27 percent and rear-end striking injury crashes by 20 percent, and that AEB functional at high-speeds reduced these crashes by 50 and 56 percent, respectively. She also found that low speed AEB without driver warning reduced all crashes by 43 percent and injury crashes by 45 percent. She also found that even low-speed AEB could impact crashes at higher speed limits. Reductions were found of 53 percent, 59 percent, and 58 percent for all rear-end striking crash rates, rear-end striking injury

2189 Leslie, A, Kiefer, R., Meitzner, M, and Flannagan, C. (2019). Analysis of the Field Effectiveness of General Motors Production Active Safety and Advanced headlighting Systems. University of Michigan Transportation Research Institute, UMTRI-2019-6, September, 2019.

crash rates, and rear-end third party injury crash rates, respectively, at speed limits of 40-45 mph. For speed limits of 35 mph or less, reductions of 40 percent, 40 percent, and 43 percent were found. For speed limits of 50 mph or greater, reductions of 31 percent, 30 percent, and 28 percent, were found. Further, Cicchino (2016) found significant reductions (30 percent) in rear-end injury crashes even in crashes on roadways where speed limits exceeded 50 mph.

Kusano and Gabler (2012) examined the effectiveness of various levels of forward collision technologies including FCW and AEB based on simulations of 1,396 real world rear end crashes from 1993-2008 NASS CDS data-bases. The authors developed a probability-based framework to account for variable driver responses to the warning systems. Kusano and Gabler found FCW systems could reduce rear-end crashes by 3.2 percent and driver injuries in rear-end crashes by 29 percent. They also found that full AEB systems with FCW, pre-crash brake assist, and autonomous pre-crash braking could reduce rear-end crashes by 7.7 percent and reduce moderate to fatal driver injuries in rear-end crashes by 50 percent.

Fildes et al. (2015) performed meta-analyses to evaluate the effectiveness of low-speed AEB technology in passenger vehicles based on real-world crash experience across six different predominantly European countries. Data from these countries was pooled into a standard analysis format and induced exposure methods were used to control for extraneous effects. The study found a 38 percent overall reduction in rear-end crashes for vehicles with AEB compared to similar vehicles without this technology. The study also found no statistical evidence for any difference in effectiveness between urban roads with speed limits less than or equal to 60 km/h, and rural roads with speed limits greater than 60 km/h. Fildes et al. (2015) found no statistical difference in the performance of AEBs on lower speed urban or higher speed rural roadways.

Kusano and Gabler (2015) simulated rear-end crashes based on a sample of 1,042 crashes in the 2012 NASS-CDS. Modelling was based on 54 model year 2010-2014 vehicles that were evaluated in NHTSA's New Car Assessment Program (NCAP). Kusano and Gabler found FCW systems could prevent 0-67 percent of rear-end crashes and 2-69 percent of serious to fatal driver injuries.

Leslie et al. (2019) analyzed the relative crash performance of 123,377 General Motors (GM) MY 2013 to 2017 vehicles linked to State police-reported crashes by Vehicle Identification numbers (VIN). GM provided VIN-linked safety content information for these vehicles to enable precise identification of safety technology content. The authors analyzed the effectiveness of a variety of crash avoidance technologies including both FCW and AEB separately. They estimated effectiveness comparing system-relevant crashes to baseline (control group) crashes using a quasi-induced exposure method in which rear-end struck crashes are used as the control group. Leslie et al. found that FCW reduced rear-end striking crashes of all severities by 21 percent, and that AEB (which includes FCW) reduced these crashes by 46 percent.[2190]

[2190] The agencies note that UMTRI, the sponsoring organization for the Leslie et al. study, published a previous version of this same study utilizing the same methods in March of 2018 (Flannagan, C. and Leslie, A, Crash

For this analysis, the agencies based their projections on Leslie et al. because they are the most recent study, and thus reflect the most current versions of these systems in the largest number of vehicles, and also because they arguably have the most precise identification of the presence of the specific technologies in the vehicle fleet. Furthermore, Leslie et al. was the only study to report estimates for each of the six crash avoidance technologies analyzed for the final rule, hence providing a certain level of consistency amongst estimates. The agencies recognize that there is uncertainty in estimates of these technologies effectiveness, especially at this early stage of deployment. For this reason, the agencies examine a range of effectiveness rates to estimate boundary outcomes in a sensitivity analysis.

Leslie et al. measured effectiveness against all categories of crashes, but did not specify effectiveness against crashes that result in fatalities or injuries. The agencies examined a range of effectiveness rates against fatal crashes using a central case based on boundary assumptions of no effectiveness and full effectiveness across all crash types. Our central case is thus a simple average of these two extremes. Sensitivity cases were based on the 95th percent confidence intervals calculated from this central case. Leslie et al. found effectiveness rates of 21 percent for FCW and 46 percent for AEB. Our central fatality effectiveness estimates will thus be 10.5 percent for FCW and 23 percent for AEB. The calculated 95th percentile confidence limits range is 8.11 to 12.58 percent effective for FCW and 20.85 to 25.27 for AEB. The agencies note that our central estimate is conservative compared to averages of those studies that did specifically examine fatality impacts; that is, the analysis assumes reduced future fatalities less than most of, or the average of, those studies, and thus minimizes the estimate of lives saved under alternatives to the augural standards. Furthermore, the agencies note that the estimates against fatal crashes is higher in the recent studies in Table VI-263, which reflects the agencies' understanding that earlier iterations of AEB and FCW may have been less effective against crashes that result in fatalties than newer and improved versions.[2191]

(ii) Lane Departure Crash Technologies

For lane departure crashes, manufacturers are currently equipping vehicles with lane departure warning (LDW), which monitors lane markings on the road and alerts the driver when their vehicle is about to drift beyond a delineated edge line of their current travel lane, as well as

---

Avoidance Technology Evaluation Using Real-World crashes, University of Michigan Transportation Research Institute, March 22, 2018). The agencies focused on the more recent 2019 study because its sample size is significantly larger and it represents more recent model year vehicles. The revised (2019) study uses the same basic techniques but incorporated a larger data-base of system-relevant and control cases (123,377 cases in the 2019 study vs. 35,401 in the 2018 study). Relative to the Flannagan and Leslie (2018) findings, the results of the 2019 study varied by technology. The revised study found effectiveness rates of 21% for FCW and 46% for AEB, compared to 16% and 45% in the 2018 study. The revised study found effectiveness rates of 10% for LDW and 20% for LKA, compared to 3% and 30% for these technologies in the 2018 study. The revised study found effectiveness rates of 3% for BSD and 26-37% for LCA systems, compared to 8% and 19-32% for these technologies in the 2018 study. Thus, some system effectiveness estimates increased while others decreased.

[2191] As an example of improvements, the agencies note that the Mercedes system described in their 2015 owner's manual specified that for stationary objects the system would only work in crashes below 31 mph, but that in their manual for the 2019 model, the systems are specified to work in these crashes up to 50 mph.

lane keep assist (LKA), which provides gentle steering adjustments to help drivers avoid unintentional lane crossing. Table VI-264 summarizes studies which have measured effectiveness for LDW and LKA

Table VI-264 – Summary of LDW Technology Effectiveness Estimates

				Injury Reduction		
Authors	**LDW Type**	**Crash Reduction**	**Fatalities**	**Serious**	**Minor**	**All Injuries**
Cicchino (2018)[2192]	LDW	11%				21%
Sternlund, Strandroth, et al. (2017)[2193]	LDW/LKA					6-30%
Leslie et al. (2019)[2194]	LDW	10%				
	LKA	20%				
Kusano & Gabler (2015)[2195]	LDW	11-23%	13-22%	13-22%		
Kusano, Gorman, et al. (2014)[2196]	LDW	29%		24%		

Cicchino (2018) examined crash involvement rates per insured vehicle year for vehicles that offered LDW as an option and compared crash rates for those that had the option installed to those that did not. The study focused on single-vehicle, sideswipe, and head-on crashes as the relevant target population for LDW effectiveness rates. The study examined 5,433 relevant crashes of all severities found in 2009-2015 police-reported data from 25 States. The study was limited to crashes on roadways with 40 mph or greater speed limits not covered in ice or snow since lower travel speeds would be more likely to fall outside of the LDW systems' minimum operational threshold. Cicchino found an overall reduction in relevant crashes of 11 percent for vehicles that were equipped with LDW. She also found a 21 percent reduction in injury crashes. The result for all crashes was statistically significant, while that for injury crashes approached significance ($p<0.07$). Cicchino did not separately analyze LKA systems.

Sternlund et al. (2017) studied single vehicle and head-on injury crash involvements relevant to LDW and LKA in Volvos on Swedish roadways. They used rear-end crashes as a control and compared the ratio of these two crash groups in vehicles that had elected to install LDW or LCA to the ratio in vehicles that did not have this content. Studied crashes were limited to roadways with speeds of 70-120 kph and not covered with ice or snow. Sternlund et al. found that LDW/LKA systems reduced single vehicle and head-on injury crashes in their crash population by 53 percent, with a lower limit of 11 percent, which they determined corresponded

2196 Kusano, K., Gorman, T.I., Sherony, R., and Gabler, H.C. Potential occupant injury reduction in the U.S. vehicle fleet for lane departure warning-equipped vehicles in single-vehicle crashes. Traffic Injury Prevention 2014 Suppl 1:S157-64.

to a reduction of 30 percent (lower limit of 6 percent) across all speed limits and road surface assumptions.

Leslie et al. (2019) analyzed the relative crash performance of 123,377 General Motors (GM) MY 2013 to 2017 vehicles linked to state police-reported crashes by Vehicle Identification numbers (VIN). GM provided VIN-linked safety content information for these vehicles to enable precise identification of safety technology content. The authors analyzed the effectiveness of a variety of crash avoidance technologies including both LDW and LKA separately. They estimated effectiveness comparing system-relevant crashes to baseline (control group) crashes using a quasi-induced exposure method in which rear-end struck crashes are used as the control group. Leslie et al. found that LDW reduced lane departure crashes of all severities by 10 percent, and that LKA (which includes LDW) reduced these crashes by 20 percent.

Kusano et al. (2014) developed a comprehensive crash and injury simulation model to estimate the potential safety impacts of LDW. The model simulated results from 481 single-vehicle collisions documented in the NASS-CDS data-base for the year 2012. Each crash was simulated as it actually occurred and again as it would occur had the vehicles been equipped with LDW. Crashes were simulated multiple times to account for variation in driver reaction, roadway, and vehicle conditions. Kusano et al. found that LDW could reduce all roadway departure crashes caused by the driver drifting from his or her lane by 28.9 percent, resulting in 24.3 percent fewer serious injuries.

Kusano and Gabler (2015), simulated single-vehicle roadway departure crashes based on a sample of 478 crashes in the 2012 NASS-CDS. Modelling was based on 54 model year 2010-2014 vehicles that were evaluated in NHTSA's New Car Assessment Program (NCAP). Kusano and Gabler found LDW systems could prevent 11-23 percent of drift-out-of-lane crashes and 13-22 percent of serious to fatally injured drivers.

As noted previously for frontal crash technologies, the agencies will base our projections on Leslie et al. because they are the most recent study, thereby reflecting the most current versions of these systems in the largest number of vehicles, and because they arguably have the most precise identification of the presence of the specific technologies in the vehicle fleet. However, unlike forward crash technologies, lane change technologies are operational at travel speeds where fatalities are likely to occur. Both LDW and LKA typically operate at speeds above roughly 35 mph. For this reason, and because the research noted in Table VI-264 indicates similar effectiveness against fatalities, injuries, and crashes, the agencies believe it is reasonable to assume the Leslie et al. crash reduction estimates are generally applicable to all crash severities, including fatal crashes. Our central effectiveness estimates are thus 10 percent for LDW and 20 percent for LKA. For sensitivity analysis, the agencies adopt the 95 percent confidence intervals from Flannagan & Leslie. For LKA this range is 14.95-25.15 percent. For LDW, the upper range was 4.95-13.93 percent.

Blind Spot Crash Technologies

To address blind spot crashes, manufacturers are currently equipping vehicles with BSD, which detects vehicles in either of the adjacent lanes that may not be apparent to the driver. The system warns the driver of an approaching vehicle's presence to help facilitate safe lane changes and avoid crashes. A more advanced version of this, LCA, also detects vehicles that are rapidly approaching the driver's blind spot. Table VI-265 summarizes studies which have measured effectiveness for BSD and LCA.

Table VI-265 – Summary of BSD Technology Effectiveness Estimates

				Injury Crash Reduction		
Authors	**BSD Type**	**Crash Reduction**	**Fatalities**	**Serious**	**Minor**	**Injuries**
Cicchino (2017b)[2197]	BSD	14%				23%
Leslie et al. (2019)[2198]	BSD	3%				
	LCA	26%				
Isaksson-Hellman & Lindman (2018)[2199]	LCA	30%*				31%**
* reduction in claim costs across all lane change crashes						
** reduction in severe crashes with repair costs greater than $1250						

Cicchino (2017) used Poisson regression to compare crash involvement rates per insured vehicle year in police-reported lane-change crashes in 26 U.S. States during 2009-2015 between vehicles with blind spot monitoring and the same vehicle models without the optional system, controlling for other factors that can affect crash risk. Systems designs across the 10 different manufacturers included in the study varied regarding the extent to which the size of the adjacent lane zone that they covered exceeded the blind spot area, speed differentials at which vehicles could be detected, and their ability to detect rapidly approaching vehicles, but these different systems were not examined separately. The study examined 4,620 lane change crashes, including 568 injury crashes. Cicchino found an overall reduction of 14 percent in blind spot related crashes of all severities, with a non-significant 23 percent reduction in injury crashes.

Leslie et al. (2019) analyzed the relative crash performance of 123,377 2013-2017 General Motors (GM) vehicles linked to State police-reported crashes by Vehicle Identification numbers (VIN). GM provided VIN-linked safety content information for these vehicles to enable precise identification of safety technology content. The authors analyzed the effectiveness of a variety of crash avoidance technologies including both BSD and LCA separately. They estimated effectiveness comparing system-relevant crashes to baseline (control group) crashes using a quasi-induced exposure method in which rear-end struck crashes are used as the control group. Flannagan and Leslie found that BSD reduced lane departure crashes of all severities by 3 percent (non-significant), and that LCA (which includes BSD) reduced these crashes by 26 percent.

2197 Cicchino, J.B. (2017b). Effects of blind spot monitoring systems on police-reported lane-change crashes. Insurance Institute for Highway Safety, August 2017.
2198 Leslie et al. (2019), op. cit.
2199 Isaksson-Hellman, I., Lindman, M., An evaluation of the real-world safety effect of a lane change driver support system and characteristics of lane change crashes based on insurance claims. Traffic Injury Prevention, February 28, 2018: 19 (supp. 1).

Isaksson-Hellman and Lindman (2018) evaluated the effect of the Volvo Blind Spot Information System (BLIS) on lane change crashes. Volvo's BLIS functions as an LCA, detecting vehicles approaching the blind spot as well as those already in it. The authors analyzed crash rate differences in lane change situations for cars with and without the BLIS system based on a population of 380,000 insured vehicle years. The authors found the BLIS system did not significantly reduce the overall number of lane change crashes of all severities, but they did find a significant 31 percent reduction in crashes with a repair cost exceeding $1250, and a 30 percent lower claim cost across all lane change crashes, indicating a reduced crash severity effect.

Like lane change technologies, blind spot technologies are operational at travel speeds where fatalities are likely to occur. The agencies therefore assume the Leslie et al. crash reduction estimates are generally applicable to all crash severities, including fatal crashes. Our central effectiveness estimates are thus 3 percent for BSD and 26 percent for LCA. For sensitivity analysis, the agencies adopt the 95 percent confidence intervals from Flannagan & Leslie. For LCA this range is 16.59-33.74 percent. For BSD, the upper range was 14.72 percent, but the findings were not statistically significant. The agencies therefore limit the range to 0-14.72 percent.

Table VI-266 summarizes the effectiveness rates calculated in Leslie et al. and used in this analysis. Differences between the rates listed as "Used in CAFE Fatality Analysis" and those computed from Leslie et al. are explained in the above discussion.

Table VI-266 – Summary of Advanced Technology Effectiveness Rates for Central and Sensitivity Cases

	UMTRI September 2019 Report					**Used in CAFE Fatality Analysis**		
Tech.	**Estimate**	**Std. Error**	**Central**	**Low**	**High**	**Central**	**Low**	**High**
FCW	-0.2334	0.0288	21	16.22	25.16	10.5	8.11	12.58

LCA	-0.2965	0.0587	26	16.59	33.74	26	16.59	33.74

(iii)Target Populations for Crash Avoidance Technologies

The impact on fatality rates that will occur due to these technologies will be a function of both their effectiveness rate and the portion of occupant fatalities that occur under circumstances that are relevant to the technologies function. The agencies base our target population estimates on a recent study that examined these portions specifically for a variety of crash avoidance technologies including those analyzed here. Wang (2019) documented target populations for five groups of collision avoidance technologies in passenger vehicles including forward collisions, lane keeping, blind zone detection, forward pedestrian impact, and backing collision avoidance. The first three of these affect the light occupant target population examined in this analysis. Wang separately examined crash populations stratified by severity including fatal injuries, non-fatal injuries, and property damaged only (PDO) vehicles. She based her analysis on 2011-2015 data from NHTSA's Fatality Analysis Reporting System (FARS), National Automotive Sampling System (NASS), and General Estimates System (GES). FARS data was the basis for fatal crashes while nonfatal injuries and PDOs were derived from the NASS and GES.

Wang followed the pre-crash typology concept initially developed by the Volpe National Transportation Systems Center (Volpe). Under this concept, crashes are categorized into mutually exclusive and distinct scenarios based on vehicle movements and critical events occurring just prior to the crash. Table VI-267 summarizes the portion of total annual crashes and injuries for each crash severity category that is relevant to the three crash scenarios examined.

Table VI-267 – Summary of Target Crash Proportions by Technology Group

Safety System Crash Type	Crashes	Fatalities	MAIS 1-5 Injuries	PDOVs
Frontal Crashes	29.4%	3.8%	31.5%	36.3%
Lane Departure Crashes	19.4%	44.3%	17.1%	11.9%
Blind Spot Crashes	8.7%	1.6%	6.7%	11.8%

The relevant proportions vary significantly depending on the severity of the crash. The rear-end crashes that are addressed by FCW and AEB technologies tend to be low-speed crashes and thus account for a larger portion of non-fatal injury and PDO crashes than for fatalities. Only 4 percent of fatal crashes occur in front-to-rear crashes, but over 30 percent of nonfatal crashes are this type. By contrast, fatal crashes are highly likely to involve inadvertent lane departure, 44 percent of all light vehicle occupant fatalities occur in crashes that involve lane departure, but only 17 percent of non-fatal injuries and 12 percent of PDOs involve this crash scenario. Blind spot crashes account for only about 2 percent of fatalities, 7 percent of MAIS1-5 injuries, and 12 percent of PDOs.

The target population of this analysis is occupants of the light vehicles subject to CAFE. The values in Table VI-267 are portions of all crashes that occur annually. These include crashes of motor vehicles not subject to the current CAFE rulemaking such as medium and large trucks, buses, motorcycles, bicycles, etc. To adjust for this, the values in Wang were normalized to represent their portion of all light passenger vehicle (PV) crashes, rather than all crashes of any type. Wang provides total PV fatalities consistent with her technology numbers which are used as a baseline for this process. Based on 2011-2015 FARS data, Wang found an average of 29,170 PV occupant fatalities occurred annually.

A second adjustment to Wang's results was made to make them compatible with the effectiveness estimates found in Leslie et al. In her target population estimate for lane departure warning, Wang included both head-on collisions and rollovers, but Leslie et al. did not. The Leslie et al. effectiveness rate is thus applicable to a smaller target population than that examined by Wang. To make these numbers more compatible, counts for these crash types were removed from Wang's lane departure totals.

Electronic Stability Control (ESC) has been standard equipment in all light vehicles in the US since the 2012 model year. ESC is highly effective in reducing roadway departure and traction loss crashes, and although it will be present in all future model year vehicles, it was present in only about 30 percent of the 2011-2015 on-road fleet examined by Wang. To reflect the impact of ESC on future on-road fleets therefore, the agencies further adjusted Wang's numbers to reflect a 100 percent ESC presence in the on-road fleet. The agencies allocated the reduced roadway departure fatalities to the LDW target population, and the reduced traction loss fatalities to the AEB target population. This has the effect of reducing the total fatalities in both groups as well as in the total projected fatalities baseline.

Table VI-268 summarizes the revised incidence counts and re-calculated proportions of total PV occupant crash /injury. Revised totals are derived from original totals referenced in Table 1-3 in Wang (2019).

Table VI-268 – Adjusted Target Crash Counts and Proportions

Crash Type	Crashes	Fatalities	MAIS 1-5	PDOVs
Frontal Crashes	1,703,541	1,048	883,386	2,641,884
% All PV Occupant Crashes	30.2%	4.0%	32.4%	36.8%
Lane Departure Crashes	1,126,397	9,428	479,939	863,213
% All PV Occupant Crashes	20.0%	35.8%	17.6%	12.0%
Blind Spot Crashes	503,070	542	188,304	860,726
% All PV Occupant Crashes	8.9%	2.1%	6.9%	12.0%
Total, all Tech Groups	3,333,008	11,017	1,551,629	4,365,823
% All PV Occupant Crashes	59.1%	41.8%	56.8%	60.9%
All Crashes	**5,640,000**	**26,364**	**2,730,000**	**7,170,000**

(iv) Fleet Penetration Schedules

The third element of the rule's safety projections is the fleet technology penetration schedules. Advanced safety technologies (ADAS) will only influence the safety of future MY fleets to the extent that they are installed and used in those fleets. These technologies are already being installed on some vehicles to varying degrees, but the agencies expect that over time, they will become standard equipment due to some combination of market pressure and/or safety regulation. The agencies adopt this assumption based on the history of most previous vehicle safety technologies, which are now standard equipment on all new vehicles sold in the US.

The pace of technology adoption is estimated based on a variety of factors, but the most fundamental is the current pace of adoption in recent years. These published data were obtained from Ward's Automotive Reports for each technology.[2200] Since these technologies are relatively recent, only a few years of data—typically 2 or 3 years—were available from which to derive a trend. This makes these projections uncertain, but under these circumstances, a

[2200] Derived from Ward's Automotive Yearbooks, 2014 through 2018, % Factory Installed Electronic ADAS Equipment tables, weighting domestic and imported passenger cars and light trucks by sales volume.

continuation of the known trend is the baseline assumption, which the agencies modify only when there is a rationale to justify it.

The technologies were examined in pairs reflecting their mutual target populations. Both FCW and AEB affect the same target population—frontal collisions. Both systems have been installed in some current MY vehicles, but their relative paces are expected to diverge significantly due to a formal agreement brokered by NHTSA and IIHS involving nearly all auto manufacturers, to have AEB installed in 100 percent of their vehicles by September 2022 (MY 2023).[2201] Wards first published installation rates for FCW and AEB for the 2016 model year and as of this analysis the 2017 MY is the latest data they have published. The agencies thus have data indicating that FCW was installed in 17.6 percent of MY 2016 vehicles and 30.5 percent of MY 2017 vehicles. AEB was installed in 12.0 percent of MY 2016 vehicles and 27.0 percent of MY 2017 vehicles. AEB was installed in 12.0 percent of MY 2016 vehicles and 27.0 percent of MY 2017 vehicles. More recent reports submitted by manufacturers to the Federal Register indicate that installation rates accelerated in MY 2018 and 2019 vehicles. Four manufacturers, Tesla, Volvo, Audi, and Mercedes, have already met their voluntary commitment of 100 percent installation 3 years ahead of schedule. During the period September 1, 2018 through August 31, 2019, 12 of the 20 manufacturers equipped more than 75 percent of their new passenger vehicles with AEB, and overall manufacturers equipped more than 9.5 million new passenger vehicles with AEB.[2202]

Because of the NHTSA/IIHS agreement, the agencies assume that AEB will be in 100 percent of light vehicles by the 2023 MY. To derive installation rates for MYs 2018 through 2022, the agencies interpolate between the MY 2017 rate of 27 percent and the MY 2023 rate of 100 percent. To derive a MY 2015 estimate, the agencies modelled the results for MYs 2016-2023 and calculated a value for year x=0, essentially extending the model results back one year on the same trendline.

For FCW, the agencies used the same interpolation/modeling method as was used for AEB to derive an initial baseline trend. However, while both systems are available on some portion of the current MY fleet, the agencies anticipate that by MY 2023, all vehicles will have AEB systems that essentially encompass both FCW and AEB functions. The agencies therefore project a gradual increase in both systems until the sum of both systems penetration rates exceeds 100 percent. At that point, the agencies project a gradual decrease in FCW only installations until FCW only systems are completely replaced by AEB systems in MY 2023.

For LDW, Wards penetration data were available as far back as MY 2013, giving a total of 5 data points through MY 2017. The projection for LDW was derived by modelling these data points. The data indicate a near linear trend and our initial projections of future years were derived directly from this model. Wards did not report any of the more advanced LKA systems until MY 2016, leaving only 2 data points. The agencies modelled a simple trendline through

---

[2201] https://www.nhtsa.gov/press-releases/nhtsa-iihs-announcement-aeb.

[2202] NHTSA Announces Update to Historic AEB Commitment by 20 Automakers. December 17, 2019. https://www.nhtsa.gov/press-releases/nhtsa-announces-update-historic-aeb-commitment-20-automakers.

these data points to estimate the pace of future LKA installations. As with Frontal crashes, the agencies assume a gradual phase-in of the most effective technology, LKA, will eventually replace the lesser technology, LDW, and the agencies allow gradual increases in both systems penetration until their sum exceeds 100 percent, at which point LDW penetration begins to decline to zero while LKA penetration climbs to 100 percent.

For blind spot crashes, Wards data was available for MYs 2013-2017 for BSD, but no data was available to distinguish LCA systems. LCA systems were available as optional equipment on at least 10 MY 2016 vehicles.[2203] In addition, Flannagan and Leslie found numerous cases in State data-bases involving vehicles with LCA. Because LCA data is not specifically identified, the agencies will estimate its frequency based on the samples found in Flannagan & Leslie. In that study, 62 percent of vehicles with blind spot technologies has BSD alone, while 38 percent had LCA (which includes BSD). The agencies employ this ratio to establish the relative frequency of these technologies in our projections. As with frontal and lane change technologies, the agencies assume a gradual phase-in of the most effective technology, LCA, will eventually replace the lesser technology, BSD, and the agencies allow gradual increases in both systems penetration until their sum exceeds 100 percent, at which point BSD penetration begins to decline to zero while LCA penetration climbs to 100 percent.

(v) Impact Calculations

Table VI-269, Table VI-270, and Table VI-271 summarize the resulting estimates of impacts on fatality rates for frontal crash technologies, lane change technologies, and blind spot technologies respectively for MYs 2016-2035. All previously discussed inputs are shown in the tables. The effect of each technology is the product of its effectiveness, it’s percent installation in the MY fleet, and the portion of the total light vehicle occupant target population that each technology might address. Since installation rates for each technology apply to different portions of the vehicle fleet (i.e., vehicles have either the more basic or more advanced version of the technology), the effect of the two technologies combined is a simple sum of the two effects. Likewise, since each crash type addresses a unique target population, there is no overlap among the three crash types and the sum of the normalized crash impacts across all three crash types represents the total impact on fatality rates from these 6 technologies for each model year. These cumulative results are shown in the last column of Table VI-271. As technologies phase in to newer MY fleets[2204], their impact on the light vehicle occupant fatality rate increases proportionally to roughly 8.5 percent before levelling off. That is, eventually, by approximately MY 2026, these technologies are expected to reduce fatalities and fatality rates for new vehicles by roughly 8.5 percent below their initial baseline levels.

[2203] https://www.autobytel.com/car-buying-guides/features/10-cars-with-lane-change-assist-using-cameras-or-sensors-130847.

[2204] While it is technically possible to retrofit these systems into the on-road fleet, such retrofits would be significantly more expensive than OEM installations. The agencies thus assume all on-road fleet penetration of these technologies will come through new vehicle sales.

Table VI-269 – Phased Impact of Crashworthiness Technologies on Fatality Rates, Forward Collision Crashes

MY	Forward Collision Warning		Automatic Emergency Braking		% T.P.	Weighted Effectiveness
	FCW Eff.	% Inst.	AEB Eff.	% Inst.		
2015	10.5%	0.047	23.0%	0.011	4.0%	0.000292

(e) Fatality Trend Model

The revised fatality trend model differs from the model employed in the NPRM in four main respects:

- The fatality rates for individual model years and ages were re-calculated to correct the counts of fatalities to occupants of light-duty vehicles and to reflect the revised VMT estimates, the latter of which incorporate revisions to both vehicle registration counts and the estimated relationship between vehicle age and annual use;[2205]
- In response to comments on the version used in the NPRM, the revised model controls for changes to factors (such as driver demographics and behavior, and geographic patterns of travel) that can affect fatality rates for vehicles of all model years and ages;
- The revised analysis clusters past model years into "safety cohorts," which are groups of successive model years that exhibit similar fatality rates during their first years of use, in order to represent the actual historical pattern of safety improvements more realistically; and
- The model employs a slightly less complex mathematical relationship between a model year's age and its fatality rate (fatalities per mile driven), which still describes the observed relationship accurately.

Similar to the fatality trend model employed in the proposal, the revised estimates of annual travel were combined with tabulations of annual fatalities occurring among occupants of light-duty vehicles of each model year during past calendar years, tabulated from NHTSA's FARS data. Fatalities occurring in vehicles produced during each model year making up a calendar year's light-duty vehicle fleet are divided by the estimated number of miles they were driven during that calendar year to calculate historical fatality rates by model year and calendar year, measured as fatalities per billion miles traveled. These data represent the dependent variable in the revised statistical model of fatality rates.

Longitudinal or time-series analyses such as the model of historical variation in fatality rates for individual model years need to incorporate three separate effects to account for all potential sources of variation. First, they need to employ model year in some form as an explanatory variable, to account for improvements in the safety of vehicles produced during successive model years that persist throughout their lifetimes in the vehicle fleet. This is an example of a "cohort effect" in the age-period-cohort framework that is widely used to of analysis of population-wide behavior.[2206] Second, such a model must account for the effect of age on the safety of each individual model year as it grows older, accumulates mileage, and in

---

[2205] These revised estimates of the number of miles traveled by vehicles of each model year during past calendar years were developed form the expanded sample of vehicles' odometer readings obtained by NHTSA.
[2206] For a detailed explanation of the rationale and methods for age-period-cohort analysis, *see* for example Columbia University Mailman School of Public Health, Population Health Methods: Age-Period-Cohort Analysis, available at https://www.mailman.columbia.edu/research/population-health-methods/age-period-cohort-analysis (accessed February 12, 2020); and Kupper, Lawrence L. *et al*., "Statistical age-period-cohort analysis: A review and critique," *Journal of Chronic Diseases* 38:10 (1985), at 811-830, available at https://www.sciencedirect.com/science/article/abs/pii/0021968185901055#! (accessed February 12, 2020).

most cases changes ownership one or more times during its expected service lifetime (the "aging effect" in age-period-cohort analysis).

Finally, most longitudinal analyses, including the historical safety model developed here, need to account explicitly for factors that vary over time—in this case, calendar years. By doing so, they can affect the safety of vehicles of all model years and ages making up the fleet during successive calendar years, or change the composition of total travel by vehicles of different model years and ages. In either case, such time-related factors—often referred to as "period effects"—can change the overall safety performance of the entire fleet from one calendar year to the next, *independently of and in addition to* the changes that would result from the combination of new model years entering the fleet while older ones are retired from service (the cohort effect), and the aging of all model years making up the fleet. For example, an increase in seat belt use among all drivers during a calendar year would be expected to reduce the fatality rates of vehicles of all model years and ages in use during that year, while an economic recession may change the composition of drivers and vehicles on the road during a calendar year. In either case, one result will be a change in the fleet-wide composite fatality rate for that calendar year. Figure VI-157 below illustrates the contributions of cohort, aging, and time-period effects to changes over time in population-wide behavior. As the figure indicates, these effects are conceptually independent, but interact in ways that combine to produce the observed historical evolution of the fleet-wide fatality rate for light-duty vehicle occupants. Again, calendar year or time-period factors can affect the safety performance of the entire fleet *independently of* the effect that would result from the combination of changes in the specific model years making up the fleet and the advancing ages of all model years, and any "period effect" effect attributable to factors that vary over time is *in addition to* cohort and aging effects.

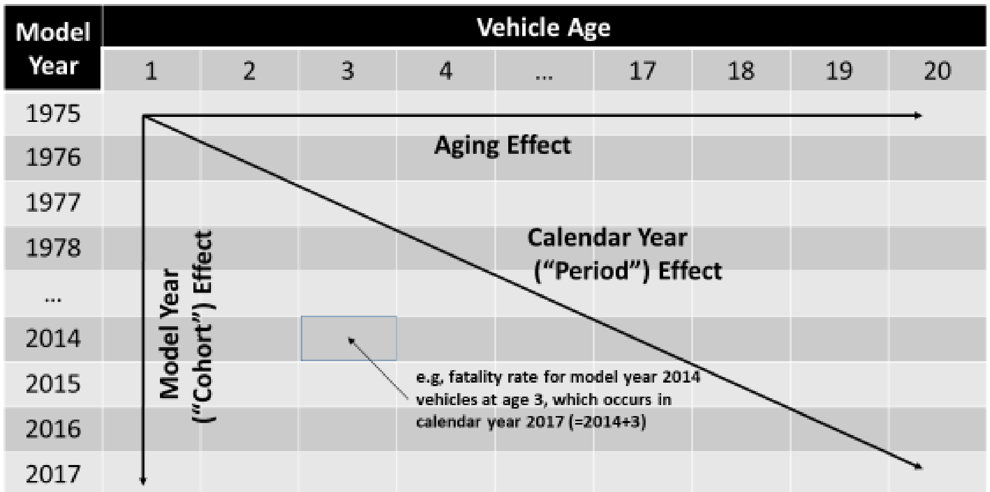

Figure VI-157 – Contributions of Cohort, Aging, and Time-Period Effects to Historical Changes in Fleet-Wide Fatality Rate

To introduce such period effects into the fatality trend model, which were absent from the NPRM analysis, the agencies obtained historical data on factors that varied by calendar year, and were expected to be responsible for such effects. As indicated previously, these included the following:

- Seat belt use, as measured by the fraction of drivers observed to be wearing lap and shoulder belts, estimated by NHTSA's National Occupant Protection Survey (NOPUS);
- Driving under the influence of alcohol or drugs, measured by the fraction of drivers reporting having recently done so in surveys conducted by the U.S. Centers for Disease Control (CDC);[2207]
- Use of hand-held electronic devices, measured by the fraction of drivers visually observed to be doing so in NHTSA's NOPUS;
- The fraction of licensed drivers who are male and under the age of 25 (historically the riskiest cohort of drivers), as reported by the FHWA's annual Highway Statistics publication;[2208]

[2207] The agencies also experimented with measures of drivers appearing to be under the influence of alcohol or drugs included in NHTSA's NOPUS.
[2208] Federal Highway Administration, Highway Statistics, various years, Table DL-20. https://www.fhwa.dot.gov/policyinformation/statistics.cfm.

- The fraction of miles traveled in rural areas, also as reported by FHWA;[2209] and
- The overall performance of the U.S. economy, as measured by the annual rate of unemployment.[2210]

The agencies were unable to obtain useful measures of roadway design parameters or road conditions that would be expected to affect safety. Although such measures exist, they tend to be reported for individual road and highway segments or routes, and it is difficult to combine these data into meaningful, aggregate measures that describe overall driving conditions that are likely to vary by calendar year. Nor could they identify satisfactory measures of incident response time or the effectiveness of emergency medical treatment in reducing the consequences of injuries occurring in motor vehicle crashes.

An important challenge to incorporating these time-period effects into the fatality trend model arose from the fact that their patterns of variation over the historical period the agencies analyzed (which extended from calendar year 1995 to 2017) were extremely closely correlated, making it virtually impossible to distinguish their independent contributions to improvements in fleet-wide safety over time. Table VI-272 below reports the pairwise correlation coefficients among the potential measures of period effects listed above. As it suggests, patterns of variation about their respective mean values over the period analyzed were very similar (with the exception of the unemployment rate), and the resulting high statistical correlations (or "collinearity") among them made it nearly impossible to identify their independent effects on variation in safety over time, even when controlling for the effects of model year and vehicle age.

Table VI-272 – Pairwise Correlation Coefficients Between Period Effect Variables

Variable	Unemployment Rate	% of VMT by Young Males	% of VMT in Rural Areas	% of Occupants Wearing Lap/Shoulder Belts	% of Young Drivers Using Hand-Held Electronic Devices	% of Drivers Consuming Alcohol
Unemployment Rate	1.00	-0.59	-0.54	0.54	0.4	-0.64

% of Drivers Consuming Alcohol	-0.64	0.95	0.96	-0.93	-0.80	1.00

[2209] Federal Highway Administration, Highway Statistics, various years, Table VM-1. https://www.fhwa.dot.gov/policyinformation/statistics.cfm.
[2210] Bureau of Labor Statistics, historical data series LNS14000000. https://data.bls.gov/cgi-bin/surveymost?ln.

To address this difficulty, the agencies substituted a time trend—that is, a variable that takes the value of one in the first calendar year and increases by one in each successive calendar year—in an effort to capture the joint movements in the variables that were intended to measure time-period effects on safety. The agencies experimented with both linear and more complex time trends to capture the apparently declining rate of improvement in fleet-wide safety over time, but found that the linear trend captured the combined effects most reliably.

Because the model's dependent variable is the natural logarithm of model year and age-specific fatality rates, using a linear time trend corresponds to assuming a constant *percentage* decline in fatality rates each year (rather than a constant absolute decline each year), and this pattern appeared to provide the best fit to the observed historical pattern of safety improvements. Finally, after noting that the linear time trend did not fully capture the effects on fleet-wide safety associated with the economic recessions in 2001 and 2007-11, the agencies supplemented the time trend with indicator (or "dummy") variables for these years, finding that only those for 2008, 2009, and 2010 improved its explanatory power significantly.

Another significant improvement to the NPRM analysis was to group model years into "safety cohorts" on the basis of similarity in their fatality rates when new (that is, during their first year in service), rather than treating each model year as a separate cohort. Groupings were created through a combination of identifying years when new safety regulations initially took effect or were phased in, examining of first-year fatality rates, and limited statistical experimentation. Grouping successive model years reduces the number of cohorts significantly, since similar fatality rates were typically observed during the first year of use for at least five, and sometimes as many as ten, consecutive model years over the historical period the agencies examined. Grouping model years into cohorts rather than treating each one as a separate cohort offers the advantage of introducing some variation in the ages of vehicles making up the same cohort during a calendar year, which improves the statistical reliability with which the independent effect of age itself can be estimated. Figure VI-158 below shows historical variation in the fatality rates of past model years when each one was newly-introduced (*i.e.*, during its first year in use).[2211] It clearly displays the significant improvement in the safety of new vehicles over time in response to improvements in safety features, including those required by NHTSA's safety regulations. The figure also clearly documents the natural clustering of fatality rates for successive model years that was used to identify and define the safety cohorts used in the revised model. In the panel structure of the model, which combines time-series and cross-section variation in fatality rates for individual model years as their ages vary across calendar years, the clustering of first-year fatality rates for successive model years is captured by using separate "fixed effects" for each cohort of model years with similar fatality rates during their first year of use. Some judgment is inevitably required to distinguish between successive cohorts and identify when the fatality rate for new model years has changed significantly; the

[2211] For simplicity, the figure assumes that each model year's first year of use was the calendar year identical to its designated model year; for example, the first full year of use for model year 2000 was assumed to be calendar year 2000. In fact, new vehicles frequently become available for purchase during the calendar year preceding their designated model year and continue to be sold through the calendar year following it, although most sales occur during the calendar year matching their designated model year.

agencies experimented with using from five to eight cohorts, ultimately finding that the agencies could distinguish most reliably among the fatality rates for five cohorts.

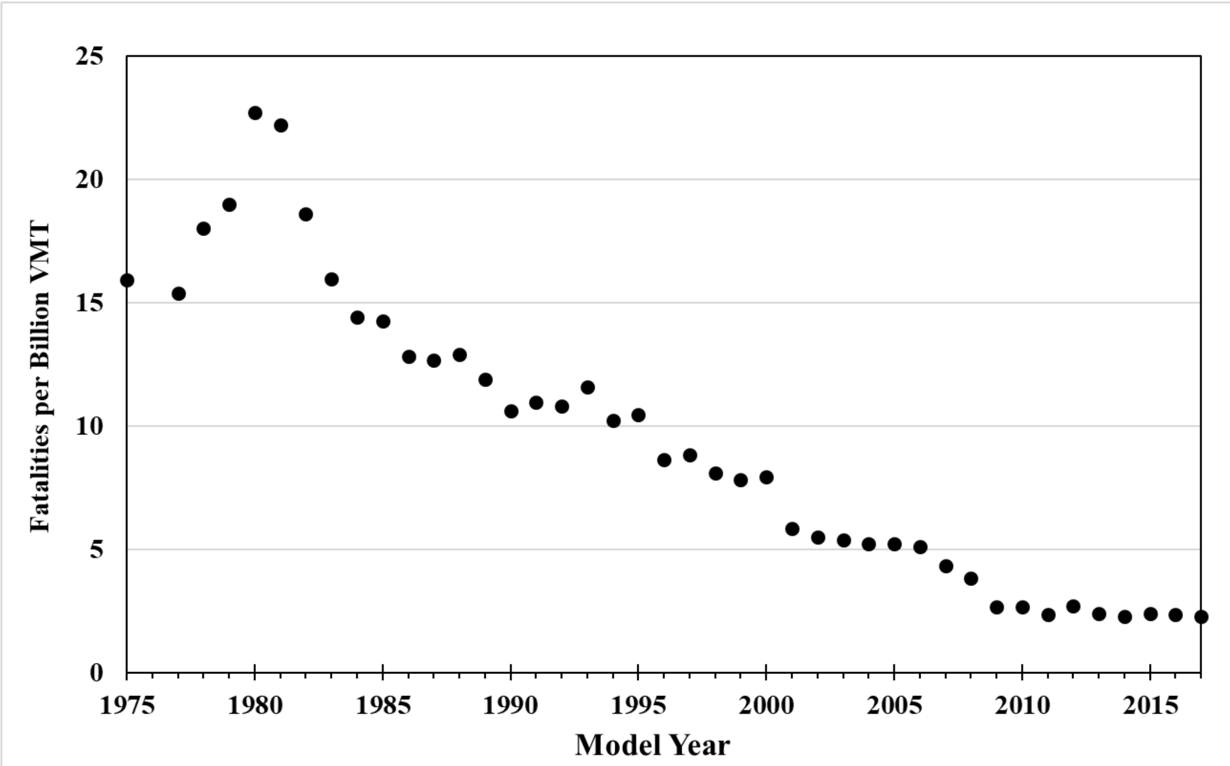

Figure VI-158 – Fatality Rates for New Light-Duty Vehicles by Model Year

A final revision to the NPRM model was to employ a slightly less complex mathematical relationship between a model year's age and its fatality rate than had been used in the NPRM version. Specifically, the revised model relates fatality rates to age itself as well as the second and third powers of age (that is, age squared and age cubed), but omits the fourth power of age, which was included in the model developed for the NPRM. This slightly simpler relationship proved adequate to capture fully the complex—but strongly recurring—pattern of fatality rates for past model years as they aged. Specifically, fatality rates have tended to remain approximately constant for the first few years of most recent model years' lifetimes, before increasing steadily through age 15-20 and then declining gradually over the remainder of their lifetimes.

As discussed previously, the increase in fatality rates through approximately age 20 is generally thought to result primarily from the fact that used vehicles are commonly purchased and driven by members of households whose demographic characteristics, driving behavior, and geographic locations are associated with more risky driving behavior and thus more frequent or severe crashes. Of course, increased frequency of mechanical failures as vehicles age and accumulate mileage also seems likely to contribute to this pattern. In contrast, the consistent tendency for fatality rates to decline after about age 20 is less well understood, but may owe partly to the demographic characteristics and driving behavior of owners of very old vehicles.

Whatever its source, the number of vehicles remaining in service past age 20 is so small and their use typically so limited that their contribution to the fleet-wide fatality rate is minimal.

Figure VI-159 documents the relationship between age and fatality rate for selected past model years.[2212] As it shows, fatality rates for recent model years follow a complex but strikingly similar pattern of increase and subsequent decline with increasing age, although the figure also shows that the earliest model years included in the sample (1975-1980) tended not to display increasing fatality rates in the first half of their lifetimes. At the same time, the figure illustrates the gradual downward shift in fatality rates at all ages for successive past model years, although there is considerable variation in the extent of this shift for individual model years, particularly when they are examined at specific ages. That is, the downward shift in fatality rates for successive model years is not necessarily "monotonic," particularly when it is examined at specific individual ages.

The agencies believe that the increase in fatality rates for cars and light trucks produced during recent model years through approximately age 20 reflects the fact that as aging vehicles change ownership via the used car market, they are often purchased and driven by households whose demographic characteristics and locations are associated with riskier driving behavior and conditions. The decline in vehicles' fatality rates after this age is not well understood, but seems likely to reflect the fact that the relatively small fraction of those originally produced in a model year that survive beyond age 20-25 are owned and driven by households that maintain them carefully, are likely to reside in areas where driving conditions are safest, and whose members engage in less risky driving behavior.

[2212] Without the use of colors to distinguish model years, the figure is difficult to interpret when all model years are included.

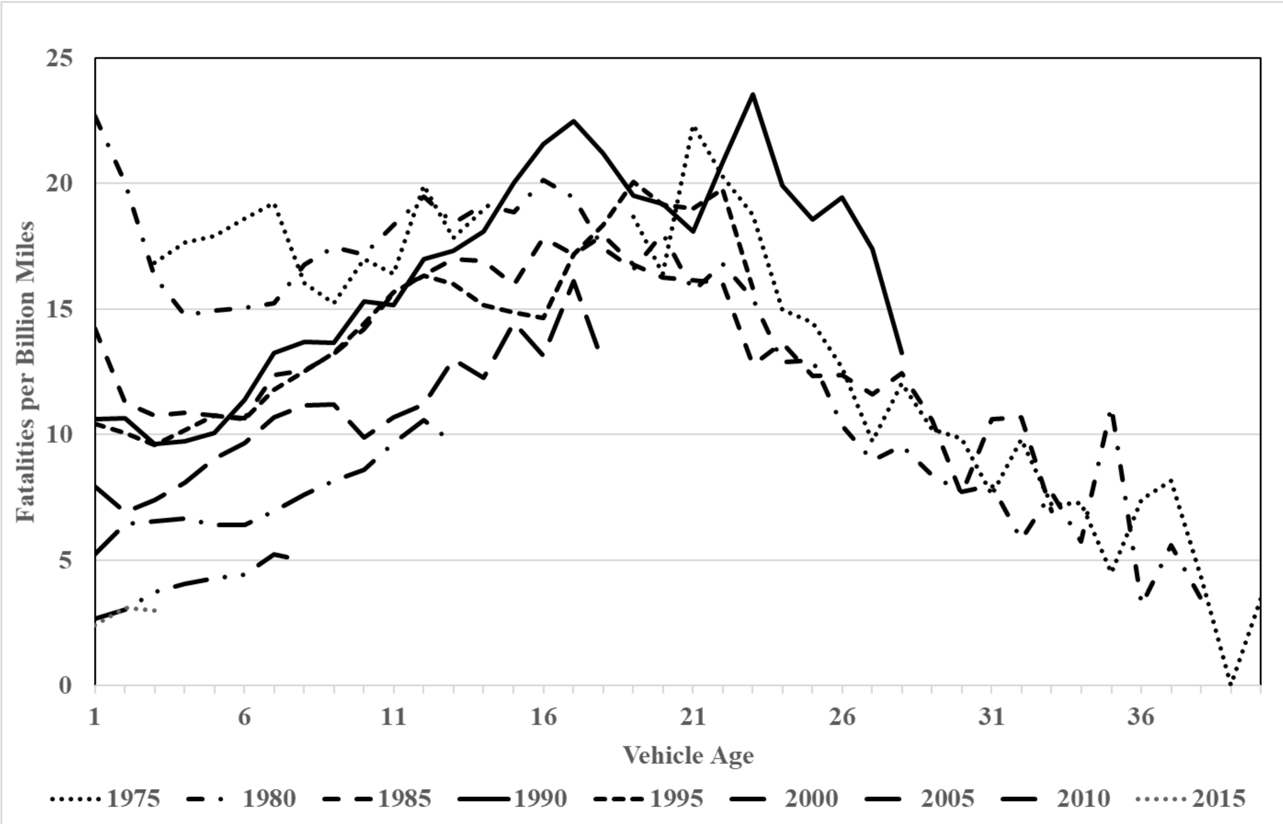

Figure VI-159 – Fatality Rate for Light-Duty Vehicle Occupants by Age for Selected Model Years

Based on examination of the information summarized in Figure VI-159, the agencies conclude that the effect of increasing age on vehicle safety appears to be largely independent of the improvement in new cars' fatality rates over successive model years, and appears to operate similarly for all except the earliest model years in our historical sample (which includes model years 1975-2017).[2213] As a formal statistical test, the agencies experimented with allowing the aging effect to change across model years when the agencies estimated the revised model, anticipating that newer safety technologies and vehicle designs might "flatten" the relationship between fatality rates and age—that is, reduce the degree to which fatality rates increased over the 5-20 year range of vehicle ages—for newer model years.

[2213] Of course, the agencies cannot observe the safety performance of all model years included in the agencies' data sample over their entire lifetimes, because the data the agencies use to estimate the model start in calendar year 1990, by which time all model years before 1990 were no longer new–for example, MY 1975 cars are already 15 years old by then–while the newest model years in the agencies' sample are still very "young" when the agencies' data ends in calendar year 2017. Thus, the agencies have only incomplete information about the relationship of fatality rates to age over the entire lifetimes of these model years, so it is possible that this relationship differs at particularly early or advanced ages for the oldest and newest model years in the agencies' sample.

However, the agencies found no evidence that the effect of age on safety changed significantly for more recent model years compared to older ones, so the agencies retained the assumption of identical aging effects for all model years in the revised model.[2214] Thus the revised model shows progressively lower fatality rates for more recent model years when they are new, but fatality rates for all model years increase with age and subsequently decline according to the same non-linear pattern displayed in Figure VI-159. On a related question, the agencies also found that including the squared and cubed values of age in addition to age itself as explanatory variables in the model, while excluding the fourth power of age, which had been included in the NPRM model, proved adequate to capture the pattern of variation in fatality rates with increasing age that most past model years have exhibited.

Table VI-273 below reports the estimated parameter values for alternative specifications of the model, together with various goodness-of-fit and other diagnostic measures. The analysis described in the following section uses the estimated time trend from Model 2 in the table, which implies an annual reduction in fatality rates for all model years of 2.1 percent.

[2214] Specifically, the agencies tested for interactions between the age variables and individual model years, which would reveal changes in the relationship between fatality rates and age for more recent model years, but found that such interaction effects were generally not statistically significant. Allowing for interactions between age and the indicator variables for safety cohorts (recall that these represent groupings of successive model years) produced this same result—few of the interaction effects were statistically significant.

Indicates proportion of variance among individual model year cohorts model accounts for.
Indicates proportion of variance for all model year cohorts over time model accounts for.
Indicates proportion of total variance among individual model year cohorts and over.
Correlation between model error term and explanatory variable included in model.
Standard deviation of residual terms for individual model year cohorts across time periods.
Standard deviation of overall model error terms.
Proportion of total variance accounted for by differences among model year cohorts

(f) Using the Model and Technology Analysis to Forecast Fatality Rates

The newest safety cohort includes model years from 2009 to 2017, so in effect the agencies estimate that all those model years have essentially the same fatality rate in their first year of use. The agencies apply the estimated effectiveness of crash avoidance technologies in reducing fatal crashes to the observed fatality rate for model years 2009 to 2017 vehicles during their first year in use to estimate fatality rates for future model years during the first year each one is introduced. Figure VI-160 below shows the result of this process; as it indicates, fatality rates for new model years decline gradually through 2035 and then stabilize, reflecting the fact that the agencies are only able to project the effectiveness of emerging crash avoidance technologies on the safety of new vehicles through that year.

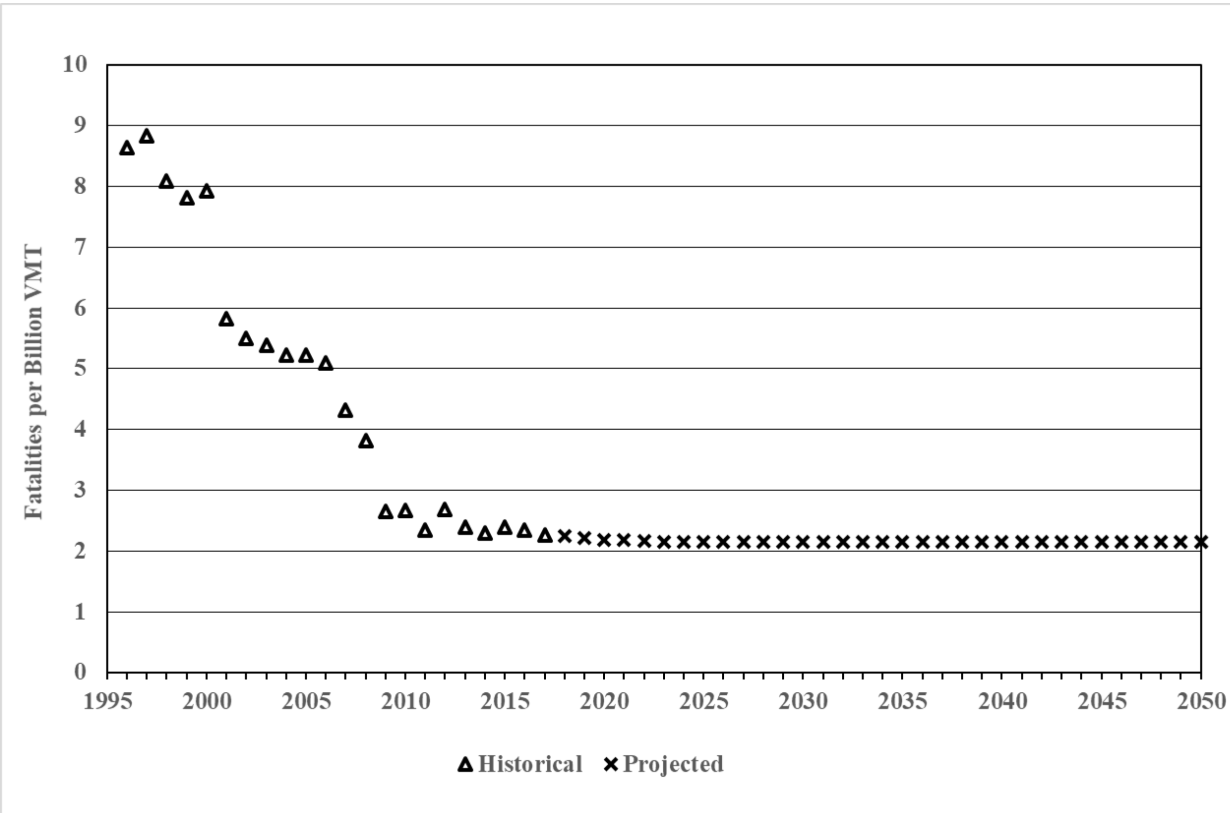

Figure VI-160 - Fatality Rates for New Cars and Light Trucks by Model Year

The next step in constructing the forecast of fleet-wide fatality rates is to apply the age-related increases in the fatality rate for each model year making up the previous calendar year's fleet. For example, the agencies assume that the fatality rates for all model years comprising the light-duty vehicle fleet in 2017 increase with age according to the relationship captured by the estimated coefficients on the age variables in the preferred model specification shown in Table VI-273. The same assumption is applied to all new model years introduced in subsequent years. Finally, the agencies also assume that the historical decline in fatality rates observed over past calendar years (the "period effect" captured by the time trend variable) will continue into the future. This implies that fatality rates for all model years and ages will decline by an additional 2.41 percent in each successive future calendar year from the rates that would have resulted from the combined effects of continuing improvements in the safety of newly-introduced model years and the effect of increasing age.[2215]

This process produces an estimate of the fatality rate for each model year making up the fleet during each future calendar year. That estimate reflects the combination of (1) reductions in fatality rates for new cars, reflecting the continued improvements in their safety due to crash avoidance technologies (through MY 2035); (2) increases in the fatality rates for each model year in the fleet from the previous calendar year, which represent the effect of age estimated by the historical model; and (3) the continuing downward trend in fatality rates for all vehicles except the newest model year in each calendar year's fleet, which is derived from the historical model.

The agencies then weight the fatality rate for each model year making up a future year's fleet by the fraction of total fleet-wide VMT it accounts for, and sum the results to produce an estimate of the fleet-wide fatality rate. The CAFE Model does not actually use this fleet-wide fatality rate, because all of the fatality calculations are performed separately for each individual model year making up the fleet, which are then aggregated; nevertheless, the agencies provide the fleet-wide rate as a useful check on the reasonableness of our fatality rate forecasts for individual model years as they enter the fleet and age over their respective lifetimes. Figure I-5 displays the projected fleet-wide fatality rates for future calendar years, as well as the trend in their recent historical values.

[2215] The agencies do not apply this trend reduction to the fatality rates for the newest model year in each calendar year's fleet, because it is assumed to be independent of both the decline in new-car fatality rates and the aging effect.

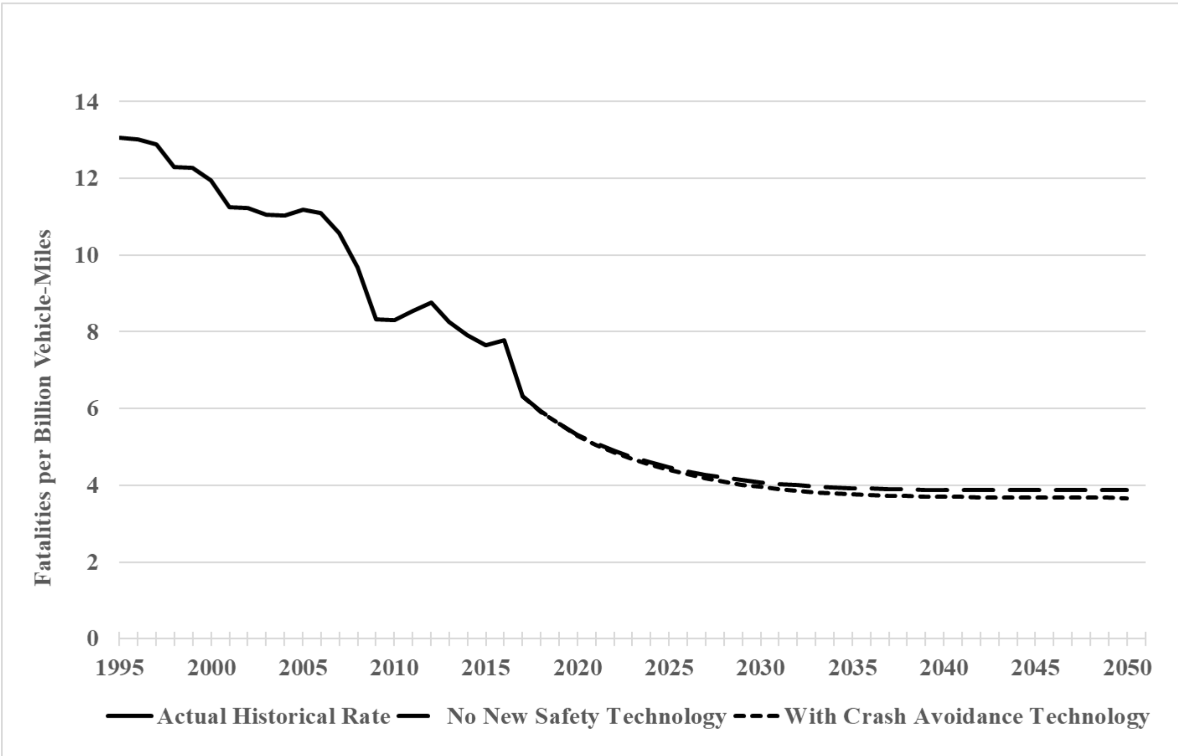

Figure VI-161 – Historical and Projected Fleet-Wide Fatality Rates

(g) Impact of Advanced Technologies on Older Vehicles' Fatality Rates

In the NPRM, the agencies calculated the potential safety impacts of delayed purchases of vehicles with new safety technology that might result from higher vehicles prices associated with more stringent CAFE standards. A number of commenters noted that since these improvements will be driven by crash avoidance technologies, they will also benefit older vehicles and reduce their fatality rates as well. For example, CARB noted that "safety improvements generally provide systematic safety benefits to all vehicles in the on-road fleet, not only to new vehicles. However, NHTSA's safety model assigns safety coefficients to vehicles solely based on their model year and it fails to incorporate the effect that new safety designs and technologies will have on systematically improving fleet-wide on-road safety." IPI similarly noted that should "new safety technologies be adopted, the predicted fatalities for all the older vehicle vintages will have to be lowered as well because effective crash avoidance technologies will lower all vehicles' fatality costs."

The agencies agree that the users of older vehicles will also benefit from crash avoidance technologies on newer vehicles. In response, the agencies have modified our methodology to reflect lower fatality rates on older vehicles resulting from the new crash avoidance technologies. Crash avoidance technologies prevent crashes from happening and thus benefit both the vehicle with the technology and any other vehicles that it might have collided with. However, the scope of these impacts on older vehicle's fatality rates are somewhat limited due to several factors:

- Single vehicle crashes, which make up about half of all fatal crashes, will not be affected. Only multi-vehicle crashes involving a newer vehicle with the advanced technology and an older vehicle will be affected. Multi-vehicle crashes account for roughly half of all light vehicle occupant fatalities.
- For a new safety technology to benefit an older vehicle in a multi-vehicle crash, the vehicle with the technology must have been in a position to control, or prevent the crash. For example, in front-to-rear crashes which can be addressed by FCW and AEB, the older vehicle would only benefit if it was the vehicle struck from behind. If the struck vehicle were the newer vehicle, its AEB technology would not prevent the crash. Logically this would occur in roughly half of two-vehicle crashes and a third of all three-vehicle crashes. Since most multi-vehicle crashes involve only two vehicles, roughly half of all multi-vehicle crashes might qualify.
- The benefits experienced by older vehicles are proportional to the probability that the vehicles they collide with are newer vehicles with advanced crash avoidance technology. The agencies estimate that the probability that this would occur is a function of the relative exposure of vehicles by age, measured by the portion of total VMT driven by vehicles of that age. Based on VMT schedules (*see* CY 2016 example in Table VI-274), new (current MY) vehicles account for about 9.6 percent of annual fleet VMT. The relevant portion would increase over time as additional MY vehicles are produced with advanced technologies. However, the portion of older vehicle crashes that might be affected by newer technologies is initially very small—only about 2 percent (.5*.5*.096) of older vehicles involved in crashes might benefit from advanced crash avoidance technologies in other vehicles in the first year.

Total		**223,005,486**	**2,816,209,994**	**1**

To reflect this safety benefit for older vehicles, the agencies calculated a revised fatality rate for each older MY vehicle on the road based on its interaction with each new MY starting with MY 2021 vehicles based on the following relationship:

Revised fatality rate = Fm-((x-y)mnp)+F(1-m)

Where: F = initial fatality rate for each MY

x = baseline MY fatality rate

y = current MY fatality rate

m = proportion of occupant fatalities that occur in multi-vehicle crashes (52 percent)

n = probability that crash is with a new MY vehicle containing advanced technologies

p = probability that new vehicle is "striking" vehicle

The initial fatality rate for each vehicle MY (F) was derived by combining fatality counts from NHTSA's Fatality Analysis Reporting System (FARS) with VMT data from IHS/Polk.

The baseline MY fatality rate (x) represents the baseline rate over which the impact of new crash avoidance technologies should be measured It establishes the baseline rate for each MY that will be compared to the most current MY rate to determine the change in fatality rate (FR) for each MY. The relative effectiveness of new crash-avoidance technologies in modifying the fatality rate of older model vehicles is measured differently depending on the age of the older vehicle. The fatality rate is a historical measure that reflects safety differences due to both crashworthiness technologies such as air bags and crash avoidance technologies such as electronic stability control, but up through MY 2017, crashworthiness standards are the predominate cause of these differences.

The most recent significant crashworthiness safety standard, which upgraded roof strength standards which was effective in all new passenger vehicles in MY 2017. Crashworthiness standards would not have secondary benefits for older MY vehicles. Post MY 2017, the agencies believe crash avoidance technologies will drive safety improvements. To isolate the added crash avoidance safety expected in newer vehicles, the marginal impact of the difference between the MY 2017 fatality rate and the most current MY fatality rate represents the added marginal effectiveness of new crash-avoidance technologies of each subsequent MY for MYs 2017 and earlier. Beginning with MY 2018, the difference between the older MY fatality rate and most current MY rate determines the potential safety benefit for the older vehicles.

The current MY fatality rate (y), represents the projected fatality rate of future MY vehicles after adjustment for the impacts of the advanced crash avoidance technologies and projected improvements in non-technology factors examined in this analysis. This process was discussed in detail in the previous section.

The proportion of passenger vehicle occupant fatalities that occur in multi-vehicle crashes (m), was derived from an analysis of occupants of fatal passenger vehicle crashes from 2002-2017 FARS. The analysis indicated that 47.8 percent of fatal crash occupants were in single vehicle crashes, 40.2 percent were in two vehicle crashes, and 12 percent were in crashes involving 3 or more vehicles. Overall, 52.2 percent were in multi-vehicle crashes.

The portion of older vehicle crashes involving newer vehicles containing advanced crash avoidance technologies (n), is assumed to be equal to the cumulative risk exposure of vehicles that have these technologies. This exposure is measured by the product of annual VMT by vehicle age and registrations of vehicles of that age. The CAFE Model calculates this dynamically, but as an example, based on 2016 registration data (*see* Table VI-274 above), the most current MY would represent 9.6 percent of all VMT in a calendar year, implying a 9.6 percent probability that the vehicle encountered would be from the most current MY. This percentage would increase for each CY as more MY vehicles adopt advanced crashworthiness technologies. The agencies note that other factors such as uneven concentrations of newer vs.

older vehicles or improved crash avoidance in the younger vehicles already on the road that are the basis for the agencies' VMT proportion table might disrupt this assumption, but it is likely that this would only serve to slow the probability of these encounters, making this a conservative assumption in that it maximizes the probability that older vehicles might benefit from newer technologies.

The probability that the vehicle with advanced crash avoidance technology is the controlling or striking vehicle (p), was calculated using the relative frequency of fatal crash occupants in multi-vehicle crashes. As noted previously, 40.2 percent were in two vehicle crashes, and 12 percent were in crashes involving 3 or more vehicles. The agencies assume a probability of 50 percent for two vehicle crashes and 33 percent for crashes with 3 or more vehicles. Weighted together the agencies estimate a 46.1 percent probability that, given a multi-vehicle crash involving a vehicle with advanced technologies and an older vehicle without them, the newer vehicle will be the striking vehicle or in a position where its crash avoidance technologies might influence the outcome of the crash with the older vehicle.

This process is illustrated in Table VI-275 below for adjustments due to improvements in MY 2021 vehicles back through MY 1995. In Table VI-275, the actual model year fatality rate is shown in the second column. As noted above, the base fatality rate, shown in column 3, is the MY 2017 rate for all MYs prior to 2018, after which it becomes the actual MY rate. Column 4 shows the difference between the fatality rate for MY 2021 and the base rate for each MY. Column 5 shows the resulting revised fatality rate that would be used for each older MY, and column 6 and 7 list the change in that rate. The various factors noted in the above formula are applied in column 5. The results indicate a 0.006 decrease in pre-2018 MY vehicles fatality rates, with declining impacts going forward to MY 2021. In subsequent years, this impact would grow to reflect the both the increased probability that an older vehicle would crash with vehicles containing advanced technology, as well as the increased technology levels in progressively newer vehicles. This table was created using NPRM inputs and is provided for explanatory purposes only. The actual impacts are dynamically calculated within the Volpe model and reflect revised fatality rate trends going forward and cover even older model years.

Table VI-275 – Adjustment to Fatality Rates of Older Vehicles to Reflect Impact of Advanced Crash Avoidance Technologies in Newer Vehicles

Model Year	MY Fatality Rate	Base Fatality Rate	Difference Base FR - New MY FR	Revised Fatality Rate	% Change	Difference

(h) Dynamic Fleet Composition

As described in the sales discussion in Section VI.D.1.b)(2)(c), the standards may impact the distribution of cars and trucks purchased. As light trucks, SUVs and passenger cars respond differently to technology applied to meet the standards—namely mass reduction—fleets with different compositions of body styles will have varying amounts of fatalities. Since mass-safety fatalities are calculated by multiplying mass point-estimates by VMT, which implicitly captures the impact of the dynamic fleet share model, the estimates of mass-safety fatalities in the previous section include the impact of vehicle prices on fleet composition.

c) Impact of Rebound Effect on Fatalities

The “rebound effect” is a measure of the additional driving that occurs when the cost of driving declines. More stringent standards reduce vehicle operating costs, and in response, some consumers may choose to drive more. Driving more increases exposure to risks associated with on-road transportation, and this added exposure translates into higher fatalities. The agencies have calculated this impact by estimating the change in VMT that results from alternative standards.

As noted previously, rebound miles are not imposed on consumers by regulation. They are a freely chosen activity resulting from reduced vehicle operational costs. As such, the agencies believe a large portion of the safety risks associated with additional driving are offset by the benefits drivers gain from added driving. For the proposal, the agencies assumed that, in deciding to drive more, drivers internalize the full cost to themselves and others, including the cost of accidents, associated with their additional driving.

In response to the NPRM, EDF noted that consumers may not fully value the added safety risk, such as risk to other drivers.[2216] In making this point, EDF suggested a value of 50 percent would be conservative, but did not provide supporting evidence for that value. The agencies agree that the level of risk internalized by drivers is uncertain, and for the final rule have revised the portion of the added monetized safety risk that consumers internalize to 90 percent, which mostly offsets the societal impact of any added fatalities from this voluntary consumer choice.

The actual portion of risk from crashes that drivers internalize is unknown. The agencies suspect that drivers are more likely to internalize serious crash consequences than minor ones, and some drivers may not perfectly internalize injury consequences to other individuals, especially occupants of other vehicles and pedestrians. However, legal consequences from crash liability, both criminal and civil, should also act as a caution for drivers considering added crash risk exposure. The agencies considered several approaches to estimating internalized crash risk. The first assumes that drivers value harm to themselves as well as legal liability for causing harm to others. It considers that all fatalities in single vehicle crashes are fully valued, that there is roughly a 50 percent chance that each driver would be the one killed in multi-vehicle crashes, and that there is roughly a 50 percent chance that each driver would be at-fault in a multi-vehicle crash that they survived. This produces an estimate of roughly 87 percent. Another approach assumes that drivers fully value all damage in single vehicle crashes, and only discount property damage incidents in multi-vehicle crashes. Based on data in Blincoe, *et al.* (2015),[2217] multi-vehicle property-damage-only crashes account for about 7 percent of all societal crash costs, leaving 93 percent recognized under this approach. Yet another approach would assume drivers value injury crashes, but discount non-injury related costs such as property damage and traffic congestion. This approach results in roughly an 88 percent estimate of costs internalized.

[2216] EDF, Appendix B, NHTSA-2018-0067-12108, at 101.
[2217] Blincoe, L., Miller, T.R., Zaloshnja,E., Lawrence, B. A., (May 2015, Revised) The Economic and Societal Impact of Motor Vehicle Crashes, 2010, (DOT HS 812 012), National Highway Traffic Safety Administration, Washington, D.C.

Overall, while the agencies recognize this proportion is uncertain, we believe it is reasonable to assume that drivers internalize 90 percent of the crash risk that results from added driving.

IPI commented that additional mileage attributable to the scrappage and dynamic fleet models is "inexplicably and unjustifiably not offset by countervailing mobility benefits in the benefit cost analysis—and the agencies inappropriately claim that these traffic fatalities—which comprise the other half of the 12,700 projection—also justify the roll back."[2218] In this comment, IPI has erroneously conflated the rebound effect and the scrappage effect. The agencies have appropriately accounted for the additional value consumers get out of increases in fuel efficiency, which manifest in two ways: reductions in fuel costs, and the additional driving resulting from the reductions in per-mile fuel costs. The agency cannot appropriately consider one without the other, as the two effects trade off, one against the other, according to consumer preferences between the two.

The scrappage effect represents the behavior of consumers when their choices are restricted by more stringent fuel economy standards. For instance, the consumer loses lower-price and less fuel-efficient bundles of vehicle attributes that would be available in the absence of more stringent alternatives. If anything, these consumers experience an un-estimated cost regarding the lost utility from being priced out of the new car market and being forced to drive an older, less safe –and likely less fuel efficient—vehicle. That the agencies have assessed the benefits of the rebound effect by assuming they are at least as great as 90 percent of the additional safety costs of rebound driving, does not mean that other channels of safety effects must be offset. However, the agencies did evaluate whether the sales, scrappage, and dynamic fleet share model could lead to changes in fuel economy in the legacy fleet that may result in significant changes in VMT and/or fuel economy. Upon further review, the agencies determined that such an effect—if it were to exist—would be very small and would not impact the analysis meaningfully, so the agencies declined to include this effect in the final rule's analysis.

d) Fatalities by Source

For the NPRM, the agencies calculated rebound fatalities by running the model with a 20 percent rebound assumption and again with a 0 percent rebound assumption. The following difference was assumed to assign the change in fatalities of the rule due to rebound:

$$Rebound\ Fatalities = \left(Fatalities_{Alt,20\%} - Fatalities_{Alt,0\%}\right) - (Fatalities_{Aug,20\%} - Fatalities_{Aug,0\%})$$

Similarly, the agencies calculated mass reduction fatalities by running the model using the central assumptions about coefficients on delta curb weight and again setting these coefficients to 0, so that a change in mass reduction would not affect the fatality rate of a vehicle. The following difference assigned the change in fatalities of the rule due to changes in mass reduction levels:

$$\Delta CW\ Fatalities = \left(Fatalities_{Alt,MR} - Fatalities_{Alt,NoMR}\right) - (Fatalities_{Aug,MR} - Fatalities_{Aug,NoMR})$$

[2218] IPI, Appendix, NHTSA-2018-0067-12213, at 12 (internal citation omitted).

Where "Alt" represents the alternative being estimated, "Aug" is the augural or baseline, "MR" stands for mass reduction, and "NOMR" means no mass reduction or mass reduction equaling zero.

The NPRM modeling then assumed that the remaining incremental fatalities were due to changes in sales, scrappage, and the dynamic fleet share. This can be represented by the following:

$$Sales/Scrap\ Fatalities = \left(Fatalities_{Alt} - Fatalities_{Aug}\right) - Rebound\ Fatalities - \Delta CW\ Fatalities$$

The changes to the VMT model (mainly the constraint that fixes total non-rebound VMT to be constant across alternatives) necessitated revising how fatalities are partitioned by source. The number of vehicles of each regulatory class and age changes in each regulatory alternative. Because of this, taking the increment of the rebound fatalities solved in each scenario as described above would capture changes both to the usage per vehicle from rebound, but also differences in the number of vehicles. This would wrongly attribute some of the sales and scrappage fatalities to rebound. Similarly, taking the increment of the mass reduction fatalities solved in each scenario as described above would capture the changes both to the fatality rate for vehicles (from mass reduction) and the difference in the number of vehicles across alternatives. This would likewise have the potential of wrongly attributing the source of sales and scrappage fatalities to mass reduction.

Instead of computing the fatalities due to rebound in each scenario and then taking the incremental values across alternatives, rebound fatalities are computed by taking the difference in per vehicle rebound miles in the regulatory alternative and the augural case multiplied by the augural fatality rate per mile and augural vehicle count. Holding the number of vehicles constant addresses the concern about the NPRM fatality allocation method wrongly attributing rebound fatalities to the sales and scrappage models. Fatalities due to rebound are computed as follows:

$$Rebound\ Fatalities_{Alt} = \left[\frac{R\ VMT_{Alt} - NR\ VMT_{Alt}}{Veh_{Alt}} - \frac{R\ VMT_{Aug} - NR\ VMT_{Aug}}{Veh_{Aug}}\right] * \ Fatality\ Rate_{Aug} * Veh_{Aug}$$

Where "RVMT" is VMT including rebound miles, "NRVMT" is VMT excluding rebound miles, "Veh" is the quantity of vehicles, and "Alt" and "Aug" have the same meaning described above. The rebound fatalities will show as zero for the augural scenario, and all alternatives will show fatalities due to rebound miles using the augural vehicle counts.

The fatalities due to mass reduction will use the augural vehicle counts, augural per vehicle VMT including rebound—this simplifies to total VMT including rebound, as shown below. Using a constant vehicle count addresses the concern of the NPRM method wrongly assigning some mass reduction fatalities to the sales and scrappage models. As with the fatalities attributable to rebound, the fatalities attributable to changes in mass reduction are calculated inherently as incremental values, relative to the augural standards (the values will appear as zero for augural standards in the outputs). The equation used to calculate the fatalities due to curb weight changes is as follows:

$$\Delta CW\ Fatalities_{Alt} = (Fatality\ Rate_{Alt} - Fatality\ Rate_{Aug}) * R\ VMT\ _{Aug}$$

The agencies then computed the sales/scrappage fatalities as the remainder, as was done in the NPRM.

$$Sales/Scrap\ Fatalities = \left(Fatalities_{Alt} - Fatalities_{Aug}\right) - Rebound\ Fatalities - \ \Delta CW\ Fatalities$$

e) Adjustment for Non-Fatal Crashes

Fatalities are valued as a societal cost within the CAFE Models' cost and benefit accounting. Their value is based on the comprehensive value of a fatality, which includes lost quality of life and is quantified in the value of a statistical life (VSL) as well as economic consequences such as medical and emergency care, insurance administrative costs, legal costs, and other economic impacts not captured in the VSL alone. These values were derived from data in Blincoe et al. (2015), adjusted to 2018 economics, and updated to reflect the official DOT guidance on the value of a statistical life. This gives a societal value of $10.4 million for each fatality, which is an update to the value used in the NPRM.[2219] The CAFE safety model estimates traffic fatalities but does not directly estimate the corresponding non-fatal injuries and property damage that would result from the same factors that influence fatalities. To address this, the agencies developed an adjustment factor applied to fatality costs that accounts for these crashes and related costs. The agencies' approach to estimating non-fatal costs remains relatively unchanged from the proposal, however the agencies have made one minor adjustment to account for advance crash technologies as advocated by commenters.

In the proposal, development of this factor was premised on the assumption that non-fatal crashes would be affected by the standards in proportion to their current nationwide rate of incidence and severity. The agencies assumed the injury profile—the relative number of crashes of each injury severity level that occur nationwide—would increase or decrease congruent with changes in fatalities, meaning that the ratio between fatal and non-fatal costs remained constant across alternatives. The agencies recognized that this may not be the case, but did not have data to support individual injury estimates across injury severities. The agencies provided several explanations as to why a proportionality assumption may be an oversimplification.[2220] For example, the agencies reviewed NHTSA's separate analysis of traffic crash data showing that older model year vehicles are generally less safe than newer vehicles, meaning fatalities would comprise a larger portion of the total injury picture for older vehicles. This would imply lower ratios across the non-fatal injury and property damage only (PDO) crash profiles and would imply the adjustment overstates total societal impacts.

As noted previously, in response to requests by commenters, the agencies have added the estimated impact of six advanced crash avoidance technologies that are currently being deployed commercially to their analysis of future fatality rates. The same data and methods described

[2219] The NPRM used a societal value of $9,900,000 in 2016 dollars.
[2220] *See* NPRM at 43146.

previously in this section to compute the impact of advanced crash avoidance technologies on fatalities can also be used to examine the effectiveness of these technologies against non-fatal and PDO crashes. The inputs and results are summarized for nonfatal injuries in Table VI-276 through Table VI-278, and for PDOs in Table VI-279 through Table VI-281.[2221]

[2221] *See* previous discussion in this section for the studies and methodology used to create these estimates.

Based on a comparison of the combined average effectiveness impacts for the three crash severity groups (fatalities, non-fatal injuries, and property damage), it is apparent that these advanced crash avoidance technologies would reduce non-fatal injuries and property damage crashes by even more than they would fatalities.[2222] To explore the scope of this impact, the agencies developed an adjustment factor that reflects the ratio of the decline in the rate of non-fatal crashes to that of fatal crashes. This factor would hypothetically affect the portion of safety improvement that is attributable to safety technologies. The adjustments were based on the cumulative fatality rates (for all three technology groups) by model year, noted in Table VI-269 for fatalities, Table VI-278 for non-fatal injuries, and Table VI-281 for PDOs, which are listed by MY in the last column of Table VI-278 and Table VI-281. These factors would modify the original non-fatal impacts—which were derived using an assumption that they were proportional to fatal impacts—to reflect the higher effectiveness of these technologies against non-fatal crashes.

The agencies considered including this additional adjustment factor to account for the *additional* cost savings attributable to advance crash avoidance technologies. The impact of such a factor would decrease the incidence and severity, and thus the costs of nonfatal crashes in regulatory alternatives where new vehicle sales increase, including the preferred alternative. The agencies ultimately erred on the side of caution for this rulemaking and have excluded this factor. Therefore, today's analysis assumes that advance crash avoidance technologies impact non-fatal and PDO crashes to the same extent as fatal crashes. The agencies will consider including an adjustment for non-fatal and PDO crashes in future rulemakings.

The original proportionality-based adjustment factor, which is described in detail in the following paragraphs, was derived from Tables 1-8 and I-3 in Blincoe et al. (2015). Incidence in Table I-3 in Blincoe et al. reflects the Abbreviated Injury Scale (AIS), which ranks nonfatal injury severity based on an ascending 5 level scale with the most severe injuries ranked as level 5.[2223]

Table 1-3 in Blincoe et al. lists injured persons with their highest (maximum) injury determining the AIS level. This scale is represented in terms of maximum abbreviated injury scale (MAIS) level. MAIS0 refers to uninjured occupants in injury vehicles, MAIS1 injuries are generally considered minor (e.g., a superficial laceration) with no probability of death, MAIS2 injuries are generally considered moderate (e.g., a fractured sternum) with a 1-2% probability of death, MAIS3 injuries are serious (e.g., open fracture of the humerus) with an 8-10% probability of death, MAIS4 injuries are severe (e.g., perforated trachea) with a 5-50% probability of death, and MAIS5 injuries are critical (e.g., rupture liver with tissue loss) with a 5-50% probability of death. Counts for PDO's refer to vehicles in which no one was injured. From Table VI-282, ratios of injury incidence/fatality are derived for each injury severity level as follows:

[2222] For example, for MY 2035, the combined effectiveness for PDO crashes is .224784, as shown in the second to last column of Table VI-281, which is 2.613 times the .0860 combined effectiveness for fatalities, as seen in Table VI-271, which shows the disproportionality impact of crash avoidance technologies on non-fatal accidents.
[2223] More information on the basis for these classifications is available from the Association for the Advancement of Automotive Medicine at https://www.aaam.org/abbreviated-injury-scale-ais/.

Table VI-282 – Ratio of Injury Incidence/Fatality; Police Reported and Unreported Crashes

Injury Level	Ratio
PDO	560.88
MAIS0	138.89
MAIS1	104.83
MAIS2	10.26
MAIS3	3.05
MAIS4	0.52
MAIS5	0.17
Fatal	1

For each fatality that occurs nationwide in traffic crashes, there are 561 vehicles involved in PDOs, 139 uninjured occupants in crashes which resulted in at least one injury,[2224] 105 minor injuries, 10 moderate injuries, 3 serious injuries, and fractional numbers of the most serious categories which include severe and critical nonfatal injuries. For each fatality ascribed to the standards, it is assumed there will be non-fatal crashes in these same ratios.

Property damage costs associated with delayed fleet turnover must be treated differently than rebound- and mass-related costs because crashes that involve vehicles that are retained longer due to the standards involve damage to older, used vehicles instead of newer vehicles.[2225] Used vehicles are worth less and will cost less to repair, if they are repaired at all. The consumer's property damage loss is thus reduced by longer retention of these vehicles. To estimate this loss, average new and used vehicle prices were compared. New vehicle transaction prices were estimated from a study published by Kelley Blue Book.[2226] Based on this data, the average new vehicle transaction price in January 2017 was $34,968. Used vehicle transaction prices were obtained from Edmonds Used Vehicle Market Report published in February of 2017.[2227] Edmonds data indicate the average used vehicle transaction price was $19,189 in 2016. There is a minor timing discrepancy in these data because the new vehicle data represent January 2017, and the used vehicle price is for the average over 2016. The agencies were unable to locate exact matching data, but believe the difference is minor and negligible.

[2224] Uninjured passengers incur a cost despite being uninjured. For example, they are often transported to emergency care even tough uninjured resulting in lost time and productivity; furthermore, their vehicle might be damaged even though they are uninjured.
[2225] The agencies note that property damage costs are the costs realized given an accident has occurred. The disparity of incidence rates between new and older vehicles is accounted for above in the fatality calculations.
[2226] Press Release, "New-Car Transaction Prices Remain High, Up More Than 3 Percent Year-Over-Year in January 2017, According to Kelley Blue Book," February 1, 2017. Available at https://mediaroom.kbb.com/2017-02-01-New-Car-Transaction-Prices-Remain-High-Up-More-Than-3-Percent-Year-Over-Year-In-January-2017-According-To-Kelley-Blue-Book.
[2227] Edmonds Used Vehicle Market Report, February 2017. Available at https://dealers.edmunds.com/static/assets/articles/2017_Feb_Used_Market_Report.pdf.

Based on these data, new vehicles are on average worth 82 percent more than used vehicles. To estimate the effect of higher property damage costs for newer vehicles in crashes, the per unit property damage costs from Table I-9 in Blincoe et al. (2015) were multiplied by this factor.[2228] Results are illustrated in Table VI-283.

Table VI-283 – Property Damage Unit Cost Savings from Retained Used Cars

Injury Level	Original Unit Cost	Unit Cost Savings
PDO	$2,444	$2,007
MAIS0	$1,828	$1,501
MAIS1	$5,404	$4,438
MAIS2	$5,778	$4,745
MAIS3	$10,882	$8,937
MAIS4	$16,328	$13,409
MAIS5	$15,092	$12,394
Fatal	$11,212	$9,208

The total property damage cost reduction was then calculated as a function of the number of increased fatalities due to stricter CAFE and CO_2 standards as follows:

$$S = \sum_{i=8}^{n} F r_n p_n$$

Where:

- S = total property damage reductions from retaining used vehicles longer
- F = increase in fatalities estimated due to used vehicles being retained longer because of stricter standards
- r = ratio of non-fatal injuries or PDO vehicles to fatalities
- p = value of property damage prevented by retaining older vehicle
- n = the 8 injury severity categories

The number of fatalities ascribed to the standards because of slower fleet turnover was multiplied by the unit cost per fatality from Table I-9 in Blincoe et al. (2015) to determine the societal impact of fatalities.[2229] After subtracting the total reductions in property damage from this value, the fatality cost is divided by it to estimate that overall, fatalities account for 39 percent of the total costs that would result from older vehicle retention.

[2228] The original unit costs were derived from vehicles involved in crashes, which are predominately used vehicles. While not precise, this average cost is assumed to be a reasonable proxy for the property damage to a used vehicle.
[2229] Note—These calculations used the original values in the Blincoe et al. (2015) tables without adjusting for economics. These calculations produce ratios and are thus not sensitive to adjustments for inflation.

These calculations are summarized as follows:

$$SV = Fv/x - S$$

Where -

- SV = Value of societal impacts of all crashes resulting from changes to fleet turnover
- F = Increase in fatalities estimated due to retaining used vehicles longer because of stricter standards
- v = Comprehensive societal value of preventing 1 fatality
- x = Percent of total societal loss from crashes attributable to fatalities
- S = total property damage reductions from retaining used vehicles longer

For the fatalities that occur because of mass effects or to the rebound effect, the calculation was more direct, a simple application of the ratio of the portion of costs produced by fatalities to the change in fatalities; there is no need to adjust for property damage because all impacts were derived from the mix of vehicles in the on-road fleet. Again, from Table I-8 in Blincoe et al. (2015), the agencies derived this ratio based on all cost factors including property damage to be 36 percent.

For purposes of application in the CAFE Model, these two factors (the factor for sales/scrappage, and the factor for mass and rebound) were combined based on the relative contribution to total fatalities of different factors. As noted previously, although a safety impact from the rebound effect is calculated, these impacts are considered to be freely chosen rather than imposed by the standards and imply personal benefits at least equal to the sum of their added operational costs and the portion of safety consequences internalized. However, the agencies still calculate and report the impacts of the rebound effect to provide a comprehensive view of the impacts of the standards. There are two different factors depending on which metric is considered (total impacts or CAFE imposed impacts). The agencies created these two adjustment factors by weighting components by the relative contribution to changes in fatalities associated with each component. This process and results are shown in Table VI-284. Note that due to programming constraints, the agencies applied the average weighted factor to all fatalities. This will tend to overstate costs slightly because of sales and scrappage and to understate costs associated with mass and rebound.

Table VI-284 – Contributing Factors of Societal Impacts

Contributing Factor	**Fatalities Portion of Crash Costs**	**Weights - All Factors**	**Weights - CAFE Imposed Factors**
Sales and Scrappage	0.3903	0.140	0.969
Rebound Effect	0.3611	0.855	
Mass	0.3611	0.005	0.0311
Total	NA	1	1
Weighted Factor		0.37	0.39

f) Summary of Safety Impacts

Table VI-285 through Table VI-288 summarize the safety effects of CAFE standards across the various alternatives under the 3 percent and 7 percent discount rates. Table VI-290 through Table VI-292 summarize these impacts for CO_2 standards. As noted in Section VI.D.2e), societal impacts are valued using a $10.4 million value per statistical life (VSL). Note that fatalities in these tables are undiscounted—only the monetized societal impact is discounted.

These tables present aggregations or averages of results for calendar years through 2050. Underlying model output files provide results for each model year in each calendar year.[2230] These results can be used for more detailed review and analysis of estimated trends. For example, for each calendar year through 2050, the following two tables—one for CAFE standards and one for CO_2 standards—show (a) the number of light-duty vehicles in service, (b) the travel accumulated by those vehicles, and (c) the total number fatalities among the types included in today's analysis.

The analysis shows the annual number of fatalities for the final standards growing more slowly than under the baseline standards, reflecting the combined effects of fleet turnover, mass reduction, and shifts between passenger cars and light trucks in the new vehicle fleet.

Table VI-293 summarizes the non-fatal safety impacts under alternative CAFE and CO_2 standards:

The Pennsylvania Department of Environmental Protection commented that the agencies did not fully account for safety improvements associated with the augural standards.[2231] The agencies note that the analysis accounts for the safety impacts of mass reduction, sales and scrappage, rebound, vehicle model year and vehicle age for each of the alternatives relative to the augural baseline. The commenter did not provide any specific items that were omitted from the analysis. The agencies believe the analysis thoroughly assesses the safety effects of all the alternatives.

3. Simulating Environmental Impacts of Regulatory Alternatives

This final rulemaking predominantly addresses fuel economy of the light-duty vehicle fleet in the United States through different technologies to improve efficiency. Inherently, these technologies will reduce the fuel consumed and therefore impact CO_2 and other greenhouse gases foremost. Certain technologies will also impact air quality through changes to criteria pollutants and air toxics emitted at the tailpipe as well as upstream of the fuel source. Upstream emissions for conventional fuels occur during crude oil extraction, transportation, refining, and the transportation, storage, and distribution of the finished fuel. For electricity, upstream emissions are dependent on the mix of feedstocks such as coal, natural gas, nuclear, and renewable sources for power generation. Similarly, specific hydrogen production pathways such as natural gas reforming or electrolysis of water molecules will determine the upstream emissions of hydrogen fuel. Emission impacts are described in greater detail in the following sections.[2232]

The impacts of both greenhouse gases (GHGs) and criteria pollutant emissions that result from changes in vehicle usage and fuel consumption were estimated and considered as part of this analysis. GHGs are gaseous constituents in the atmosphere, both natural and anthropogenic, and absorb infrared radiation. Primary GHGs in the atmosphere are water vapor, CO_2, nitrous oxide (N_2O), methane (CH_4), and ozone. Criteria air pollutants include carbon monoxide (CO), nitrogen dioxide (NO_2) (one of several oxides of nitrogen), ozone, sulfur dioxides (SO_2), particulate matter (including fine particulate matter, or $PM_{2.5}$), and lead. Vehicles do not directly emit ozone, but ozone impacts are evaluated based on emissions of the ozone precursor pollutants nitrogen oxides (NO_X) and volatile organic compounds (usually referred to as VOC). These pollutants are emitted during vehicle storage and use, as well as throughout the fuel production and distribution system. While increases in domestic fuel refining, storage, and distribution that result from higher fuel consumption will increase emissions of these pollutants, reduced vehicle use associated with the fuel economy rebound effect will decrease their emissions. The net effect of CAFE and CO_2 standards on total emissions of each criteria pollutant depends on the relative magnitudes of increases in its emissions during fuel refining and distribution, and decreases in its emissions resulting from vehicle use. Because the relationship between emissions in fuel refining and vehicle use is different for each criteria pollutant, the net effect of fuel consumption on total emissions of each pollutant differs between regulatory alternatives.

[2232] NHTSA also uses the results of the CAFE model to analyze the potential environmental impacts of the regulatory alternatives in its Environmental Impact Statement (EIS). That EIS informs the agency's decision-making process.

a) *Climate Change and CO_2 Emissions considered in this Rule*

The NPRM described how both agencies consider climate change and GHG emissions under their respective programs for fuel economy and CO_2. As noted in the NPRM, "In 1988, NHTSA included climate change concepts in its CAFE notices and prepared its first environmental assessment addressing that subject."[2233] Additionally, NHTSA "cited concerns about climate change as one of its reasons for limiting the extent of its reduction of the CAFE standard for MY 1989 passenger cars."[2234] As stated in the NPRM, "Since then, NHTSA has considered the effects of reducing tailpipe emissions of CO_2 in its fuel economy rulemakings pursuant to the need of the United States to conserve energy by reducing petroleum consumption.[2235]

Similarly, in the NPRM, EPA described that "the primary purpose of Title II of the Clean Air Act is the protection of public health and welfare. EPA's light-duty vehicle GHG standards serve this purpose, as the GHG emissions from light-duty vehicles have been found by EPA to endanger public health and welfare (see EPA's 2009 Endangerment Finding for on-highway motor vehicles), and the goal of these standards is to reduce these emissions that contribute to climate change."[2236] In the NPRM, EPA summarized its purpose for establishing CO_2 standards as follows:

> Section 202(a)(1) of the Clean Air Act (CAA) states that "the Administrator shall by regulation prescribe (and from time to time revise) … standards applicable to the emission of any air pollutant from any class or classes of new motor vehicles …, which in his judgment cause, or contribute to, air pollution which may reasonably be anticipated to endanger public health or welfare." If EPA makes the appropriate endangerment and cause or contribute findings, then section 202(a) authorizes EPA to issue standards applicable to emissions of those pollutants. Indeed, EPA's obligation to do so is mandatory: *Coalition for Responsible Regulation*, 684 F.3d at 114; *Massachusetts v. EPA*, 549 U.S. at 533.[2237]

The agencies modeled the estimated physical changes in quantity of CO_2, CH_4, and NO_2 emissions in the NPRM analysis, and conducted additional modeling of climate-related impacts, including sea-level rise, global temperate increases, and ocean pH changes in the Draft EIS accompanying the NPRM. The Draft EIS also included a comprehensive discussion of climate change impacts, drawing from various Intergovernmental Panel on Climate Change (IPCC) reports, the U.S. Global Change Research Program (USGCRP) National Climate Assessment (NCA) reports, and other peer-reviewed reports and assessment reports. The agencies also considered the increase in climate damages from an increase in CO_2 emissions,[2238] also known as the social cost of carbon and discussed previously in Section VI.D.1, above.

Many commenters expressed a desire for more information on the rule's potential climate impacts, so the discussion has been expanded here and in the Final EIS. Specifically, commenters stated that the agencies failed to address climate change in the proposal, and that the proposal ignored "scores of studies and reports" on climate change published since EPA's 2009 Endangerment Finding and promulgation of the

[2233] 83 FR 43211 (citing 53 FR 33080, 33096 (Aug. 29, 1988)).
[2234] *Id.* (citing 53 FR 39275, 39302 (Oct. 6, 1988)).
[2235] 83 FR 43211.
[2236] 83 FR 4228 (citing 74 FR 66496 (Dec. 15, 2009)).
[2237] 83 FR 43228.
[2238] 83 FR 43106.

existing CO_2 and CAFE standards.[2239] Several commenters presented summaries of climate impacts, citing IPCC, USGCRP, and other reports explicitly relied on in the DEIS, on temperature increases, increases in extreme weather events, ocean warming, acidification, and sea level rise, impacts on the United States' water supply, human health impacts, impacts to crop productivity and global food security, potential increases in the spread of infectious disease, national security impacts, and impacts to animal and plant species, including Federally protected species, among other impacts.[2240]

In addition to comments stating the agencies had presented too little information on climate change in the NPRM, some commenters disagreed with how the agencies framed the impact of the rule on climate change. Many commenters cited IPCC and USGCRP to reinforce their understanding that human activities are the dominant cause of global warming since the mid-20th century. NHTSA considered both the IPCC and USGCRP reports in the DEIS accompanying the NPRM and in this final rule, and did not dispute those findings. Commenters also cited IPCC and the National Climate Assessments, among other reports, as support to their understanding that regardless of the perceived magnitude of the rule on total CO_2 emissions, any additional actions taken now to reduce CO_2 emissions would affect the degree of climate impacts in the future. Further discussion of these comments occurs in Section VIII.

Just as NHTSA does with both the draft and final EIS, and as EPA did for its *Endangerment and Cause or Contribute Findings for Greenhouse Gases under the Clean Air Act*, for this rule, both agencies relied on existing studies and reports to summarize the current state of climate science and provide a framework for the analysis of impacts. The agencies drew primarily on panel-reviewed synthesis and assessment reports from the Intergovernmental Panel on Climate Change (IPCC) and the U.S. Global Change Research Program (GCRP), supplemented with past reports from the U.S. Climate Change Science Program (CCSP), the National Research Council, and the Arctic Council and EPA's *Technical Support Document for Endangerment and Cause or Contribute Findings for Greenhouse Gases under the Clean Air Act*,[2241] which, as stated above, relied on past major international or national scientific assessment reports.

Assessment reports assess numerous individual studies to draw general conclusions about the potential impacts of climate change. Even where assessment reports include consensus conclusions of expert authors, uncertainty still exists, as with all assessments of environmental impacts. Given the global nature of climate change and the need to communicate uncertainty to a variety of decision-makers, IPCC has focused considerable attention on developing a systematic approach to characterize and communicate this information. The IPCC is a United Nations panel, founded in 1988, which evaluates climate science by assessing research on climate change and synthesizing relevant research into major assessment reports. The IPCC provides regular assessments on climate impacts and future risks, and options for adaptation and risk mitigation. The agencies used the system developed by IPCC to describe uncertainty associated with various climate change impacts.

Available at: https://www.epa.gov/sites/production/files/2016-08/documents/endangerment_tsd.pdf.

The IPCC reports communicate uncertainty and confidence bounds using commonly understood but carefully defined words in italics to represent likelihood of occurrence. The referenced IPCC documents provide a full understanding of the meaning of those uncertainty terms in the context of the IPCC findings. The IPCC notes that there are two primary uncertainties with climate modeling: model uncertainties and scenario uncertainties:[2242]

- ***Model uncertainties.*** *These uncertainties occur when a climate model might not accurately represent complex phenomena in the climate system. For some processes, the scientific understanding could be limited regarding how to use a climate model to "simulate" processes in the climate system.*
- ***Scenario uncertainties.*** *These uncertainties arise because of uncertainty in projecting future GHG emissions, concentrations, and forcings (e.g., from solar activity).*

According to IPCC, these types of uncertainties are described by using two metrics for communicating the degree of certainty: confidence in the validity of findings, expressed qualitatively, and quantified measures of uncertainties, expressed probabilistically.[2243] The confidence levels synthesize the judgments about the validity of the findings, determined through evaluation of the evidence and the degree of scientific agreement. The qualitative expression of confidence ranges are described, in italics, from *very low* to *very high*, with higher confidence levels assigned to findings that are supported by high scientific agreement. The quantitative expression of confidence ranges from *exceptionally unlikely* to *virtually certain*, with higher confidence representing findings supported by robust evidence. Table VI-294 shows that the degree of confidence increases as evidence becomes more robust and agreement is greater.

Table VI-294 – Standard Terms to Define the Likelihood of a Climate-Related Event

Likelihood Terminology	Likelihood of the Occurrence/Outcome
Virtually certain	99–100% probability
Very likely	90–100% probability
Likely	66–100% probability
About as likely as not	33–66% probability
Unlikely	0–33% probability
Very unlikely	0–10% probability
Exceptionally unlikely	0–1% probability
Notes: Additional terms that were used in limited circumstances in the IPCC Fourth Assessment Report, extremely likely = 95−100% probability, more likely than not ≥ 50−100% probability, and extremely unlikely = 0−5% probability) were also used in IPCC Working Group I to the Fifth Assessment Report when appropriate, and in the Climate Science Special Report: Fourth National Climate Assessment in 2017 by U.S. Global Change Research Program. Source: IPCC 2013.	

As described in more detail in the Final EIS, the process known as the *greenhouse effect* is responsible for trapping a portion of a planet's heat in the planet's atmosphere, rather than allowing all of that heat to be radiated into space. GHGs trap heat in the lower atmosphere (the atmosphere extending from Earth's surface to approximately 4 to 12 miles above the surface), absorb heat energy emitted by Earth's surface and lower atmosphere, and reradiate much of it back to Earth's surface, thereby causing warming. Human activities, particularly fossil-fuel combustion, lead to the presence of increased concentrations of GHGs in the atmosphere; this buildup of GHGs is changing the Earth's energy balance. IPCC states the warming experienced over the past century is due to the combination of natural climatic forcers (e.g., natural GHGs, solar activity) and human-made climate forcers.[2244] IPCC concluded, "[h]uman influence has been detected in warming of the atmosphere and the ocean, in changes in the global water cycle, in reductions in snow and ice, in global mean sea-level rise, and in changes in some climate extremes. … This evidence for human influence has grown since [the IPCC *Working Group 1 (WG1) Fourth Assessment Report (AR4)*].

[2244] IPCC 2013.

IPCC reports that it is *extremely likely* that human influence has been the dominant cause of the observed warming since the mid-20th century."[2245]

Although the climate system is complex, IPCC has identified the following drivers of climate change:

- **GHGs**. Primary GHGs in the atmosphere are water vapor, atmospheric CO_2, N_2O (nitrous oxide), CH_4(methane), and ozone.[2246]
- **Aerosols.** Aerosols are natural (e.g., from volcanoes) and human-made particles in the atmosphere that scatter incoming sunlight back to space, causing cooling. Some aerosols are hygroscopic (i.e., attract water) and can affect the formation and lifetime of clouds. Large aerosols (more than 2.5 micrometers in size) modify the amount of outgoing long-wave radiation.[2247] Other particles, such as black carbon, can absorb outgoing terrestrial radiation, causing warming. Natural aerosols have had a negligible cumulative impact on climate change since the start of the industrial era.[2248] Further discussion of black carbon and other aerosols is located in Chapter 4 of the FEIS.
- **Clouds**. Depending on cloud height, cloud interactions with terrestrial and solar radiation can vary. Small changes in the properties of clouds can have important implications for both the transfer of radiative energy and weather.[2249]
- **Ozone.** Ozone is created through photochemical reactions from natural and human-made gases. In the troposphere, ozone absorbs and reemits long-wave radiation. In the stratosphere, the ozone layer absorbs incoming short-wave radiation.[2250]
- **Solar radiation.** Solar radiation, the amount of solar energy that reaches the top of Earth's atmosphere, varies over time. Solar radiation has had a negligible impact on climate change since the start of the industrial era compared to other main drivers.[2251]
- **Surface changes**. Changes in vegetation or land surface properties, ice or snow cover, and ocean color can affect surface albedo.[2252] The changes are driven by natural seasonal and diurnal changes (e.g., snow cover) as well as human influences (e.g., changes in vegetation type).[2253]

Effects of emissions and the corresponding processes that affect climate are highly complex and variable, which complicates the measurement and detection of change. However, IPCC indicates that an increasing number of studies conclude that anthropogenic GHG emissions are affecting climate in detectable

[2252] Surfaces on Earth (including land, oceans, and clouds) reflect solar radiation back to space. This reflective characteristic, known as *albedo*, indicates the proportion of incoming solar radiation the surface reflects. High albedo has a cooling effect because the surface reflects rather than absorbs most solar radiation.
[2253] IPCC 2013.

and quantifiable ways.[2254,2255] GHGs occur naturally and because of human activity. Other GHGs, such as the fluorinated gases,[2256] are primarily anthropogenic in origin and are used in commercial applications such as refrigeration and air conditioning and industrial processes such as aluminum production.

In its most recent assessment of climate change (*IPCC WG1 AR5*), IPCC states that, "Warming of the climate system is unequivocal, and since the 1950s, many of the observed changes are unprecedented over decades to millennia. The atmosphere and ocean have warmed, the amounts of snow and ice have diminished, sea level has risen, and the concentrations of greenhouse gases have increased."[2257] IPCC concludes that, at continental and global scales, numerous long-term changes in climate have been observed. To be more specific, IPCC and the GCRP include the following trends observed over the 20th century as further supporting the evidence of climate-induced changes:

- Most land areas have very likely experienced warmer and/or fewer cold days and nights along with warmer and/or more frequent hot days and nights.[2258,2259] From 1880 to 2016, the global mean surface temperature rose by about 0.9°C (1.6°F).[2260] Air temperatures are warming more rapidly over land than over oceans.[2261,2262] Similar to the global trend, the U.S. average temperature is about 1.8°F warmer than it was in 1895, and this rate of warming is increasing—most of the warming has occurred since 1970.[2263] IPCC projects a continuing increase in surface temperature between 2081 and 2100, with a likely range between 0.3°C (0.5°F) and 4.8°C (8.6°F), compared with 1986 through 2005, where the lower value corresponds to substantial future mitigation of carbon emissions.[2264]
- Cold-dependent habitats are shifting to higher altitudes and latitudes, and growing seasons are becoming longer.[2265,2266] According to the IPCC, "it is virtually certain that there will be more

frequent hot and fewer cold temperature extremes over most land areas on daily and seasonal timescales" and it is very likely that heat wave frequency and duration will also increase.[2267]

- Sea level is rising, caused by thermal expansion of the ocean and melting of snowcaps and ice sheets.[2268,2269] Between 1971 and 2010, global ocean temperature warmed by approximately 0.25°C (0.45°F) in the top 200 meters (approximately 660 feet).[2270] IPCC concludes that mountain glaciers, ice caps, and snow cover have declined on average, further contributing to sea-level rise. Losses from the Greenland and Antarctic ice sheets very likely contributed to sea-level rise from 1993 to 2010, and satellite observations confirm that they have contributed to sea-level rise in subsequent years.[2271] IPCC projects that the global temperature increase will continue to affect sea level, causing a likely rise of 0.26 meter (0.85 foot) to 0.82 meter (2.7 feet) in the next century.[2272]
- More frequent weather extremes such as droughts, floods, severe storms, and heat waves have been observed.[2273,2274] Average atmospheric water vapor content has increased since at least the 1970s over land and the oceans, and in the upper troposphere, largely consistent with air temperature increases.[2275] Because of changes in climate, including increased moisture content in the atmosphere, heavy precipitation events have increased in frequency over most land areas.[2276,2277] Observations of increased dryness since the 1950s suggest that some regions of the world have experienced longer, more intense droughts caused by higher temperatures and decreased precipitation, particularly in the tropics and subtropics.[2278] Heavy precipitation events have increased globally since 1951, with some regional and subregional variability.[2279] A warmer atmosphere holds more moisture and increases the energy available for convection, causing stronger storms and heavier precipitation.[2280,2281]
- Oceans are becoming more acidic because of increasing absorption of CO_2 by seawater, which is driven by a higher atmospheric concentration of CO_2.[2282,2283,2284] There is high

confidence that oceans have become increasingly more acidic.[2285,2286] A recent assessment found that the oceans have become about 30 percent more acidic over the last 150 years since the Industrial Revolution.[2287]

Based on the current trajectory, IPCC projects that the atmospheric CO_2 concentration could rise to more than three times preindustrial levels by 2100.[2288] The effects of the CO_2 emissions that have accumulated in the atmosphere prior to 2100 will persist well beyond 2100. If current trends continue, this elevation in atmospheric CO_2 concentrations will persist for many centuries, with the potential for temperature anomalies continuing much longer.[2289]

Many commenters expressed concerns about trends of increased temperature, sea level rise, and extreme weather events in relation to climate change impacts from increased GHG emissions. The Joint Submission from Colorado local governments stated "[t]here is overwhelming scientific evidence that CO_2 and other greenhouse gases released into the atmosphere are exerting a profound effect on the earth's climate—increasing extreme weather events, changing rainfall and crop productivity patterns, and fueling the migration of infectious diseases. Since 1983, average temperatures in Colorado have risen 2°F and continue to rise. Climate change will impact the health of those who live, work, and play in Colorado and around the world."[2290] The California Air Resources Board (CARB) stated that:

> [P]rojections show that these effects will continue and worsen over the coming centuries. Changes in weather patterns can influence the frequency of meteorological conditions conducive to the development of high pollutant levels. Some of the key air pollutants (ozone, secondary particulate matter) depend strongly on temperature. Increases in atmospheric GHGs since the Industrial Revolution are well-known to warm global near- surface and tropospheric air temperatures. Some of the other broad range of effects of higher temperatures on air quality could include increases in emissions of biogenic gases year-around, in electric power and vehicle-fuel emissions in summer, in the temperature-dependent rates of photochemical reactions, and vaporization of volatile particle components. Higher temperatures will also impact meteorology by increasing atmospheric stability due to enhanced cloudiness but decreasing in stability due to warmer near-surface temperatures.[2291]

The agencies received additional public comments on concerns with worsening effects of climate change due to increased GHG emissions. States, localities, and individual commenters summarized broad and specific impacts that climate change would have in their area both in writing and at the three public meetings held on the proposal;[2292] for example, the joint submission from Colorado local governments and Colorado municipal agencies stated that "[m]any Colorado communities are already experiencing the

impacts of a destabilized climate in the form of reduced snowpack, earlier snowmelt, increased risk of high-intensity wildfires and their associated air pollution and later flash flooding, extreme weather events, and an increased number of "high heat" days."[2293]

Many commenters urged the agencies to consider more stringent standards to address GHG emissions. The Northeast States for Coordinated Air Use Management (NESCAUM) stated that "effectively combatting climate change requires GHG reductions on a national and international scale. Maintaining an aggressive downward trend in transportation sector GHG emissions will not occur in the absence of strong national GHG emission reductions."[2294] Similarly, the Center for Biological Diversity et al. stated "the scientific record is now overwhelming that climate change poses grave harm to public health and welfare; that its hazards have become even more severe and urgent than previously understood; and that avoiding devastating harm requires substantial reductions in greenhouse gas emissions, including from the critically important transport sector, within the next decade."[2295] Minnesota Pollution Control Agency (MPCA), the Minnesota Department of Transportation (MnDOT), and the Minnesota Department of Health (MDH) stated "Tackling climate change will require aggressive and immediate action on reducing emissions from the transportation sector. The existing GHG and CAFE standards are a critical piece to the multifaceted and global effort to reduce GHG emissions."[2296]

Commenters also expressed concerns that the agencies did not accurately consider the effects of climate change resulting from the rulemaking. Pennsylvania Department of Environmental Protection (PA DEP) stated "the Proposed Rule does not fully consider the potential effects of global climate change resulting from these forgone reductions or the interests of states in preventing or mitigating the impacts of climate change on their citizens and environment."[2297] The Center for Biological Diversity et al. stated "the agencies callously disregard the demonstrated need to reduce emissions sharply over the next decade if severe impacts of a destabilized climate are to be avoided."[2298] Similarly, the Joint Submission from the States of California et al. and the Cities of Oakland et al. stated "discussion of the effect of the Proposed Rollback on GHG emissions significantly understates the outcome," and "the overwhelming scientific consensus is that immediate and continual progress toward a near-zero GHG-emission economy by mid-century is necessary to avoid truly catastrophic climate change impacts."[2299]

The agencies have carefully considered these comments in the context of the information on climate change summarized in the NPRM and DEIS, and have updated information for this final rule. The agencies drew upon updates to climate science and impacts for the analysis from reports and studies that were updated or released since the NPRM, including IPCC's *Global Warming of 1.5 degrees C* report, Volume 2 of the *4th National Climate Assessment*, and IPCC's *Special Report on Climate Change and Land*, and the IPCC's *Special Report on the Ocean and Cryosphere in a Changing Climate*.

The following sections also provide additional context about climate impacts from this final rule; the results of the agencies' quantitative analysis presented in Section VII shows estimated CO_2, CH_4, and N_2O emissions resulting from the rule, and the discussion of how each agency balanced climate change as a factor

considered in decision-making is presented in Section VIII. This Final EIS also includes a comprehensive discussion of climate impacts, and additional climate modeling that estimates climate-related effects. As discussed in more detail in the FEIS and following sections, but relevant for placing the following discussion in context, climate modeling performed for this final rule shows the following impacts as a result of the final standards selected: CO_2 concentrations of 789.80 ppm in 2100, compared with 789.11 ppm under the augural standards; global mean surface temperature increases of 3.487°C in 2100, compared with 3.484°C under the augural standards; sea-level rise increases of 76.34 cm in 2100, compared with 76.28 cm under the augural standards; and ocean pH of 8.2172 in 2100, compared with 8.2176 under the augural standards. These equal differences of 0.69 ppm, 0.003°C, 0.06 cm, and -0.0004, respectively. Additionally, the agencies valued anticipated climate-related economic effects in accordance with EO 13783, as discussed in Section VI.D.1.

(1) Global Greenhouse Gas Emissions

According to NOAA and IPCC, Global atmospheric CO_2 concentrations have increased 46.4 percent, from approximately 278 parts per million (ppm) in 1750[2300] to approximately 407 ppm in 2018.[2301] According to IPCC and WRI, in 2014, CO_2 emissions[2302] accounted for 76 percent of global GHG emissions on a global warming potential (GWP)-weighted basis,[2303] followed by CH_4 (16 percent), N_2O (6 percent), and fluorinated gases (2 percent).[2304,2305] IPCC notes that atmospheric concentrations of CH_4 and N_2O increased approximately 150 and 20 percent, respectively, over roughly the same period.[2306]

According to WRI, developed countries, including the United States, have been responsible for the majority of historical GHG emissions since the mid-1800s and still have some of the highest GHG emissions per capita.[2307] While annual emissions from developed countries have been relatively flat over the last few decades, world population growth, industrialization, and increases in living standards in developing countries are expected to cause global fossil-fuel use and resulting GHG emissions to grow substantially. According to IPCC, global GHG emissions since 2000 have been increasing nearly three times faster than in the 1990s.[2308] This is further illustrated in Figure VI-162 showing carbon dioxide emissions since 1990 by world region:[2309]

[2300] IPCC 2013.
[2301] NOAA. Globally Averaged Marine Surface Annual Mean CO_2 Data. Available at: ftp://aftp.cmdl.noaa.gov/products/trends/co2/co2_annmean_gl.txt.
[2302] These global GHG estimates *do not* include contributions from land-use change and forestry or international bunker fuels.
[2303] Each GHG has a different radiative efficiency (the ability to absorb infrared radiation) and atmospheric lifetime. To compare their relative contributions, GHG emission quantities are converted to carbon dioxide equivalent (CO_2e) using the 100-year time horizon global warming potential (GWP) as reported in IPCC's *Second Assessment Report (AR2): The Science of Climate Change* in Sections B.7 Summary of Radiative Forcing and B.8 Global Warming Potential.

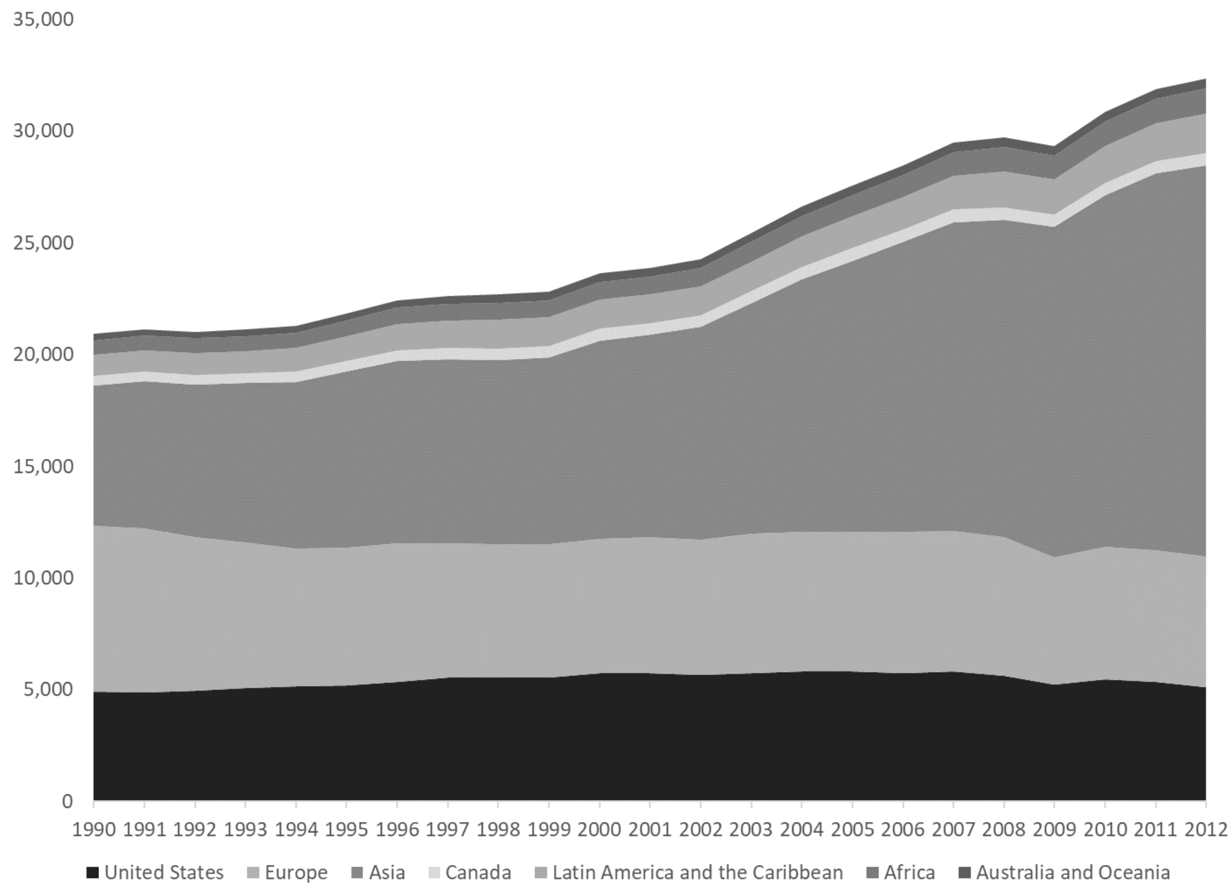

Figure VI-162 – Annual CO_2 Emissions (mmt) by World Region, 1990-2012

GHGs are emitted from a wide variety of sectors, including energy, industrial processes, waste, agriculture, and forestry. According to WRI, the energy sector is the largest contributor of global GHG emissions, accounting for 72 percent of global emissions in 2014; other major contributors of GHG emissions are agriculture (10 percent) and industrial processes (6 percent).[2310] Transportation CO_2 emissions—from the combustion of petroleum-based fuels—account for roughly 15 percent of total global GHG emissions, and have increased by 64 percent from 1990 to 2014.[2311, 2312]

In general, global GHG emissions continue to increase, although annual increases vary according to factors such as weather, energy prices, and economics. Comparing observed carbon emissions to projected emissions, the current global trajectory is similar to the most fossil fuel-intensive emissions scenario (A1Fi)

[2310] WRI 2018.
[2311] The energy sector is largely composed of emissions from fuels consumed in the electric power, transportation, industrial, commercial, and residential sectors. The 15 percent value for transportation is therefore included in the 72 percent value for energy.
[2312] WRI 2018.

in the *IPCC Special Report on Emissions Scenarios* (2000) and the highest emissions scenario (RCP8.5) represented by the more recent Representative Concentration Pathways (RCP).[2313,2314]

(2) U.S. Greenhouse Gas Emissions and the Transportation Sector

Most GHG emissions in the United States are from the energy sector, with the majority of those being CO_2 emissions coming from the combustion of fossil fuels. Fossil fuel combustion CO_2 emissions alone account for 76 percent of total U.S.GWP-weighted emissions, with the remaining 24 percent contributed by other sources such as industrial processes and product use, agriculture and forestry, and waste.[2315] CO_2 emissions due to combustion of fossil fuels are from fuels consumed in the transportation (37 percent of fossil fuel combustion CO_2 emissions), electric power (35 percent), industrial (16 percent), residential (6 percent), and commercial (5 percent) sectors.[2316] In 2017, U.S. GHG emissions were estimated to be 6,456.7 $MMTCO_2e$,[2317] or approximately 14 percent of global GHG emissions.[2318,2319]

Similar to the global trend, CO_2 is by far the primary GHG emitted in the U.S., representing 82 percent of U.S. GHG emissions in 2017 (on a GWP-weighted basis),[2320] and accounting for 15 percent of total global CO_2 emissions.[2321,2322] Although CO_2 is the GHG with the largest contribution to warming, methane accounts for 10.2 percent of U.S. GHGs on a GWP-weighted basis, followed by N_2O (5.6 percent) and the fluorinated gases (2.6 percent).[2323]

When U.S. CO_2 emissions are apportioned by end use, transportation is the single leading source of U.S. emissions from fossil fuels, causing over one-third of total CO_2 emissions from fossil fuels.[2324] Passenger cars and light trucks account for 59 percent of total U.S. CO_2 emissions from transportation, an increase of 14 percent since 1990.[2325] This increase in emissions is attributed to about 50 percent increase in vehicle miles traveled (VMT) because of population growth and expansion, economic growth, and low fuel prices. Additionally, the rising popularity of sport utility vehicles and other light trucks with lower fuel

---

[2313] The Representative Concentration Pathways (RCPs) were developed for the IPCC AR5 report. They define specific pathways to emission concentrations and radiative forcing in 2100. The RCPs established four potential emission concentration futures, a business-as-usual pathway (RCP8.5), two stabilization pathways (RCP6.0, 4.5), and an aggressive reduction pathway (RCP2.6).

economy than passenger cars has contributed to higher emissions.[2326,2327] Although emissions typically increased over this period, emissions declined from 2008 to 2009 because of decreased economic activity associated with the most recent recession.[2328]

Today's rule addresses light-duty vehicle fuel economy and CO_2 emissions from new-model passenger cars and light trucks. Several commenters observed that the transportation sector accounted for a large, if not the largest, portion of the United States greenhouse gas emissions, and that light-duty vehicle emissions contributed to a large fraction of that portion.[2329] Many commenters referenced the IPCC Report from 2018 on *Global Warming of 1.5 Degrees Celsius*, which considered transportation sector greenhouse gas emissions in describing pathways to limit climate impacts.

Graphically, historical trends in U.S. GHG emissions reported by EPA appear as follows.[2330]

*Excluding emissions from land use, land use change, and forestry (LULCF)

Figure VI-163 – Historical U.S. GHG Emissions (million metric tons or MMT CO_2eq) from Light-Duty Vehicles and Other Sectors

Notably, light-duty vehicle CO_2 emissions outweigh other GHG emissions from light-duty vehicles, and light-duty vehicle CO_2 emissions have been relatively stable over a nearly 30-year period during which highway vehicles miles traveled has increased by about 50 percent.[2331] Without fuel economy increases that have accumulated since EPCA's passage in 1975, recent light-duty vehicle CO_2 emissions would have been 50 percent greater than shown above.[2332]

For fuel combustion, EIA's National Energy Modeling System (NEMS), which EIA uses to produce its Annual Energy Outlook (AEO) forecasts of U.S. energy consumption and supply, provides corresponding estimates of CO_2 emissions. For the final rule, modeling conducted by the agencies using the AEO2019 version of NEMS shows the following levels of future CO_2 emissions from sectors other than light-duty

[2331] https://www.fhwa.dot.gov/policyinformation/travel_monitoring/historicvmt.pdf.
[2332] DOT reports fuel economy levels of the historical on-road fleet at https://www.bts.gov/content/average-fuel-efficiency-us-light-duty-vehicles.

vehicles (which this rule impacts directly) and refineries (which this rule is estimated to impact through changes in fuel consumption):

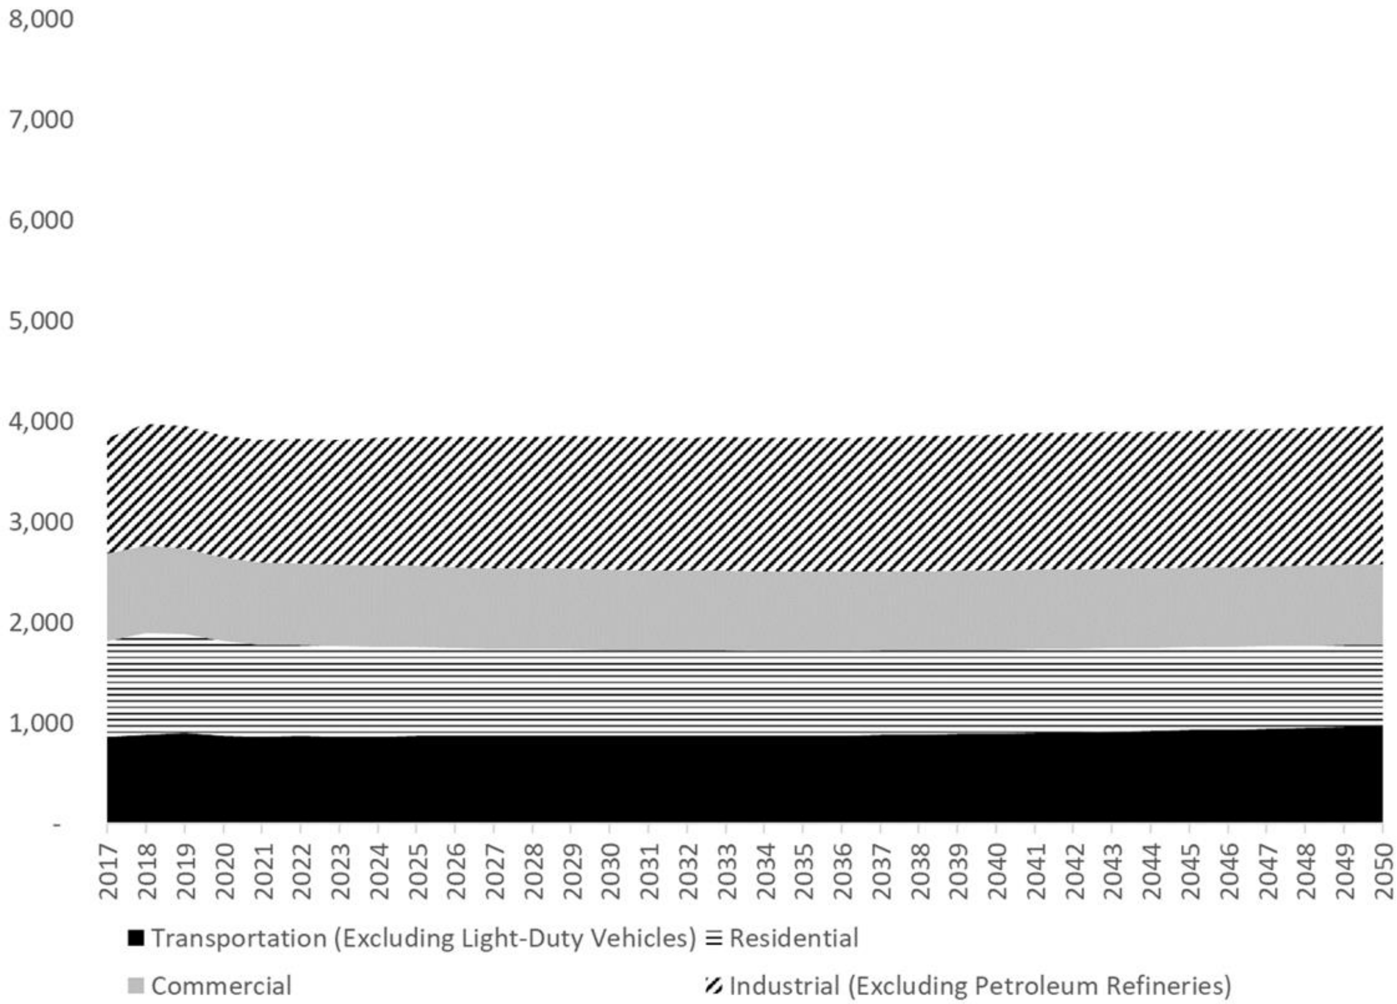

Figure VI-164 – Projected U.S. CO_2 Emissions (mmt) from Fuel Combustion

As this chart indicates, EIA's representation of laws and regulations current as of AEO2019 shows aggregate emissions from these sectors remaining remarkably stable through 2050, despite projected growth in the U.S. population and economy.

The agencies agree with commenters that the transportation sector, and specifically light-duty vehicle emissions, contribute to the largest portion of the United States' greenhouse gas emissions.[2333] However, the fuel economy and CO_2 of vehicles, regulated in this rulemaking, is not the only determining factor for whether the light-duty transportation sector would see a rise or decline in CO_2 emissions. As discussed elsewhere in this rule, the standards from the final rule affect only new vehicles, which are responsible for approximately 3.5 percent of on-road VMT in any year. The agencies recognize that the revised standards result in additional CO_2 emissions, and these emissions are accounted for in the analysis. It is worthwhile to

[2333] *See* U.S. Energy Information Administration available at https://www.eia.gov/todayinenergy/detail.php?id=29612 and EPA, Sources of Greenhouse Gas Emissions available at https://www.epa.gov/ghgemissions/sources-greenhouse-gas-emissions.

note that the difference between the augural standard and the new standard is a small change to a small fraction of total VMT, and it is important to consider in context the different mechanisms that contribute to transportation sector greenhouse gas emissions. These mechanisms are considered in the 2018 IPCC special report cited by commenters as well; in addition to vehicle fuel efficiency, IPCC considers preventing (or reducing) the need for transport,[2334] as "increasingly efficient fleets of vehicles over time . . . does not necessarily limit the driven distance." (internal citations omitted).[2335]

b) Air Quality

This section discusses the health and environmental effects associated with exposure to some of the criteria and air toxic pollutants impacted by the proposed vehicle standards. The agencies note that these impacts are, compared to the impacts on vehicular fuel consumption and CO_2 emissions, small and mixed. CAFE and CO_2 standards directly impact vehicular fuel consumption and CO_2 emissions. Notwithstanding modest indirect impacts, such as impacts on vehicle sales, retention, and mileage accumulation, one can "draw a direct line" between CAFE/CO_2 standards and resultant changes in overall fuel consumption and CO_2 emissions, and these follow the expected trends.

Changes in emissions of criteria pollutants due to these rules will impact air quality. The Clean Air Act (CAA) is the primary federal statute that addresses air quality. Pursuant to its CAA authority, the EPA has established National Ambient Air Quality Standards (NAAQS) for six criteria pollutants: CO, NO_2, ozone, SO_2, particulate matter (PM), and lead. Vehicles do not directly emit ozone, but ozone impacts are evaluated based on emissions of the ozone precursor pollutants nitrogen oxides (NO_X) and volatile organic compounds (VOC). When the measured concentrations of a criteria pollutant in a geographic region are less than those permitted by NAAQS, EPA designates the region as an attainment area for that pollutant; regions where concentrations of criteria pollutants exceed Federal standards are called nonattainment areas. Former nonattainment areas that are now in compliance with NAAQS are designated as attainment areas and are commonly referred to as maintenance areas. Each state with a nonattainment area is required to develop and implement a State Implementation Plan (SIP) documenting how the region will reach attainment levels within periods specified in the CAA. For maintenance areas, the SIP must document how the State intends to maintain compliance with NAAQS. When EPA changes a NAAQS, each State must revise its SIP to address how it plans to attain the new standard. In addition to analyzing criteria pollutants, the agencies considered hazardous air pollutants emitted from vehicles that are known or suspected to cause cancer or other serious health and environmental impacts and are referred to as mobile source air toxics, as further discussed in this section. Table VI-295 below provides an overview of criteria pollutants and mobile source air toxics with a high level overview of health effects. See further within this section for details on the pollutants and toxics.

[2334] IPCC 2018 at 349 (citing Gota et al., 2018.).
[2335] IPCC 2018 at 377 (citing Ajanovic and Haas, 2017; Sen et al., 2017).

Table VI-295 – Overview of Health Effects of Criteria Pollutant and Air Toxics

Pollutant	Health Effects
Particulate Matter	PM is a generic term for a broad class of chemically and physically diverse substances that exist as discrete particles. PM includes dust, dirt, soot, smoke, and liquid droplets directly emitted into the air, as well as particles formed in the atmosphere by condensation or by the transformation of emitted gases such as NO_X, SOx, and VOCs. Fine particles are produced primarily by combustion processes and by these atmospheric transformations of emitted gases. PM can damage lung tissue, aggravate existing respiratory and cardiovascular diseases, alter the body's defense systems against foreign materials, and cause cancer and premature death.
Ozone	Ozone is a photochemical oxidant and the major component of smog. Ozone is not emitted directly into the air, but is formed through complex chemical reactions among precursor emissions of VOCs and NO_X. Ground-level ozone causes health problems because it irritates the mucous membranes, damages lung tissue, reduces lung function, and sensitizes the lungs to other irritants.
Nitrogen Dioxide	NO_2, one of the oxides of nitrogen formed by high-temperature combustion (as in vehicle engines) of nitrogen and oxygen, is a reddish-brown, highly reactive gas. NO_2 can irritate the lungs and mucous membranes, aggravate asthma, cause bronchitis and pneumonia, and reduce resistance to respiratory infections.
Sulfur Dioxide	SO_2, one of various oxides of sulfur, is a gas formed from combustion of fuels containing sulfur. Most SO_2 emissions are produced by stationary sources such as power plants. SO_2 is also formed when gasoline is extracted from crude oil in petroleum refineries and in other industrial processes. High concentrations of SO_2 cause severe respiratory distress (difficulty breathing), irritate the upper respiratory tract, and aggravate existing respiratory and cardiovascular disease.
Carbon Monoxide	CO is a colorless, odorless, poisonous gas produced by incomplete combustion of carbon in fuels. When CO enters the bloodstream, it acts as an asphyxiant by reducing the delivery of oxygen to the body's organs and tissues. It can affect the central nervous system and impair the brain's ability to function properly.
Mobile Source Air Toxics (including benzene, 1,3-butadiene, formaldehyde, acetaldehyde, acrolein, polycyclic organic matter, and naphthalene)	Mobile source air toxics are hazardous air pollutants that can cause cancer or other serious health effects.

The CAA requires the EPA to review periodically the NAAQS and the supporting science, and to revise the standards as appropriate.[2336] Schedules for recently completed and ongoing reviews are summarized here. In February 2019, the EPA issued a decision to retain the existing primary NAAQS for SO_2.[2337] For the ongoing reviews of the NAAQS for PM and ozone, the EPA intends to issue proposed decisions in early 2020 and final decisions in late 2020.

Nationally, levels of $PM_{2.5}$, ozone, NO_2, SO_2, CO and air toxics have declined significantly in the last 30 years. However, as of January 31, 2020, more than 130 million people lived in counties designated nonattainment for one or more of the NAAQS, and this figure does not include the people living in areas with a risk of exceeding a NAAQS in the future. Many Americans continue to be exposed to ambient concentrations of air toxics at levels which have the potential to cause adverse health effects. In addition, populations who live, work, or attend school near major roads experience elevated exposure concentrations to a wide range of air pollutants. As discussed in the FEIS, concentrations of many air pollutants are elevated near high-traffic roadways. If minority populations and low-income populations disproportionately live near such roads, then an issue of environmental justice (EJ) may be present. Comments were received from multiple entities expressing concern about emissions and EJ communities. The agencies considered EJ when considering the effects of this rule; EJ considerations and EJ-related comments received on the NPRM and DEIS are discussed in Section X and the FEIS.

Total emissions from on-road mobile sources (highway vehicles) have declined dramatically since 1970 because of pollution controls on vehicles and regulation of the chemical content of fuels, despite continuing increases in vehicle miles traveled (VMT). From 1970 to 2016, emissions from on-road mobile sources declined 89 percent for CO, 71 percent for NO_X, 59 percent for $PM_{2.5}$, 40 percent for PM_{10}, 93 percent for SO_2, and 90 percent for VOCs.[2338] The figure below further shows the highway vehicle emissions trends that indicate reduced pollutants regulated under NAAQS.

[2336] https://www.epa.gov/criteria-air-pollutants/naaqs-table.

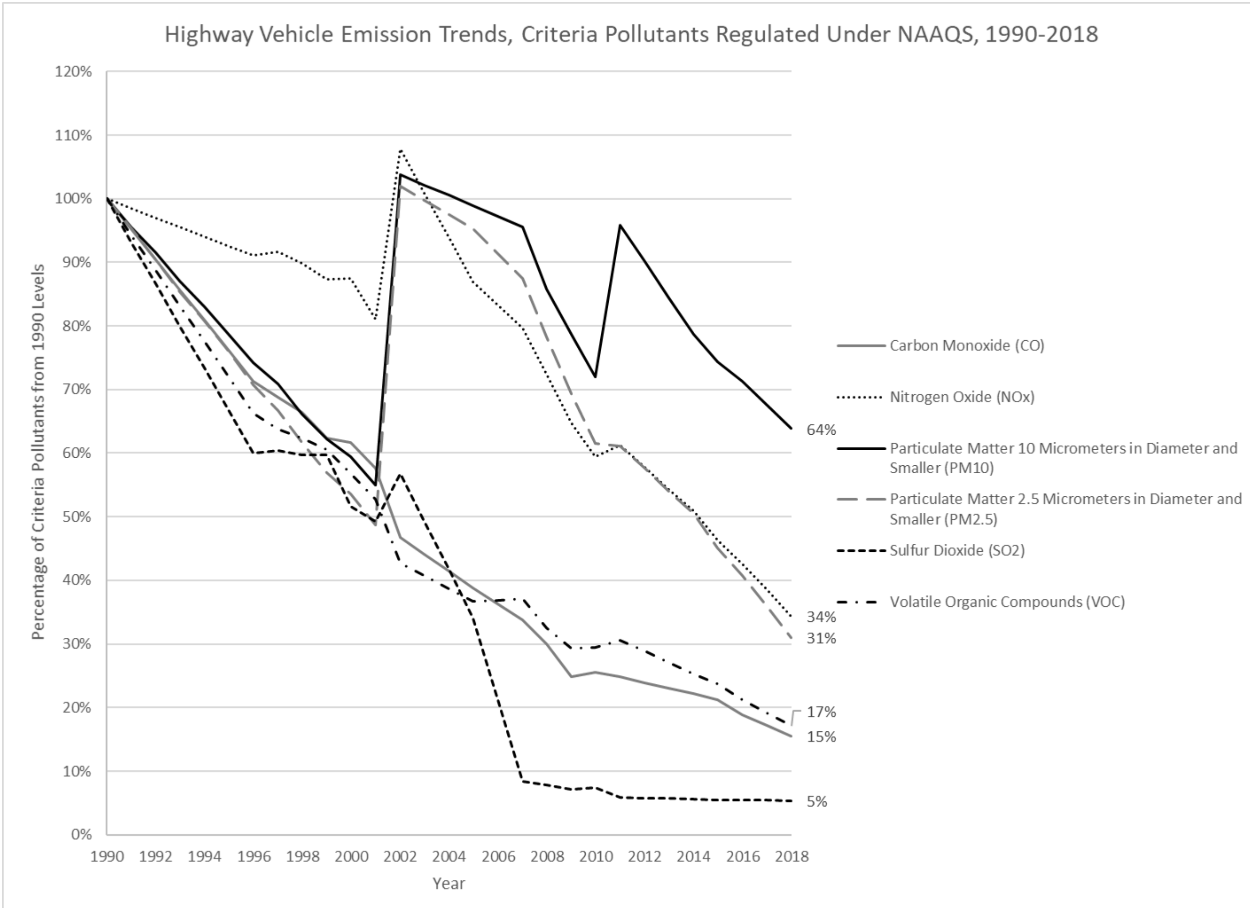

Figure VI-165 – Highway Vehicle Emission Trends, Criteria Pollutants Regulated under NAAQS, 1990-2018

Many commenters expressed concerns about the increase of emissions leading to regions in nonattainment for ozone and particulate matter and concerns regarding the inability to meet the NAAQS. The Center for Biological Diversity et al., and a number of State and local governments and government agencies asserted that State and local jurisdictions would be at jeopardy of becoming nonattainment areas under the proposed rule.[2339] CARB and the joint submission from the States of California and Cities of Oakland stated that the proposed rule would result in "increases in emissions [which] will undermine state implementation plans" and the proposed rule "would create an additional 1.24 tons per day of NOx emissions in the South Coast basin."[2340] The South Coast Air Quality Management District (SCAQMD) stated "[a]s a regional air quality district, we have limited authority to control emissions from mobile sources, and rely on the Federal government to take action," and they expressed concern about meeting the

[2339] Center for Biological Diversity, et al., NHTSA-2018-0067-12123.
[2340] CARB, NHTSA-2018-0067-11873, Joint Submission from States of California and Cities of Oakland, NHTSA-2018-0067-11735.

NAAQS under the proposed rule because, to meet that standard, the Basin would have to “reduce NOx emissions by 45% beyond existing requirements.”[2341]

In particular, commenters including PA DEP, the Regional Air Pollution Control Agency (RAPCA), and CARB, expressed the importance of existing CAFE standards in meeting the NAAQS.[2342] The Northeast States for Coordinated Air Use Management (NESCAUM) also asserted that regulation and reduction of GHG was necessary to meet the NAAQS, and “[o]ur states recognize the urgent need to reduce GHG emissions across all sectors of our economy.”[2343] Similarly, the agencies from Minnesota stated that “[t]he existing standards are critical for states to attain and maintain the NAAQS because vehicles account for about 24% of Minnesota’s overall air pollution emissions.”[2344] The Pima County Department of Environmental quality stated that “[f]reezing emission reductions for six years could put this region in jeopardy of being designated as non-attainment of the ozone standard and impact the health of many of our most vulnerable residents.”[2345] The Washington State Department of Ecology stated that increases in NOx and VOC would increase ozone levels in two areas at rise of ozone nonattainment in the Puget Sound and the Tri-Cities.”[2346] The Pennsylvania Department of Environmental Protection stated “[r]emoving currently realized emissions reductions and forgoing future achievable emissions reductions may make it more difficult for areas to attain and maintain the NAAQS. PADEP relies on emission reductions from mobile sources as part of its SIP planning to attain and maintain the NAAQS.”[2347] The North Carolina Department of Environmental Quality asserted that based on modeling analysis conducted by NCDEQ, “we believe that the fleet changes predicted by the CAFE modeling would lead to emissions increases that would interfere with the ability of some ozone maintenance areas to meet transportation conformity budgets and maintain compliance with the NAAQS.”[2348]

Many State commenters also expressed concern about their ability to conform with their State Implementation Plan (SIP) after this rule, as the Federal vehicle emissions standards previously set were incorporated into the SIPs and a rollback could result in further increased emissions.[2349] CARB stated that its “2016 SIP calls for reducing NOx emissions by approximately 6 tons per day,” and according to CARB, the proposed rule would not allow California to achieve its South Coast SIP commitments without dramatic countermeasures to reduce emissions elsewhere.[2350] Similarly, other agencies expressed concern about SIP requirements, such as PA DEP, who stated that “[b]y flatlining emissions standards at the MY 2020 level, the agencies’ Proposed Rule increases vehicle emissions. The Proposed Rule would interfere with Pennsylvania’s SIP planning requirements.”[2351]

The commenters expressed concerns that this final rule will present challenges in fulfilling existing SIP requirements and in attaining or maintaining the NAAQS, resulting in the need for emission reductions to offset increases due to this rule. This final rulemaking predominantly addresses fuel economy and CO_2 emissions of the light-duty vehicle fleet. It does not affect EPA's Tier 3 vehicle and gasoline (Tier 3) standards or California's low emission vehicle III (LEV III) emission standards. Tier 3 and LEV III regulations are predominantly responsible for regulating criteria pollutant emissions (e.g. NOx, VOCs, and carbon monoxide) from light-duty vehicles. While this final rulemaking will result in increases in the amount of gasoline produced, the number of vehicle re-fueling events and emissions of certain criteria pollutants and precursors the emissions impact will vary from area to area depending on factors such as the composition of the local vehicle fleet and the amount of gasoline produced in the area. The agencies expect that states will evaluate any adverse emissions or air quality impacts that result from the finalization of this rule in the context of state implementation plan development for relevant NAAQS, such as the relevant ozone and $PM_{2.5}$ NAAQS.

CARB, the joint submission from the States of California and Cities of Oakland, and other commenters also stated that the rulemaking "fails to meet the general conformity requirements under the Clean Air Act."[2352] Similarly, the Center for Biological Diversity, et al., stated "it is highly unlikely that the Proposal would not violate general conformity."[2353] The states and cities expressed that the General Conformity rule applies to this action because "[f]irst, an increase in criteria pollutants is reasonably foreseeable as the agencies quantified those emissions as part of this rulemaking. Second, the agencies can practically control those emissions as they possess ultimate regulatory authority over standards that govern vehicle operation."[2354] CARB stated "NHTSA's determination regarding its own conformity obligations… does not address conformity-related obligations EPA may have that flow from the joint rulemaking."[2355] SCAQMD similarly stated that "EPA counts as a federal agency that must comply with general conformity requirements. The proposal leaves unclear whether EPA also determined its actions comply with the general conformity requirements under 40 C.F.R. § 93.150 and general conformity SIP revisions allowed under 40 C.F.R. § 51.851."[2356] SCAQMD concluded that EPA must make its own conformity determination, "and it is not clear that EPA can rely on NHTSA's analysis given its dissimilar position in having continuing program responsibility over mobile source emissions."[2357]

EPA and NHTSA disagree with the commenters that this rule is subject to the CAA section 176(c) conformity requirement and the General Conformity regulations. A General Conformity evaluation is required for a general Federal action proposed to occur within specific nonattainment or maintenance areas. For a General Conformity evaluation to be necessary, the action must cause emissions of the criteria and precursor pollutants for which the areas are nonattainment or maintenance, and the emissions must originate within those areas. Further, the evaluation would require a demonstration that the action conforms to a specific State Implementation Plan's strategy for air pollution prevention and control applicable to the nonattainment and maintenance areas. In addition, any mitigation or offsets required to demonstrate

[2352] CARB, NHTSA-2018-0067-11873, Joint Submission from States of California and Cities of Oakland, NHTSA-2018-0067-11735.

[2357] SCAQMD, NHTSA_2018-0067-11813.

conformity may require written commitments that must be fulfilled, and offsets must occur during the same calendar year as the emission increases from the action.

While the EPA established the framework of methods and procedures that Federal agencies must follow when General Conformity applies to their actions, it is the responsibility of each Federal agency to prepare its own General Conformity evaluation for actions the agency supports, funds, permits or approves. When the EPA functions as a lead agency for actions that are subject to General Conformity, such as water projects, and the agency may issue permits or approve actions that require a General Conformity evaluation, EPA is responsible for and sometimes is required to prepare its own General Conformity evaluation. For the reasons specified here and in Section X.E.2, a General Conformity evaluation is not necessary for either agency.

As stated in section 4.1.1.4 of the DEIS and in section 4.1.1.4 of the FEIS, the agencies do not believe the proposed rule would result in either direct or indirect emissions as defined for General Conformity at 40 CFR § 93.152 or as required for applicability of the rule under section 93.153(b). Furthermore, as described in the proposal, emissions from operation of vehicles produced during the model years covered by this rule, while reasonably foreseeable, cannot be quantified with any certainty in any particular nonattainment or maintenance area. In addition, while the emissions rates from MY 2021-2026 vehicles are projected for future years in this rule, neither NHTSA nor EPA has control over where, when or how many of the vehicles will operate during a given future year or within a certain geographical area. Therefore, the emissions are not quantifiable. Furthermore, the General Conformity applicability analysis requires an analytical comparison of the emissions from MY 2021-2026 vehicles in some specific nonattainment or maintenance area in a specific future year, to the emissions projected from the operation of vehicles produced in other model years that would otherwise operate in that same area in the same future year. Without the identity of the future year vehicle fleet by type/make/model (which depends on a specific nonattainment or maintenance location and year), the net emissions, or total of direct and indirect emissions, cannot be quantified. Thus, this rule, in and of itself, is not subject to a General Conformity evaluation.

CARB stated that this rulemaking would, if finalized, invalidate the model underlying California's SIPs (the EMFAC 2014 model), which would result in the SIPs being disapproved by EPA.[2358] CARB expressed further concern that as a result of the Clean Air Act's conformity requirements, this disapproval would put significant limits on new RTPs, TIPS, or regionally significant transportation projects being adopted or approved in California.[2359]

The commenter expressed the opinion that if this rule is finalized, EPA would disapprove its SIPs because its on-road emission factor model (EMFAC) would be invalidated. The commenter also opined that such disapprovals would limit the ability of metropolitan planning organizations in California to make transportation conformity determinations for metropolitan transportation plans, transportation improvement programs and certain transportation projects. It is premature to assume that EPA will disapprove SIPs because they are based on EMFAC2014 or EMFAC2017. EPA will evaluate and address, as appropriate, the impact of the SAFE action on future SIP approval actions EMFAC2014 and EMFAC2017 remain approved emission factor models for SIPs and transportation conformity analyses in California. EPA is aware that California released adjustment factors to be applied to EMFAC2014 and EMFAC2017 model results to account for impacts of the SAFE Part 1 rule for on-road criteria pollutant emissions from light-duty vehicles.

[2358] CARB, NHTSA-2018-0067-11873.
[2359] CARB, NHTSA-2018-0067-11873.

EPA will work with CARB and DOT on the appropriate implementation of federal requirements based on current and available information.

Because passenger cars and light trucks are subject to gram-per-mile emissions standards for criteria pollutants, more fuel-efficient (and, correspondingly, less CO_2-intensive) vehicles are not, from the standpoint of air quality, "cleaner" vehicles. Therefore, to the extent that CAFE/CO_2 standards lead to changes in overall quantities of vehicular emissions that impact air quality, these are dominated by induced changes in highway travel. Changes in overall fuel consumption do lead to changes in emissions from "upstream" processes involved in supplying fuel to vehicles. Depending on how total vehicular emissions and total upstream emissions change in response to less stringent standards, overall emissions could increase or decrease. While small in magnitude, net impacts could also vary considerably among different geographic areas. In other words, CAFE and CO_2 standards impact fuel consumption and CO_2 emissions in ways that are direct and unambiguous, and impact air quality in ways that are indirect and ambiguous.

The following sections, included in prior rules setting fuel economy and CO_2 standards and updated based on EPA's latest scientific assessments, describe the criteria and air toxics considered in this rule, and their health and environmental effects. Additionally, the section that follows describes how the estimated effects of each pollutant were modeled in this rulemaking. Section VII discusses the interactions between upstream, tailpipe, and highway travel that result in the net emissions of criteria and air toxic pollutants estimated as a result of this rule.

(1) Particulate Matter

(a) Background

Particulate matter consists of both primary and secondary particles. Primary particles are emitted directly from sources, such as combustion-related activities (e.g., industrial activities, motor vehicles, biomass burning), while secondary particles are formed through atmospheric chemical reactions of gaseous precursors (e.g., sulfur oxides (SOx), nitrogen oxides (NOx) and volatile organic compounds (VOCs) and ammonia). From 2000 to 2017, national annual average $PM_{2.5}$ concentrations have declined by over 40%,[2360] largely reflecting reductions in emissions of precursor gases.

(b) Health Effects of PM

Scientific evidence spanning animal toxicological, controlled human exposure, and epidemiologic studies shows that exposure to ambient PM is associated with a broad range of health effects. The *Integrated Science Assessment for Particulate Matter* (PM ISA) (U.S. EPA 2009) synthesizes the toxicological, clinical and epidemiological evidence to determine whether each pollutant is causally related to an array of adverse human health outcomes associated with either acute (i.e., hours or days-long) or chronic (i.e. years-long) exposure; for each outcome, the ISA reports this relationship to be causal, likely to be causal, suggestive of a causal relationship, inadequate to infer a causal relationship or not likely to be a causal relationship.

In brief, the ISA for $PM_{2.5}$ found acute exposure to $PM_{2.5}$ to be causally related to cardiovascular effects and mortality (i.e., premature death), and respiratory effects as likely-to-be-causally related. The ISA identified cardiovascular effects and total mortality as being causally related to long-term exposure to $PM_{2.5}$

[2360] *See* https://www.epa.gov/air-trends/particulate-matter-pm25-trends and https://www.epa.gov/air-trends/particulate-matter-pm25-trends#pmnat for more information and respiratory effects as likely-to-be-causal; and the evidence was suggestive of a causal relationship for reproductive and developmental effects as well as cancer, mutagenicity and genotoxicity. The ISA for ozone found acute exposure to ozone to be causally related to respiratory effects, a likely-to-be-causal relationship with cardiovascular effects and total mortality and a suggestive relationship for central nervous system effects. Among chronic effects, the ISA reported a likely-to-be-causal relationship for respiratory outcomes and respiratory mortality, and suggestive relationship for cardiovascular effects, reproductive and developmental effects, central nervous system effects, and total mortality. DOT follows EPA's approach of estimating the incidence of air pollution effects for those health effects above where the ISA classified as either causal or likely-to-be-causal.

EPA's more recent Integrated Science Assessment for Particulate Matter (PM ISA), which was finalized in December 2019,[2361] summarizes the most recent health effects evidence for short- and long-term exposures to $PM_{2.5}$, $PM_{10—2.5}$, and ultrafine particles, characterizing the strength of the evidence and whether the relationship is likely to be causal nature in nature. The 2019 PM ISA reinforces the findings of the 2009 ISA, and supports the decision to continue monetizing the respiratory and cardiovascular health endpoints monetized in the current analysis. EPA is currently in the process of considering how the 2019 ISA and eventual decision by the Administrator regarding the National Ambient Air Quality Standards for particulate matter will be used to update forthcoming regulatory impact analysis.

(c) Current Concentrations

There are two primary NAAQS for $PM_{2.5}$: an annual standard (12.0 micrograms per cubic meter ($\mu g/m^3$)) set in 2012 and a 24-hour standard (35 $\mu g/m^3$) set in 2006, and two secondary NAAQS for $PM_{2.5}$: an annual standard (15.0 $\mu g/m^3$) set in 1997 and a 24-hour standard (35 $\mu g/m^3$) set in 2006.[2362]

There are many areas of the country that are currently in nonattainment for the annual and 24-hour primary $PM_{2.5}$ NAAQS. As of January 31, 2020, more than 19 million people lived in the 4 areas that are designated as nonattainment for the 1997 annual $PM_{2.5}$ NAAQS. These $PM_{2.5}$ nonattainment areas are comprised of 14 full or partial counties. As of January 31, 2020, 6 areas are designated as nonattainment for the 2012 annual PM2.5 NAAQS; these areas are composed of 16 full or partial counties with a population of more than 20 million. As of January 31, 2020, 14 areas are designated as nonattainment for the 2006 24-hour $PM_{2.5}$ NAAQS; these areas are composed of 41 full or partial counties with a population of more than 31 million. In total, there are currently 17 $PM_{2.5}$ nonattainment areas with a population of more than 32 million people.

The EPA has already adopted many mobile source emission control programs that are expected to reduce ambient PM concentrations. As a result of these and other federal, state and local programs, the number of areas that fail to meet the $PM_{2.5}$ NAAQS in the future is expected to decrease. However, even with the implementation of all current state and federal regulations, there are projected to be counties violating the $PM_{2.5}$ NAAQS well into the future.

[2362] The EPA is currently reviewing the PM NAAQS and anticipates completing this review in late 2020 Available at https://www.epa.gov/naaqs/particulate-matter-pm-air-quality-standards).

(2) Ozone

(a) Background

Ground-level ozone pollution is typically formed through reactions involving VOC and NO_X in the lower atmosphere in the presence of sunlight. These pollutants, often referred to as ozone precursors, are emitted by many types of sources, such as highway and nonroad motor vehicles and engines, power plants, chemical plants, refineries, makers of consumer and commercial products, industrial facilities, and smaller area sources.

The science of ozone formation, transport, and accumulation is complex. Ground-level ozone is produced and destroyed in a cyclical set of chemical reactions, many of which are sensitive to temperature and sunlight. When ambient temperatures and sunlight levels remain high for several days and the air is relatively stagnant, ozone and its precursors can build up and result in more ozone than typically occurs on a single high-temperature day. Ozone and its precursors can be transported hundreds of miles downwind from precursor emissions, resulting in elevated ozone levels even in areas with low local VOC or NO_X emissions.

(b) Health Effects of Ozone

This section provides a summary of the health effects associated with exposure to ambient concentrations of ozone.[2363] The information in this section is based on the information and conclusions in the February 2013 Integrated Science Assessment for Ozone (Ozone ISA), which formed the basis for EPA's revision to the primary and secondary standards in 2015.[2364] The Ozone ISA concludes that human exposures to ambient concentrations of ozone are associated with a number of adverse health effects and characterizes the weight of evidence for these health effects.[2365] The discussion below highlights the Ozone ISA's conclusions pertaining to health effects associated with both short-term and long-term periods of exposure to ozone.

For short-term exposure to ozone, the Ozone ISA concludes that respiratory effects, including lung function decrements, pulmonary inflammation, exacerbation of asthma, respiratory-related hospital admissions, and mortality, are causally associated with ozone exposure. It also concludes that cardiovascular effects, including decreased cardiac function and increased vascular disease, and total mortality are likely to be causally associated with short-term exposure to ozone and that evidence is suggestive of a causal relationship between central nervous system effects and short-term exposure to ozone.

For long-term exposure to ozone, the Ozone ISA concludes that respiratory effects, including new onset asthma, pulmonary inflammation and injury, are likely to be causally related with ozone exposure. The Ozone ISA characterizes the evidence as suggestive of a causal relationship for associations between long-

[2363] Human exposure to ozone varies over time due to changes in ambient ozone concentration and because people move between locations which have notable different ozone concentrations. Also, the amount of ozone delivered to the lung is not only influenced by the ambient concentrations but also by the individuals breathing route and rate.

[2364] U.S. EPA. Integrated Science Assessment of Ozone and Related Photochemical Oxidants (Final Report). U.S. Environmental Protection Agency, Washington, DC, EPA/600/R-10/076F, 2013. The ISA is available at http://cfpub.epa.gov/ncea/isa/recordisplay.cfm?deid=247492#Download.

[2365] The ISA evaluates evidence and draws conclusions on the causal nature of relationship between relevant pollutant exposures and health effects, assigning one of five "weight of evidence" determinations: causal relationship, likely to be a causal relationship, suggestive of, but not sufficient to infer, a causal relationship, inadequate to infer a causal relationship, and not likely to be a causal relationship. For more information on these levels of evidence, please refer to Table II in the Preamble of the ISA.

term ozone exposure and cardiovascular effects, reproductive and developmental effects, central nervous system effects and total mortality. The evidence is inadequate to infer a causal relationship between chronic ozone exposure and increased risk of lung cancer.

Finally, inter-individual variation in human responses to ozone exposure can result in some groups being at increased risk for detrimental effects in response to exposure. In addition, some groups are at increased risk of exposure due to their activities, such as outdoor workers or children. The Ozone ISA identified several groups that are at increased risk for ozone-related health effects. These groups are people with asthma, children and older adults, individuals with reduced intake of certain nutrients (i.e., Vitamins C and E), outdoor workers, and individuals having certain genetic variants related to oxidative metabolism or inflammation. Ozone exposure during childhood can have lasting effects through adulthood. Such effects include altered function of the respiratory and immune systems. Children absorb higher doses (normalized to lung surface area) of ambient ozone, compared to adults, due to their increased time spent outdoors, higher ventilation rates relative to body size, and a tendency to breathe a greater fraction of air through the mouth. Children also have a higher asthma prevalence compared to adults.

(c) Current Concentrations

The primary and secondary NAAQS for ozone are 8-hour standards with a level of 0.07 ppm. The most recent revision to the ozone standards was in 2015; the previous 8-hour ozone primary standard, set in 2008, had a level of 0.075 ppm.[2366] As of January 31, 2020, there were 36 ozone nonattainment areas for the 2008 ozone NAAQS, composed of 153 full or partial counties, with a population of more than 99 million. As of January 31, 2020, there were 51 ozone nonattainment areas for the 2015 ozone NAAQS, composed of 206 full or partial countries, with a population of more than 122 million. In total, there are currently 59 ozone nonattainment areas with a population of more than 127 million people.

States with ozone nonattainment areas are required to take action to bring those areas into attainment. The attainment date assigned to an ozone nonattainment area is based on the area's classification. The attainment dates for areas designated nonattainment for the 2008 8-hour ozone NAAQS are in the 2015 to 2032 timeframe, depending on the severity of the problem in each area. Nonattainment area attainment dates associated with areas designated for the 2015 NAAQS will be in the 2021-2038 timeframe, depending on the severity of the problem in each area.

EPA has already adopted many emission control programs that are expected to reduce ambient ozone levels. As a result of these and other federal, state and local programs, 8-hour ozone levels are expected to improve in the future. However, even with the implementation of all current state and federal regulations, there are projected to be counties violating the ozone NAAQS well into the future.

(3) Nitrogen Oxides

(a) Background

Oxides of nitrogen (NO_X) refers to nitric oxide and nitrogen dioxide (NO_2). For the NO_X NAAQS, NO_2 is the indicator. Most NO_2 is formed in the air through the oxidation of nitric oxide (NO) emitted when

[2366] The EPA is currently reviewing the PM NAAQS and anticipates completing this review in late 2020 Available at (https://www.epa.gov/naaqs/ozone-o3-air-quality-standards).

fuel is burned at a high temperature. NO_X is also a major contributor to secondary $PM_{2.5}$ formation. NO_X and VOC are the two major precursors of ozone.

(b) Health Effects of Nitrogen Oxides

The most recent review of the health effects of oxides of nitrogen completed by EPA can be found in the 2016 Integrated Science Assessment for Oxides of Nitrogen - Health Criteria (Oxides of Nitrogen ISA).[2367] The primary source of NO_2 is motor vehicle emissions, and ambient NO_2 concentrations tend to be highly correlated with other traffic-related pollutants. Thus, a key issue in characterizing the causality of NO_2-health effect relationships was evaluating the extent to which studies supported an effect of NO_2 that is independent of other traffic-related pollutants. EPA concluded that the findings for asthma exacerbation integrated from epidemiologic and controlled human exposure studies provided evidence that is sufficient to infer a causal relationship between respiratory effects and short-term NO_2 exposure. The strongest evidence supporting an independent effect of NO_2 exposure comes from controlled human exposure studies demonstrating increased airway responsiveness in individuals with asthma following ambient-relevant NO_2 exposures. The coherence of this evidence with epidemiologic findings for asthma hospital admissions and ED visits as well as lung function decrements and increased pulmonary inflammation in children with asthma describe a plausible pathway by which NO_2 exposure can cause an asthma exacerbation. The 2016 ISA for Oxides of Nitrogen also concluded that there is likely to be a causal relationship between long-term NO_2 exposure and respiratory effects. This conclusion is based on new epidemiologic evidence for associations of NO_2 with asthma development in children combined with biological plausibility from experimental studies.

In evaluating a broader range of health effects, the 2016 ISA for Oxides of Nitrogen concluded evidence is "suggestive of, but not sufficient to infer, a causal relationship" between short-term NO_2 exposure and cardiovascular effects and mortality and between long-term NO_2 exposure and cardiovascular effects and diabetes, birth outcomes, and cancer. In addition, the scientific evidence is inadequate (insufficient consistency of epidemiologic and toxicological evidence) to infer a causal relationship for long-term NO_2 exposure with fertility, reproduction, and pregnancy, as well as with postnatal development. A key uncertainty in understanding the relationship between these non-respiratory health effects and short- or long-term exposure to NO_2 is copollutant confounding, particularly by other roadway pollutants. The available evidence for non-respiratory health effects does not adequately address whether NO_2 has an independent effect or whether it primarily represents effects related to other or a mixture of traffic-related pollutants.

The 2016 ISA for Oxides of Nitrogen concluded that people with asthma, children, and older adults are at increased risk for NO_2-related health effects. In these groups and life stages, NO_2 is consistently related to larger effects on outcomes related to asthma exacerbation, for which there is confidence in the relationship with NO_2 exposure.

(c) Current Concentrations

On April 6, 2018, based on a review of the full body of scientific evidence, EPA issued a decision to retain the current primary NAAQS for NO_2. The EPA has concluded that the current NAAQS are requisite

[2367] U.S. EPA. Integrated Science Assessment for Oxides of Nitrogen – Health Criteria (2016 Final Report). U.S. Environmental Protection Agency, Washington, DC, EPA/600/R-15/068, 2016.

to protect the public health, including the at-risk populations of older adults, children and people with asthma, with an adequate margin of safety. The primary NAAQS for NO_2 are a one-hour standard with a level of 100 ppb, based on the three-year average of 98th percentile of the annual distribution of daily maximum one-hour concentrations, and an annual standard at a level of 53 ppb.

(4) Sulfur Oxides

(a) Background

Sulfur dioxide (SO_2), a member of the sulfur oxide (SO_X) family of gases, is formed from burning fuels containing sulfur (e.g., coal or oil derived), extracting gasoline from oil, or extracting metals from ore. SO_2 and its gas phase oxidation products can dissolve in water droplets and further oxidize to form sulfuric acid which reacts with ammonia to form sulfates, which are important components of ambient PM.

(b) Health Effects of SO_2

This section provides an overview of the health effects associated with SO_2. Additional information on the health effects of SO_2 can be found in the 2017 Integrated Science Assessment for Sulfur Oxides - Health Criteria (SO_x ISA).[2368] Following an extensive evaluation of health evidence from animal toxicological, controlled human exposure, and epidemiologic studies, the EPA has concluded that there is a causal relationship between respiratory health effects and short -term exposure to SO_2. The immediate effect or SO_2 on the respiratory system in humans is bronchoconstriction. People with asthma are more sensitive to the effects of SO_2, likely resulting from preexisting inflammation associated with this disease. In addition to those with asthma (both children and adults), there is suggestive evidence that all children and older adults may be at increased risk of SO_2-related health effects. In free-breathing laboratory studies involving controlled human exposures to SO_2, respiratory effects have consistently been observed following 5-10 min exposures at SO2 concentrations ≥ 400 ppb in people with asthma engaged in moderate to heavy levels of exercise, with respiratory effects occurring at concentrations as low as 200 ppb in some individuals with asthma. A clear concentration-response relations hip has been demonstrated in these studies following exposures to SO_2 at concentrations between 200 and 1000 ppb, both in terms of increasing severity of respiratory symptoms and decrements in lung function, as well as the percentage of individuals with asthma adversely affected. Epidemiologic studies have reported positive associations between short-term ambient SO_2 concentrations and hospital admissions and emergency department visits for asthma and for all respiratory causes, particularly among children and older adults (≥65 years). The studies provide supportive evidence for the causal relationship.

For long-term SO_2 exposure and respiratory effects, the EPA has concluded that the evidence is suggestive or a causal relationship. This conclusion is based on new epidemiologic evidence for positive associations between long-term SO_2 exposure and increases in asthma incidence among children, together with animal toxicological evidence that provides a pathophysiologic basis for the development of asthma. However, uncertainty remains regarding the influence of other pollutants on the observed associations with SO_2 because these epidemiologic studies have not examined the potential for copollutant confounding.

Consistent associations between short-term exposure to SO_2 and mortality have been observed in epidemiologic studies, with larger effect estimates reported for respiratory mortality than for cardiovascular

---

[2368] U.S. EPA (2017). Integrated Science Assessment (ISA) for Sulfur Oxides. Health Criteria (Final Report). EPA 600/R-17/451. Washington, DC, U.S. EPA.

mortality. While this finding is consistent with the demonstrated effects of SO_2 on respiratory morbidity, uncertainty remains with respect to the interpretation of these observed mortality associations due to potential confounding by various copollutants. Therefore, the EPA has concluded that the overall evidence is suggestive of a causal relationship between short-term exposure to SO_2 and mortality.

(c) Current Concentrations

On February 25, 2019, the EPA announced its decision to retain, without revision, the existing NAAQS for SO_X of 75 ppb, as the annual 99th percentile of daily maximum SO_2 concentrations, averaged over three years (84 FR 9866, March 18, 2019). The existing primary (health-based) standard provides health protection for the at-risk group (people with asthma) against respiratory effects following short-term (e.g., 5-minute) exposures to SO_2 in ambient air. The EPA has been finalizing the initial area designations for the 2010 SO_2 NAAQS in phases and completed designations for most of the country in December 2017. The EPA is under a court order to finalize initial designations by December 31, 2020, for a remaining set of about 50 areas where states have deployed new SO_2 monitoring networks. As of January 31, 2020 there are 34 nonattainment areas for the 2010 SO_2 NAAQS. As of January 31, 2020 there also remain eight nonattainment areas for the primary annual SO_2 NAAQS set in 1971.

(5) Carbon Monoxide

(a) Background

Carbon monoxide is a colorless, odorless gas emitted from combustion processes. Nationally, particularly in urban areas, the majority of CO emissions to ambient air come from mobile sources.[2369]

(b) Health Effects of Carbon Monoxide

Information on the health effects of CO can be found in the January 2010 Integrated Science Assessment for Carbon Monoxide (CO ISA) associated with the 2010 evaluation of the NAAQS.[2370] The CO ISA presents conclusions regarding the presence of causal relationships between CO exposure and categories of adverse health effects. This section provides a summary of the health effects associated with exposure to ambient concentrations of CO, along with the ISA conclusions.[2371]

Controlled human exposure studies of subjects with coronary artery disease show a decrease in the time to onset of exercise-induced angina (chest pain) and electrocardiogram changes following CO exposure. In addition, epidemiologic studies observed associations between short-term CO exposure and cardiovascular morbidity, particularly increased emergency room visits and hospital admissions for coronary heart disease (including ischemic heart disease, myocardial infarction, and angina). Some epidemiologic evidence is also available for increased hospital admissions and emergency room visits for congestive heart failure and cardiovascular disease as a whole. The CO ISA concludes that a causal relationship is likely to exist between short-term exposures to CO and cardiovascular morbidity. It also concludes that available data

---

[2370] U.S. EPA (2010). Integrated Science Assessment for Carbon Monoxide (Final Report). U.S. Environmental Protection Agency, Washington, DC, EPA/600/R-09/019F, 2010. Available at http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=218686.
[2371] Personal exposure includes contributions from many sources, and in many different environments. Total personal exposure to CO includes both ambient and nonambient components; and both components may contribute to adverse health effects.

are inadequate to conclude that a causal relationship exists between long-term exposures to CO and cardiovascular morbidity.

Animal studies show various neurological effects with in-utero CO exposure. Controlled human exposure studies report central nervous system and behavioral effects following low-level CO exposures, although the findings have not been consistent across all studies. The CO ISA concludes the evidence is suggestive of a causal relationship with both short- and long-term exposure to CO and central nervous system effects.

A number of studies cited in the CO ISA have evaluated the role of CO exposure in birth outcomes such as preterm birth or cardiac birth defects. There is limited epidemiologic evidence of a CO-induced effect on preterm births and birth defects, with weak evidence for a decrease in birth weight. Animal toxicological studies have found perinatal CO exposure to affect birth weight, as well as other developmental outcomes. The CO ISA concludes the evidence is suggestive of a causal relationship between long-term exposures to CO and developmental effects and birth outcomes.

Epidemiologic studies provide evidence of associations between short-term CO concentrations and respiratory morbidity such as changes in pulmonary function, respiratory symptoms, and hospital admissions. A limited number of epidemiologic studies considered copollutants such as ozone, SO_2, and PM in two-pollutant models and found that CO risk estimates were generally robust, although this limited evidence makes it difficult to disentangle effects attributed to CO itself from those of the larger complex air pollution mixture. Controlled human exposure studies have not extensively evaluated the effect of CO on respiratory morbidity. Animal studies at levels of 50-100 ppm CO show preliminary evidence of altered pulmonary vascular remodeling and oxidative injury. The CO ISA concludes that the evidence is suggestive of a causal relationship between short-term CO exposure and respiratory morbidity, and inadequate to conclude that a causal relationship exists between long-term exposure and respiratory morbidity.

Finally, the CO ISA concludes that the epidemiologic evidence is suggestive of a causal relationship between short-term concentrations of CO and mortality. Epidemiologic evidence suggests an association exists between short-term exposure to CO and mortality, but limited evidence is available to evaluate cause-specific mortality outcomes associated with CO exposure. In addition, the attenuation of CO risk estimates which was often observed in copollutant models contributes to the uncertainty as to whether CO is acting alone or as an indicator for other combustion-related pollutants. The CO ISA also concludes that there is not likely to be a causal relationship between relevant long-term exposures to CO and mortality.

(c) Current Concentrations

There are two primary NAAQS for CO: an 8-hour standard (9 ppm) and a 1-hour standard (35 ppm). The primary NAAQS for CO were retained in August 2011. There are currently no CO nonattainment areas; as of September 27, 2010, all CO nonattainment areas have been predesignated to attainment.

The past designations were based on the existing community-wide monitoring network. EPA made an addition to the ambient air monitoring requirements for CO during the 2011 NAAQS review. Those new requirements called for CO monitors to be operated near roads in Core Based Statistical Areas (CBSAs) of 1 million or more persons (76 FR 54294, August 31, 2011).

(6) Diesel Exhaust

(a) Background

Diesel exhaust consists of a complex mixture composed of particulate matter, carbon dioxide, oxygen, nitrogen, water vapor, carbon monoxide, nitrogen compounds, sulfur compounds, and numerous low-molecular-weight hydrocarbons. A number of these gaseous hydrocarbon components are individually known to be toxic, including aldehydes, benzene and 1,3-butadiene. The diesel particulate matter present in diesel exhaust consists mostly of fine particles (< 2.5 µm), of which a significant fraction is ultrafine particles (< 0.1 µm). These particles have a large surface area which makes them an excellent medium for adsorbing organics, and their small size makes them highly respirable. Many of the organic compounds present in the gases and on the particles, such as polycyclic organic matter, are individually known to have mutagenic and carcinogenic properties.

Diesel exhaust varies significantly in chemical composition and particle sizes between different engine types (heavy-duty, light-duty), engine operating conditions (idle, acceleration, deceleration), and fuel formulations (high/low sulfur fuel). Also, there are emissions differences between on-road and nonroad engines because the nonroad engines are generally of older technology. After being emitted in the engine exhaust, diesel exhaust undergoes dilution as well as chemical and physical changes in the atmosphere. The lifetime for some of the compounds present in diesel exhaust ranges from hours to days.

(b) Health Effects of Diesel Exhaust

In EPA's 2002 Diesel Health Assessment Document (Diesel HAD), exposure to diesel exhaust was classified as likely to be carcinogenic to humans by inhalation from environmental exposures, in accordance with the revised draft 1996/1999 EPA cancer guidelines.[2372,2373] A number of other agencies (National Institute for Occupational Safety and Health, the International Agency for Research on Cancer, the World Health Organization, California EPA, and the U.S. Department of Health and Human Services) had made similar hazard classifications prior to 2002. EPA also concluded in the 2002 Diesel HAD that it was not possible to calculate a cancer unit risk for diesel exhaust due to limitations in the exposure data for the occupational groups or the absence of a dose-response relationship.

In the absence of a cancer unit risk, the Diesel HAD sought to provide additional insight into the significance of the diesel exhaust cancer hazard by estimating possible ranges of risk that might be present in the population. An exploratory analysis was used to characterize a range of possible lung cancer risk. The outcome was that environmental risks of cancer from long-term diesel exhaust exposures could plausibly range from as low as 10^{-5} to as high as 10^{-3}. Because of uncertainties, the analysis acknowledged that the risks could be lower than 10^{-5}, and a zero risk from diesel exhaust exposure could not be ruled out.

Non-cancer health effects of acute and chronic exposure to diesel exhaust emissions are also of concern to EPA. EPA derived a diesel exhaust reference concentration (RfC) from consideration of four well-conducted chronic rat inhalation studies showing adverse pulmonary effects. The RfC is 5 µg/m^3 for

---

[2372] U.S. EPA. (1999). *Guidelines for Carcinogen Risk Assessment*. Review Draft. NCEA-F-0644, July. Washington, DC: U.S. EPA. Retrieved on March 19, 2009 from http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=54932.
[2373] U.S. EPA (2002). *Health Assessment Document for Diesel Engine Exhaust.* EPA/600/8-90/057F Office of Research and Development, Washington DC. Retrieved on March 17, 2009 from http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=29060. pp. 1-1 & 1-2.

diesel exhaust measured as diesel particulate matter. This RfC does not consider allergenic effects such as those associated with asthma or immunologic or the potential for cardiac effects. There was emerging evidence in 2002, discussed in the Diesel HAD, that exposure to diesel exhaust can exacerbate these effects, but the exposure-response data were lacking at that time to derive an RfC based on these then-emerging considerations. The EPA Diesel HAD stated, "With [diesel particulate matter] being a ubiquitous component of ambient PM, there is an uncertainty about the adequacy of the existing [diesel exhaust] noncancer database to identify all of the pertinent [diesel exhaust]-caused noncancer health hazards." The Diesel HAD also noted "that acute exposure to [diesel exhaust] has been associated with irritation of the eye, nose, and throat, respiratory symptoms (cough and phlegm), and neurophysiological symptoms such as headache, lightheadedness, nausea, vomiting, and numbness or tingling of the extremities." The Diesel HAD noted that the cancer and noncancer hazard conclusions applied to the general use of diesel engines then on the market and as cleaner engines replace a substantial number of existing ones, the applicability of the conclusions would need to be reevaluated.

It is important to note that the Diesel HAD also briefly summarized health effects associated with ambient PM and discusses EPA's then-annual $PM_{2.5}$ NAAQS of 15 µg/m^3. In 2012, EPA revised the annual $PM_{2.5}$ NAAQS to 12 µg/m^3. There is a large and extensive body of human data showing a wide spectrum of adverse health effects associated with exposure to ambient PM, of which diesel exhaust is an important component. The $PM_{2.5}$ NAAQS is designed to provide protection from the noncancer health effects and premature mortality attributed to exposure to $PM_{2.5}$. The contribution of diesel PM to total ambient PM varies in different regions of the country and also, within a region, from one area to another. The contribution can be high in near-roadway environments, for example, or in other locations where diesel engine use is concentrated.

Since 2002, several new studies have been published which continue to report increased lung cancer risk with occupational exposure to diesel exhaust from older engines. Of particular note since 2011 are three new epidemiology studies which have examined lung cancer in occupational populations, for example, truck drivers, underground nonmetal miners and other diesel motor-related occupations. These studies reported increased risk of lung cancer with exposure to diesel exhaust with evidence of positive exposure-response relationships to varying degrees.[2374,2375,2376] These newer studies (along with others that have appeared in the scientific literature) add to the evidence EPA evaluated in the 2002 Diesel HAD and further reinforces the concern that diesel exhaust exposure likely poses a lung cancer hazard. The findings from these newer studies do not necessarily apply to newer technology diesel engines because the newer engines have large reductions in the emission constituents compared to older technology diesel engines.

In light of the growing body of scientific literature evaluating the health effects of exposure to diesel exhaust, in June 2012 the World Health Organization's International Agency for Research on Cancer (IARC), a recognized international authority on the carcinogenic potential of chemicals and other agents, evaluated the full range of cancer-related health effects data for diesel engine exhaust. IARC concluded that

diesel exhaust should be regarded as “carcinogenic to humans.”[2377] This designation was an update from its 1988 evaluation that considered the evidence to be indicative of a “probable human carcinogen.”

(c) Current Concentrations

Because DPM is part of overall ambient PM and cannot be easily distinguished from overall PM, the agencies do not have direct measurements of DPM in the ambient air. DPM concentrations are estimated using ambient air quality modeling based on DPM emission inventories. DPM emission inventories are computed as the exhaust PM emissions from mobile sources combusting diesel or residual oil fuel. DPM concentrations were recently estimated as part of the 2014 NATA. Areas with high concentrations are clustered in the Northeast, Great Lake States, California, and the Gulf Coast States and are also distributed throughout the rest of the U.S.

(7) Air Toxics

(a) Background

Light-duty vehicle emissions contribute to ambient levels of air toxics that are known or suspected human or animal carcinogens, or that have noncancer health effects. The population experiences an elevated risk of cancer and other noncancer health effects from exposure to the class of pollutants known collectively as “air toxics.”[2378] These compounds include, but are not limited to, benzene, 1,3-butadiene, formaldehyde, acetaldehyde, acrolein, polycyclic organic matter, and naphthalene. These compounds were identified as national or regional risk drivers or contributors in the 2014 or past National-scale Air Toxics Assessment and have significant inventory contributions from mobile sources.[2379,2380]

(b) Benzene

EPA’s Integrated Risk Information System (IRIS) database lists benzene as a known human carcinogen (causing leukemia) by all routes of exposure, and concludes that exposure is associated with additional health effects, including genetic changes in both humans and animals and increased proliferation of bone marrow cells in mice.[2381, 2382, 2383] EPA states in its IRIS database that data indicate a causal relationship between benzene exposure and acute lymphocytic leukemia and suggest a relationship between

benzene exposure and chronic non-lymphocytic leukemia and chronic lymphocytic leukemia. EPA's IRIS documentation for benzene also lists a range of 2.2 x 10-6 to 7.8 x 10-6 per µg/m^3 as the unit risk estimate (URE) for benzene.[2384, 2385] The International Agency for Research on Cancer (IARC) has determined that benzene is a human carcinogen and the U.S. Department of Health and Human Services (DHHS) has characterized benzene as a known human carcinogen.[2386,2387]

A number of adverse noncancer health effects including blood disorders, such as pre- leukemia and aplastic anemia, have also been associated with long-term exposure to benzene. The most sensitive noncancer effect observed in humans, based on current data, is the depression of the absolute lymphocyte count in blood. EPA's inhalation reference concentration (RfC) for benzene is 30 µg/m^3. The RfC is based on suppressed absolute lymphocyte counts seen in humans under occupational exposure conditions. In addition, recent work, including studies sponsored by the Health Effects Institute, provides evidence that biochemical responses are occurring at lower levels of benzene exposure than previously known.[2388, 2389,2390,2391] EPA's IRIS program has not yet evaluated these new data. EPA does not currently have an acute reference concentration for benzene. The Agency for Toxic Substances and Disease Registry (ATSDR) Minimal Risk Level (MRL) for acute exposure to benzene is 29 µg/m^3 for 1-14 days exposure.

(c) 1,3-Butadiene

EPA has characterized 1,3-butadiene as carcinogenic to humans by inhalation.[2392,2393] The IARC has determined that 1,3-butadiene is a human carcinogen and the U.S. DHHS has characterized 1,3-butadiene as

---

[2384] A unit risk estimate is defined as the increase in the lifetime risk of an individual who is exposed for a lifetime to 1 µg/m^3 benzene in air.

a known human carcinogen.[2394,2395,2396,2397] There are numerous studies consistently demonstrating that 1,3-butadiene is metabolized into genotoxic metabolites by experimental animals and humans. The specific mechanisms of 1,3-butadiene-induced carcinogenesis are unknown; however, the scientific evidence strongly suggests that the carcinogenic effects are mediated by genotoxic metabolites. Animal data suggest that females may be more sensitive than males for cancer effects associated with 1,3-butadiene exposure; there are insufficient data in humans from which to draw conclusions about sensitive subpopulations. The URE for 1,3-butadiene is 3×10^{-5} per $\mu g/m^3$.[2398] 1,3-butadiene also causes a variety of reproductive and developmental effects in mice; no human data on these effects are available. The most sensitive effect was ovarian atrophy observed in a lifetime bioassay of female mice.[2399] Based on this critical effect and the benchmark concentration methodology, an RfC for chronic health effects was calculated at 0.9 ppb (approximately 2 $\mu g/m^3$).

(d) Formaldehyde

In 1991, EPA concluded that formaldehyde is a carcinogen based on nasal tumors in animal bioassays.[2400] An Inhalation URE for cancer and a Reference Dose for oral noncancer effects were developed by the agency and posted on the IRIS database. Since that time, the National Toxicology Program (NTP) and International Agency for Research on Cancer (IARC) have concluded that formaldehyde is a known human carcinogen.[2401,2402,2403]

The conclusions by IARC and NTP reflect the results of epidemiologic research published since 1991 in combination with previous animal, human and mechanistic evidence. Research conducted by the National Cancer Institute reported an increased risk of nasopharyngeal cancer and specific lymph hematopoietic

malignancies among workers exposed to formaldehyde.[2404,2405,2406] A National Institute of Occupational Safety and Health study of garment workers also reported increased risk of death due to leukemia among workers exposed to formaldehyde.[2407] Extended follow-up of a cohort of British chemical workers did not report evidence of an increase in nasopharyngeal or lymph hematopoietic cancers, but a continuing statistically significant excess in lung cancers was reported.[2408] Finally, a study of embalmers reported formaldehyde exposures to be associated with an increased risk of myeloid leukemia but not brain cancer.[2409]

Health effects of formaldehyde in addition to cancer were reviewed by the Agency for Toxics Substances and Disease Registry in 1999,[2410] supplemented in 2010,[2411] and by the World Health Organization.[2412] These organizations reviewed the scientific literature concerning health effects linked to formaldehyde exposure to evaluate hazards and dose response relationships and defined exposure concentrations for minimal risk levels (MRLs). The health endpoints reviewed included sensory irritation of eyes and respiratory tract, reduced pulmonary function, nasal histopathology, and immune system effects. In addition, research on reproductive and developmental effects and neurological effects were discussed along with several studies that suggest that formaldehyde may increase the risk of asthma—particularly in the young.

EPA released a draft Toxicological Review of Formaldehyde – Inhalation Assessment through the IRIS program for peer review by the National Research Council (NRC) and public comment in June 2010.[2413] The draft assessment reviewed more recent research from animal and human studies on cancer and other health effects. The NRC released their review report in April 2011.[2414] EPA is currently developing a revised draft assessment in response to this review.

(e) Acetaldehyde

Acetaldehyde is classified in EPA's IRIS database as a probable human carcinogen, based on nasal tumors in rats, and is considered toxic by the inhalation, oral, and intravenous routes.2415 The URE in IRIS for acetaldehyde is 2.2 × 10^{-6} per μg/m^3.[2416] Acetaldehyde is reasonably anticipated to be a human carcinogen by the U.S. DHHS in the 13th Report on Carcinogens and is classified as possibly carcinogenic to humans (Group 2B) by the IARC.[2417,2418] Acetaldehyde is currently listed on the IRIS Program Multi-Year Agenda for reassessment within the next few years.

The primary noncancer effects of exposure to acetaldehyde vapors include irritation of the eyes, skin, and respiratory tract.[2419] In short-term (4 week) rat studies, degeneration of olfactory epithelium was observed at various concentration levels of acetaldehyde exposure.[2420,2421] Data from these studies were used by EPA to develop an inhalation reference concentration of 9 μg/m^3. Some asthmatics have been shown to be a sensitive subpopulation to decrements in functional expiratory volume (FEV1 test) and bronchoconstriction upon acetaldehyde inhalation.[2422]

(f) Acrolein

EPA most recently evaluated the toxicological and health effects literature related to acrolein in 2003 and concluded that the human carcinogenic potential of acrolein could not be determined because the available data were inadequate. No information was available on the carcinogenic effects of acrolein in humans and the animal data provided inadequate evidence of carcinogenicity.[2423] The IARC determined in 1995 that acrolein was not classifiable as to its carcinogenicity in humans.[2424]

Lesions to the lungs and upper respiratory tract of rats, rabbits, and hamsters have been observed after sub-chronic exposure to acrolein.[2425] The agency has developed an RfC for acrolein of 0.02 µg/m^3 and an RfD of 0.5 µg/kg-day.[2426]

Acrolein is extremely acrid and irritating to humans when inhaled, with acute exposure resulting in upper respiratory tract irritation, mucus hypersecretion and congestion. The intense irritancy of this carbonyl has been demonstrated during controlled tests in human subjects, who suffer intolerable eye and nasal mucosal sensory reactions within minutes of exposure.[2427] These data and additional studies regarding acute effects of human exposure to acrolein are summarized in EPA's 2003 Toxicological Review of Acrolein.[2428] Studies in humans indicate that levels as low as 0.09 ppm (0.21 mg/m^3) for five minutes may elicit subjective complaints of eye irritation with increasing concentrations leading to more extensive eye, nose and respiratory symptoms. Acute exposures in animal studies report bronchial hyper-responsiveness. Based on animal data (more pronounced respiratory irritancy in mice with allergic airway disease in comparison to non-diseased mice[2429]) and demonstration of similar effects in humans (e.g., reduction in respiratory rate), individuals with compromised respiratory function (e.g., emphysema, asthma) are expected to be at increased risk of developing adverse responses to strong respiratory irritants such as acrolein. EPA does not currently have an acute reference concentration for acrolein. The available health effect reference values for acrolein have been summarized by EPA and include an ATSDR MRL for acute exposure to acrolein of 7 µg/m^3 for 1-14 days' exposure; and Reference Exposure Level (REL) values from the California Office of Environmental Health Hazard Assessment (OEHHA) for one-hour and 8-hour exposures of 2.5 µg/m^3 and 0.7 µg/m^3, respectively.[2430]

(g) Polycyclic Organic Matter

The term polycyclic organic matter (POM) defines a broad class of compounds that includes the polycyclic aromatic hydrocarbon compounds (PAHs). One of these compounds, naphthalene, is discussed separately below. POM compounds are formed primarily from combustion and are present in the atmosphere in gas and particulate form. Cancer is the major concern from exposure to POM. Epidemiologic studies have reported an increase in lung cancer in humans exposed to diesel exhaust, coke oven emissions,

roofing tar emissions, and cigarette smoke; all of these mixtures contain POM compounds.[2431,2432] Animal studies have reported respiratory tract tumors from inhalation exposure to benzo[a]pyrene and alimentary tract and liver tumors from oral exposure to benzo[a]pyrene.[2433] In 1997 EPA classified seven PAHs (benzo[a]pyrene, benz[a]anthracene, chrysene, benzo[b]fluoranthene, benzo[k]fluoranthene, dibenz[a,h]anthracene, and indeno[1,2,3-cd]pyrene) as Group B2, probable human carcinogens.[2434] Since that time, studies have found that maternal exposures to PAHs in a population of pregnant women were associated with several adverse birth outcomes, including low birth weight and reduced length at birth, as well as impaired cognitive development in preschool children (3 years of age).[2435,2436] These and similar studies are being evaluated as a part of the ongoing IRIS reassessment of health effects associated with exposure to benzo[a]pyrene.

(h) Naphthalene

Naphthalene is found in small quantities in gasoline and diesel fuels. Naphthalene emissions have been measured in larger quantities in both gasoline and diesel exhaust compared with evaporative emissions from mobile sources, indicating it is primarily a product of combustion. Acute (short-term) exposure of humans to naphthalene by inhalation, ingestion, or dermal contact is associated with hemolytic anemia and damage to the liver and the nervous system.[2437] Chronic (long term) exposure of workers and rodents to naphthalene has been reported to cause cataracts and retinal damage.[2438] The National Toxicology Program listed naphthalene as "reasonably anticipated to be a human carcinogen" in 2004 on the basis of bioassays reporting clear evidence of carcinogenicity in rats and some evidence of carcinogenicity in mice.[2439] California EPA has released a new risk assessment for naphthalene, and the IARC has reevaluated naphthalene and re-classified it as Group 2B: possibly carcinogenic to humans.[2440]

Naphthalene also causes a number of chronic non-cancer effects in animals, including abnormal cell changes and growth in respiratory and nasal tissues.[2441] The current EPA IRIS assessment includes noncancer data on hyperplasia and metaplasia in nasal tissue that form the basis of the inhalation RfC of 3 $\mu g/m^3$.[2442] The ATSDR MRL for acute exposure to naphthalene is 0.6 mg/kg/day.

(i) Other Air Toxics

In addition to the compounds described above, other compounds in gaseous hydrocarbon and PM emissions from motor vehicles will be affected by this action. Mobile source air toxic compounds that will potentially be impacted include ethylbenzene, propionaldehyde, toluene, and xylene. Information regarding the health effects of these compounds can be found in EPA's IRIS database.[2443]

(j) Current Concentrations

The most recent available data indicate that the majority of Americans continue to be exposed to ambient concentrations of air toxics at levels which have the potential to cause adverse health effects. The levels of air toxics to which people are exposed vary depending on where people live and work and the kinds of activities in which they engage, as discussed in detail in EPA's most recent Mobile Source Air Toxics Rule. According to the National Air Toxic Assessment (NATA) for 2014, mobile sources were responsible for 51 percent of outdoor anthropogenic toxic emissions and were the largest contributor to cancer and noncancer risk from directly emitted pollutants. Mobile sources are also significant contributors to precursor emissions which react to form air toxics. Formaldehyde is the largest contributor to cancer risk of all 71 pollutants quantitatively assessed in the 2014 NATA. Mobile sources were responsible for more than 30 percent of primary anthropogenic emissions of this pollutant in 2014 and also contribute to formaldehyde precursor emissions. Benzene is also a large contributor to cancer risk, and mobile sources account for approximately 54 percent of ambient exposure. Over the years, EPA has implemented a number of mobile source and fuel controls which have resulted in VOC reductions, which also reduced formaldehyde, benzene and other air toxic emissions.

(k) Exposure and Health Effects Associated with Traffic

Locations in close proximity to major roadways generally have elevated concentrations of many air pollutants emitted from motor vehicles. Hundreds of such studies have been published in peer-reviewed journals, concluding that concentrations of CO, NO, NO_2, benzene, aldehydes, particulate matter, black carbon, and many other compounds are elevated in ambient air within approximately 300-600 meters (approximately 1,000-2,000 feet) of major roadways. Highest concentrations of most pollutants emitted directly by motor vehicles are found at locations within 50 meters (approximately 165 feet) of the edge of a roadway's traffic lanes.

[2443] U.S. EPA Integrated Risk Information System (IRIS) database is available at: www3.epa.gov/iris.

A large-scale review of air quality measurements in the vicinity of major roadways between 1978 and 2008 concluded that the pollutants with the steepest concentration gradients in vicinities of roadways were CO, ultrafine particles, metals, elemental carbon (EC), NO, NO_X, and several VOCs.[2444] These pollutants showed a large reduction in concentrations within 100 meters downwind of the roadway. Pollutants that showed more gradual reductions with distance from roadways included benzene, NO_2, $PM_{2.5}$, and PM_{10}. In the review article, results varied based on the method of statistical analysis used to determine the trend.

For pollutants with relatively high background concentrations relative to near-road concentrations, detecting concentration gradients can be difficult. For example, many aldehydes have high background concentrations as a result of photochemical breakdown of precursors from many different organic compounds. This can make detection of gradients around roadways and other primary emission sources difficult. However, several studies have measured aldehydes in multiple weather conditions and found higher concentrations of many carbonyls downwind of roadways.[2445,2446] These findings suggest a substantial roadway source of these carbonyls.

In the past 15 years, many studies have been published with results reporting that populations who live, work, or go to school near high-traffic roadways experience higher rates of numerous adverse health effects, compared to populations far away from major roads.[2447] In addition, numerous studies have found adverse health effects associated with spending time in traffic, such as commuting or walking along high-traffic roadways.[2448,2449,2450,2451] The health outcomes with the strongest evidence linking them with traffic-associated air pollutants are respiratory effects, particularly in asthmatic children, and cardiovascular effects.

Numerous reviews of this body of health literature have been published as well. In 2010, an expert panel of the Health Effects Institute (HEI) published a review of hundreds of exposure, epidemiology, and toxicology studies.[2452] The panel rated how the evidence for each type of health outcome supported a conclusion of a causal association with traffic-associated air pollution as either "sufficient," "suggestive but not sufficient," or "inadequate and insufficient." The panel categorized evidence of a causal association for exacerbation of childhood asthma as "sufficient." The panel categorized evidence of a causal association for

new onset asthma as between "sufficient" and "suggestive but not sufficient." "Suggestive of a causal association" was how the panel categorized evidence linking traffic-associated air pollutants with exacerbation of adult respiratory symptoms and lung function decrement. It categorized as "inadequate and insufficient" evidence of a causal relationship between traffic-related air pollution and health care utilization for respiratory problems, new onset adult asthma, chronic obstructive pulmonary disease (COPD), nonasthmatic respiratory allergy, and cancer in adults and children. Other literature reviews have been published with conclusions generally similar to the HEI panel's.[2453,2454,2455,2456] However, in 2014, researchers from the U.S. Centers for Disease Control and Prevention (CDC) published a systematic review and meta-analysis of studies evaluating the risk of childhood leukemia associated with traffic exposure and reported positive associations between "postnatal" proximity to traffic and leukemia risks, but no such association for "prenatal" exposures.[2457]

Health outcomes with few publications suggest the possibility of other effects still lacking sufficient evidence to draw definitive conclusions. Among these outcomes with a small number of positive studies are neurological impacts (e.g., autism and reduced cognitive function) and reproductive outcomes (e.g., preterm birth, low birth weight).[2458,2459,2460,2461]

In addition to health outcomes, particularly cardiopulmonary effects, conclusions of numerous studies suggest mechanisms by which traffic-related air pollution affects health. Numerous studies indicate that near-roadway exposures may increase systemic inflammation, affecting organ systems, including blood

vessels and lungs.[2462,2463,2464,2465] Long-term exposures in near-road environments have been associated with inflammation-associated conditions, such as atherosclerosis and asthma.[2466,2467,2468]

Several studies suggest that some factors may increase susceptibility to the effects of traffic-associated air pollution. Several studies have found stronger respiratory associations in children experiencing chronic social stress, such as in violent neighborhoods or in homes with high family stress.[2469,2470,2471]

The risks associated with residence, workplace, or schools near major roads are of potentially high public health significance due to the large population in such locations. According to the 2009 American Housing Survey, over 22 million homes (17.0 percent of all U.S. housing units) were located within 300 feet of an airport, railroad, or highway with four or more lanes. This corresponds to a population of more than 50 million U.S. residents in close proximity to high-traffic roadways or other transportation sources. Based on 2010 Census data, a 2013 publication estimated that 19 percent of the U.S. population (over 59 million people) lived within 500 meters of roads with at least 25,000 annual average daily traffic (AADT), while about 3.2 percent of the population lived within 100 meters (about 300 feet) of such roads.[2472] Another 2013 study estimated that 3.7 percent of the U.S. population (about 11.3 million people) lived within 150 meters (about 500 feet) of interstate highways or other freeways and expressways.[2473] On average, populations near major roads have higher fractions of minority residents and lower socioeconomic status. Furthermore, on average, Americans spend more than an hour traveling each day, bringing nearly all residents into a high-exposure microenvironment for part of the day.

In light of these concerns, EPA has required through the NAAQS process that air quality monitors be placed near high-traffic roadways for determining concentrations of CO, NO_2, and $PM_{2.5}$ (in addition to those existing monitors located in neighborhoods and other locations farther away from pollution sources). Near-roadway monitors for NO_2 began operation between 2014 and 2017 in Core Based Statistical Areas (CBSAs) with population of at least 500,000. Monitors for CO and $PM_{2.5}$ began operation between 2015 and 2017. These monitors will further the understanding of exposure in these locations.

EPA and DOT continue to research near-road air quality, including the types of pollutants found in high concentrations near major roads and health problems associated with the mixture of pollutants near roads.

(8) Environmental Effects of Non-GHG Pollutants

(a) Visibility

Visibility can be defined as the degree to which the atmosphere is transparent to visible light.[2474] Visibility impairment is caused by light scattering and absorption by suspended particles and gases. Visibility is important because it has direct significance to people's enjoyment of daily activities in all parts of the country. Individuals value good visibility for the well-being it provides them directly, where they live and work, and in places where they enjoy recreational opportunities. Visibility is also highly valued in significant natural areas, such as national parks and wilderness areas, and special emphasis is given to protecting visibility in these areas. For more information on visibility see the final 2019 PM ISA.[2475,2476]

EPA is working to address visibility impairment. Reductions in air pollution from implementation of various programs associated with the Clean Air Act Amendments of 1990 (CAAA) provisions have resulted in substantial improvements in visibility and will continue to do so in the future. Because trends in haze are closely associated with trends in particulate sulfate and nitrate due to the relationship between their concentration and light extinction, visibility trends have improved as emissions of SO_2 and NO_X have decreased over time due to air pollution regulations such as the Acid Rain Program.[2477]

In the Clean Air Act Amendments of 1977, Congress recognized visibility's value to society by establishing a national goal to protect national parks and wilderness areas from visibility impairment caused by manmade pollution.[2478] In 1999, EPA finalized the regional haze program to protect the visibility in Mandatory Class I Federal areas.[2479] There are 156 national parks, forests and wilderness areas categorized as Mandatory Class I Federal areas.[2480] These areas are defined in CAA Section 162 as those national parks

[2480] 62 FR 38680-81 (July 18, 1997).

exceeding 6,000 acres, wilderness areas and memorial parks exceeding 5,000 acres, and all international parks which were in existence on August 7, 1977.

EPA has also concluded that $PM_{2.5}$ causes adverse effects on visibility in other areas that are not targeted by the Regional Haze Rule, such as urban areas, depending on $PM_{2.5}$ concentrations and other factors such as dry chemical composition and relative humidity (i.e., an indicator of the water composition of the particles). EPA revised the $PM_{2.5}$ standards in December 2012 and established a target level of protection that is expected to be met through attainment of the existing secondary standards for $PM_{2.5}$.

(b) Plant and Ecosystem Effects of Ozone

The welfare effects of ozone include effects on ecosystems, which can be observed across a variety of scales, i.e. subcellular, cellular, leaf, whole plant, population and ecosystem. Ozone can produce both acute and chronic injury in sensitive species depending on the concentration level and the duration of the exposure.[2481] In those sensitive species,[2482] effects from repeated exposure to ozone throughout the growing season of the plant can tend to accumulate, so that even relatively low concentrations experienced for a longer duration have the potential to create chronic stress on vegetation.[2483] Ozone damage to sensitive species includes impaired photosynthesis and visible injury to leaves. The impairment of photosynthesis, the process by which the plant makes carbohydrates (its source of energy and food), can lead to reduced crop yields, timber production, and plant productivity and growth. Impaired photosynthesis can also lead to a reduction in root growth and carbohydrate storage below ground, resulting in other, more subtle plant and ecosystems impacts.[2484] These latter impacts include increased susceptibility of plants to insect attack, disease, harsh weather, interspecies competition and overall decreased plant vigor. The adverse effects of ozone on areas with sensitive species could potentially lead to species shifts and loss from the affected ecosystems,[2485] resulting in a loss or reduction in associated ecosystem goods and services. Additionally, visible ozone injury to leaves can result in a loss of aesthetic value in areas of special scenic significance like national parks and wilderness areas and reduced use of sensitive ornamentals in landscaping.[2486]

The most recent Integrated Science Assessment (ISA) for Ozone presents more detailed information on how ozone affects vegetation and ecosystems.[2487,2488] The ISA concludes that ambient concentrations of ozone are associated with a number of adverse welfare effects and characterizes the weight of evidence for

different effects associated with ozone.[2489] The ISA concludes that visible foliar injury effects on some vegetation, reduced vegetation growth, reduced productivity in terrestrial ecosystems, reduced yield and quality of some agricultural crops, and alteration of below-ground biogeochemical cycles are causally associated with exposure to ozone. It also concludes that reduced carbon sequestration in terrestrial ecosystems, alteration of terrestrial ecosystem water cycling, and alteration of terrestrial community composition are likely to be causally associated with exposure to ozone.

(c) Atmospheric Deposition

Wet and dry deposition of ambient particulate matter delivers a complex mixture of metals (e.g., mercury, zinc, lead, nickel, aluminum, and cadmium), organic compounds (e.g., polycyclic organic matter, dioxins, and furans) and inorganic compounds (e.g., nitrate, sulfate) to terrestrial and aquatic ecosystems. The chemical form of the compounds deposited depends on a variety of factors including ambient conditions (e.g., temperature, humidity, oxidant levels) and the sources of the material. Chemical and physical transformations of the compounds occur in the atmosphere as well as the media onto which they deposit. These transformations in turn influence the fate, bioavailability and potential toxicity of these compounds.

Adverse impacts to human health and the environment can occur when particulate matter is deposited to soils, water, and biota.[2490] Deposition of heavy metals or other toxics may lead to the human ingestion of contaminated fish, impairment of drinking water, damage to terrestrial, freshwater and marine ecosystem components, and limits to recreational uses. Atmospheric deposition has been identified as a key component of the environmental and human health hazard posed by several pollutants including mercury, dioxin and PCBs.[2491]

The ecological effects of acidifying deposition and nutrient enrichment are detailed in the Integrated Science Assessment for Oxides of Nitrogen and Sulfur-Ecological Criteria.[2492,2493] Atmospheric deposition of nitrogen and sulfur contributes to acidification, altering biogeochemistry and affecting animal and plant life in terrestrial and aquatic ecosystems across the United States. The sensitivity of terrestrial and aquatic ecosystems to acidification from nitrogen and sulfur deposition is predominantly governed by geology. Prolonged exposure to excess nitrogen and sulfur deposition in sensitive areas acidifies lakes, rivers and soils. Increased acidity in surface waters creates inhospitable conditions for biota and affects the abundance and biodiversity of fishes, zooplankton and macroinvertebrates and ecosystem function. Over time, acidifying deposition also removes essential nutrients from forest soils, depleting the capacity of soils to neutralize future acid loadings and negatively affecting forest sustainability. Major effects in forests include a decline in sensitive tree species, such as red spruce (*Picea rubens*) and sugar maple (*Acer saccharum*). In

---

[2489] The Ozone ISA evaluates the evidence associated with different ozone related health and welfare effects, assigning one of five "weight of evidence" determinations: causal relationship, likely to be a causal relationship, suggestive of a causal relationship, inadequate to infer a causal relationship, and not likely to be a causal relationship. For more information on these levels of evidence, please refer to Table II of the ISA.

addition to the role nitrogen deposition plays in acidification, nitrogen deposition also leads to nutrient enrichment and altered biogeochemical cycling. In aquatic systems increased nitrogen can alter species assemblages and cause eutrophication. In terrestrial systems nitrogen loading can lead to loss of nitrogen-sensitive lichen species, decreased biodiversity of grasslands, meadows and other sensitive habitats, and increased potential for invasive species.

Building materials including metals, stones, cements, and paints undergo natural weathering processes from exposure to environmental elements (e.g., wind, moisture, temperature fluctuations, sunlight, etc.). Pollution can worsen and accelerate these effects. Deposition of PM is associated with both physical damage (materials damage effects) and impaired aesthetic qualities (soiling effects). Wet and dry deposition of PM can physically affect materials, adding to the effects of natural weathering processes, by potentially promoting or accelerating the corrosion of metals, by degrading paints and by deteriorating building materials such as stone, concrete and marble.[2494] The effects of PM are exacerbated by the presence of acidic gases and can be additive or synergistic due to the complex mixture of pollutants in the air and surface characteristics of the material. Acidic deposition has been shown to have an effect on materials including zinc/galvanized steel and other metal, carbonate stone (as monuments and building facings), and surface coatings (paints).[2495] The effects on historic buildings and outdoor works of art are of particular concern because of the uniqueness and irreplaceability of many of these objects. In addition to aesthetic and functional effects on metals, stone and glass, altered energy efficiency of photovoltaic panels by PM deposition is also becoming an important consideration for impacts of air pollutants on materials.

(d) Environmental Effects of Air Toxics

Emissions from producing, transporting and combusting fuel contribute to ambient levels of pollutants that contribute to adverse effects on vegetation. Volatile organic compounds, some of which are considered air toxics, have long been suspected to play a role in vegetation damage.[2496] In laboratory experiments, a wide range of tolerance to VOCs has been observed.[2497] Decreases in harvested seed pod weight have been reported for the more sensitive plants, and some studies have reported effects on seed germination, flowering and fruit ripening. Effects of individual VOCs or their role in conjunction with other stressors (e.g., acidification, drought, temperature extremes) have not been well studied. In a recent study of a mixture of VOCs including ethanol and toluene on herbaceous plants, significant effects on seed production, leaf water content and photosynthetic efficiency were reported for some plant species.[2498]

Research suggests an adverse impact of vehicle exhaust on plants, which has in some cases been attributed to aromatic compounds and in other cases to nitrogen oxides.[2499,2500, 2501] The impacts of VOCs on plant reproduction may have long-term implications for biodiversity and survival of native species near major roadways. Most of the studies of the impacts of VOCs on vegetation have focused on short-term exposure and few studies have focused on long-term effects of VOCs on vegetation and the potential for metabolites of these compounds to affect herbivores or insects.

c) How the Agencies Estimated Impacts on Emissions

The rule implements an emissions inventory methodology for estimating impacts. Vehicle emissions inventories are often described as three-legged stools, comprised of activity (i.e., miles traveled, hours operated, or gallons of gasoline burned), population (or number of vehicles), and emission factors. An emissions factor is a representative value that attempts to relate the quantity of a pollutant released to the atmosphere with an activity associated with the release of that pollutant.[2502] Depending on the vehicle activity available, emission factors may be on a distance-, time-, or fuel-basis. For example, an emissions inventory for a light-duty fleet could simply be the vehicle miles traveled multiplied by the appropriate per-mile emission factor for a chosen pollutant.

As described in Section VI.A, Overview of Methods, the agencies used specific models to develop inputs to the CAFE model, such as fuel prices and emission factors. The CAFE model estimates how manufacturers might respond to a given regulatory scenario (CAFE/ CO_2 standards) and fuel prices, and what impact that response will have on emissions. As mentioned above, the agencies have used DOT's CAFE model to estimate impacts of the CAFE and CO_2 standards promulgated today. Details of the analysis are presented below and in the accompanying *Federal Register* notice, EIS, and model documentation. To estimate the response on emissions, several steps are involved. The estimation of emissions involves accounting for vehicular fuel type (e.g., gasoline, diesel, electric) and fuel economy (accounting for the estimated gap, discussed below, between "laboratory" and actual on-road fuel economy), vehicular turnover and travel demand, fuel properties (carbon content), and upstream process emissions. Like other models, the CAFE model includes procedures to estimate annual rates at which new vehicles are used and subsequently scrapped. Together, these procedures result in, for each vehicle model in each model year, estimates of the number remaining in service in each calendar year, as well as the annual mileage accumulation (i.e. VMT) in each calendar year. Quantities of emissions derive from this vehicle operation.

For every vehicle model in the market file, the model estimates the VMT per vehicle (using the assumed VMT schedule, the vehicle fuel economy, fuel price, and the rebound assumption). Those miles are multiplied by the number off each vehicle model/configuration remaining in service in any given calendar year. Fuel consumption is the product of miles driven and fuel economy, which can be tracked by model year cohort in the model. Carbon dioxide emissions from vehicle tailpipes are the simple product of gallons consumed and the carbon content of each gallon. As discussed in the CAFE model overview, the simulated

application of technology results in estimates of the cost, fuel type, fuel economy, and fuel share applicable to each vehicle model in each model year. Together with quantities of travel, and with estimates of the "gap" between "laboratory" and "on-road" fuel economy, these enable calculation of quantities of fuel consumed in each year during the useful life of each vehicle model produced in each model year. The model calculates emissions of CO_2, CH_4, and N_2O, criteria pollutants, and air toxics, reporting emissions both from vehicle tailpipes and from upstream processes (e.g., petroleum refining) involving in producing and supplying fuels.

In order to calculate calendar year fuel consumption, the model needs to account for the inherited on-road fleet in addition to the model year cohorts affected by this rule. Using the VMT of the average passenger car and light truck from each cohort, the model computes the fuel consumption of each model year class of vehicles for its age in a given CY. The sum across all ages (and thus, model year cohorts) in a given CY provides estimated CY fuel consumption.

For this rule, vehicle tailpipe (downstream) and upstream emission inventories were developed separately. In addition to the tailpipe emissions of carbon dioxide, each gallon of gasoline produced for consumption by the on-road fleet has associated "upstream" emissions that occur in the extraction, transportation, refining, and distribution of the fuel. The tailpipe inventories apply per-mile emission factors from the Motor Vehicle Emission Simulator (MOVES) and the upstream inventories apply per-gallon of fuel consumed emission factors from the Argonne National Laboratory's Greenhouse gases, Regulated Emissions, and Energy use in Transportation (GREET) Model. The model accounts for upstream emissions and reports them accordingly. More detailed descriptions of emission data sources and calculations are provided in the following section.

The agencies received several comments on estimation of criteria pollutant impacts in the NPRM. As discussed elsewhere in this FRIA, EDF modified aspects of the CAFE model as part of their comments to the agencies. Specifically in regards to criteria pollutant emissions, EDF made several alternative assumptions, including assertions that criteria pollutant impacts were not as negligible as the agencies claimed, and that fatalities due to criteria pollutant emissions would be higher than the agencies showed in the NPRM. The agencies declined to adopt EDF's suggested changes to the model and inputs, but did make the changes discussed in this section that refined the agencies' accounting of criteria pollutant emissions and explicitly modeled criteria pollutant fatalities, as discussed below.

Also discussed elsewhere in this FRIA, some commenters expressed that the agencies' analysis (by implication, their modeling) should account for some States' mandates that manufacturers sell minimum quantities of "Zero Emission Vehicles" (ZEVs).[2503] These commenters stressed the importance of the ZEV mandate in relation to maintaining air quality requirements and reducing effects of climate change.

The reference case analysis for today's rule, like that for the proposal, does not simulate compliance with ZEV mandates,[2504] because such mandates are subject to preemption under EPCA and are therefore not enforceable. As discussed in the One National Program Action, California and other states remain free to revise their overall average emissions standards to further reduce ozone forming emissions and seek a waiver of Clean Air Act preemption from EPA, as described above, while not violating NHTSA's preemption

[2503] CBD et al., NHTSA-2018-0067-12123; States and Cities, NHTSA-2018-0067-11735; SCAQMD, NHTSA-2018-0067-11813.
[2504] The NPRM version of the model included experimental capabilities to account for mandates and credits for the sale of ZEVs, but the agencies did not utilize those capabilities for the NPRM for the same reasons discussed above.

authority. These States and local governments would continue to be allowed to take other actions so long as those are not related to fuel economy and are consistent with any other relevant Federal law.

(1) Activity levels

As discussed in Section VI.A, for each vehicle model/configuration in each model year during 2017-2050, the CAFE model estimates and records the fuel type (e.g., gasoline, electricity), fuel economy, and number of units sold in the U.S. The model also makes use of an aggregated representation of vehicles sold in the U.S. during 1978-2016. The model estimates the numbers of each cohort of vehicles remaining in service in each calendar year, and the amount of driving accumulated by each such cohort in each calendar year. The CAFE model estimates annual vehicle-miles of travel (VMT) for each individual car and light truck model produced in each model year at each age of their lifetimes, which extend for a maximum of 40 years. Since a vehicle's age is equal to the current calendar year minus the model year in which it was originally produced, the age span of each vehicle model's lifetime corresponds to a sequence of 40 calendar years beginning in the calendar year corresponding to the model year it was produced.[2505] These estimates reflect the gradual decline in the fraction of each car and light truck model's original model year production volume that is expected to remain in service during each year of its lifetime, as well as the well-documented decline in their typical use as they age. Using this relationship, the CAFE model calculates total VMT for the entire fleet of cars and light trucks in service during each calendar year spanned by the agencies' analysis.

Based on these estimates, the model also calculates quantities of each type of fuel or energy, including gasoline, diesel, and electricity, consumed in each calendar year. By combining these with estimates of each model's fuel or energy efficiency, the model also estimates the quantity and energy content of each type of fuel consumed by cars and light trucks at each age, or viewed another way, during each calendar year of their lifetimes. As with the accounting of VMT, these estimates of annual fuel or energy consumption for each vehicle model and model year combination are combined to calculate the total volume of each type of fuel or energy consumed during each calendar year, as well as its aggregate energy content.

The procedures the CAFE model uses to estimate annual VMT for individual car and light truck models produced during each model year over their lifetimes and to combine these into estimates of annual fleet-wide travel during each future calendar year, together with the sources of its estimates of their survival rates and average use at each age, are described in detail in Section VI.D.1 of this final rule. The data and procedures it employs to convert these estimates of VMT to fuel and energy consumption by individual model, and to aggregate the results to calculate total consumption and energy content of each fuel type during future calendar years, are also described in detail in that same section.

The model documentation accompanying today's notice describes these procedures in detail.[2506] The quantities of travel and fuel consumption estimated for the cross section of model years and calendar years constitutes a set of "activity levels" based on which the model calculates emissions. The model does so by multiplying activity levels by emission factors. As indicated in the previous section, the resulting estimates

---

[2505] In practice, many vehicle models bearing a given model year designation become available for sale in the preceding calendar year, and their sales can extend through the following calendar year as well. However, the CAFE model does not attempt to distinguish between model years and calendar years; vehicles bearing a model year designation are assumed to be produced and sold in that same calendar year.

[2506] CAFE model documentation is available at https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system.

of vehicle use (VMT), fuel consumption, and fuel energy content are combined with emission factors drawn from various sources to estimate emissions of GHGs, criteria air pollutant, and airborne toxic compound that occur throughout the fuel supply and distribution process, as well as during vehicle operation, storage, and refueling. Emission factors measure the mass of each GHG or criteria pollutant emitted per vehicle-mile of travel, gallon of fuel consumed, or unit of fuel energy content. The following section identifies the sources of these emission factors and explains in detail how the CAFE model applies them to its estimates of vehicle travel, fuel use, and fuel energy consumption to estimate total annual emissions of each GHG, criteria pollutant, and airborne toxic.

(2) What emission factors did the agencies apply?

(a) Tailpipe (Downstream) Emission Factors

In a full fuel cycle analysis, emissions that occur from the fueling pump to vehicle wheels are usually referred to as tailpipe or simply downstream emissions. Today's rule primarily impacts CO_2 emissions. The agencies have calculated tailpipe CO_2 emissions based on fuel consumption and fuel properties (i.e., fuel density and carbon content) that result in gram per gallon emission factors. For all other exhaust constituents (except sulfur dioxide, discussed below), the agencies have calculated emissions by applying per-mile emission factors to quantities of travel (i.e., VMT). This rulemaking's tailpipe emission factors are from EPA's Motor Vehicle Emission Simulator (MOVES), which serves as the federal regulatory model for mobile-source emission inventories, with a few notable exceptions. In particular, light-duty gasoline and diesel tailpipe emission factors for the following criteria pollutants, greenhouse gases (other than CO_2), and air toxics are drawn from MOVES2014a:[2507]

- Criteria pollutants
  - Carbon monoxide (CO),
  - Volatile organic compounds (VOC),
  - Nitrogen oxides (NOx), and
  - Fine particulate matter ($PM_{2.5}$)
- Greenhouse gases
  - Methane (CH_4), and
  - Nitrous oxide (N_2O)
- Air toxics
  - Acetaldehyde,
  - Acrolein,
  - Benzene,
  - Butadiene,
  - Formaldehyde,
  - Diesel particulate matter (DPM_{10}), and
  - Methyl tert-butyl ether (MTBE)

These MOVES-based emission factors are specified separately for gasoline and diesel vehicles, by model year (ranging from MY 1975 to 2050), and by vehicle age (ranging from zero to 39 years old). The

[2507] For the emission factors informing the Final EIS, updating to MOVES 2014b would have produced values identical to those based on MOVES 2014a.

structure of criteria pollutant emission standards is such that these factors do not vary with fuel economy unless a change in fuel type (e.g., from gasoline to electricity) is involved.

Since tailpipe sulfur dioxide (SO_2) emissions are dependent on the sulfur content of the fuel, a single SO_2 emission factor in grams per million British thermal units (MMBTU) of fuel consumed is applied respectively for gasoline, diesel, and ethanol (E85) across all model years after MY 2017 based on a longitudinal analysis in MOVES.

As previously mentioned, EDF submitted supplemental comments on SO_2 emissions, stating that "SO_2 emissions should be proportional to fuel consumption" and "that the tailpipe SO_2 emissions by calendar year from the Volpe Model do not change proportionally to the changes in fuel consumption across various CO_2 control scenarios."[2508] The version of the model supporting the 2012 final rule calculated tailpipe SO_2 emissions on a gram per gallon basis. Supporting the ensuing rulemaking regarding heavy-duty pickups and vans, and the 2016 draft TAR, EPA staff provided SO_2 emission factors specified on a gram per mile basis. DOT modified the model in order to apply these SO2 emission factors as provided by EPA. The CAFE Model documentation released with the NPRM clearly describes how the agencies calculated emissions in the model. Although the version of model applied for the NPRM did not change this approach to calculating tailpipe SO_2 emissions, the agencies agree that SO_2 emissions should be proportional to fuel consumption, and DOT has revised the model accordingly. For SO_2 emissions, the inputs to the model include the number of grams of SO_2 emitted by a vehicle per gallon of fuel consumed by the vehicle.

The agencies also received comments on the use of MOVES. Most notably, the National Farmers Union stated "Concerns have been raised regarding the models used by EPA to determine emissions from fuels. Third-party reviews have shown that MOVES2014 may be inadequate as a tool for estimating the exhaust emissions of gasoline blends containing more than 10 percent ethanol. The model's results for mid-level ethanol blends have been shown to be inconsistent with other results from the scientific literature for both exhaust emissions and evaporative emissions, including results from real-world emissions testing."[2509] The agencies considered comments on the use of MOVES and ethanol blends and notes that MOVES may be unreliable for fuel blends over E10; however, MOVES is not designed to model mid-level ethanol blends. MOVES2014 is designed to model ethanol volumes up to 15 percent (E0 to E15), and it can also model E85 (ethanol volumes of 70 to 85 percent), but MOVES2014 is not designed to model intermediate fuel blends. Moreover, the agencies did not explicitly consider blends above E10 as part of the analysis, but rather ethanol blending is considered in relation to how to achieve a higher octane level and a higher anti-known index.

The Pennsylvania Department of Environmental Protection stated that there may be a significant State-specific rebound effect in Pennsylvania given Pennsylvania's regional role in natural gas and petroleum processing and refining. According to this commenter, the proposed rule does not adequately take into account significant local, State, and regional air quality impacts because it dilutes the emissions impact of the rule across the entire Nation. The Center for Biological Diversity, the Consumer Federation of America, and other commenters expressed concern that the proposed rule would increase criteria pollutants in areas with large minority populations, especially those in areas near oil refineries.

[2508] EDF, NHTSA-2018-0067-12363.
[2509] National Farmers Union, NHTSA-2018-0067-11972.

Results of these tailpipe emissions calculations are summarized below in Section VII and in the *Federal Register* notice, and presented in greater detail in the accompanying Final EIS.

(b) Upstream Emission Factors

Fuel cycle emissions occurring between the extraction well and the fueling pump are often called upstream emissions. This rule has drawn upstream emission factors exclusively from the Greenhouse gases, Regulated Emissions, and Energy use in Transportation (GREET) model, developed by the U.S. Department of Energy's Argonne National Laboratory. The upstream gasoline, diesel, and electricity emission factors for criteria pollutants—namely, CO, VOC, NOx, $PM_{2.5}$, and SO_2—and greenhouse gases—namely, CO_2, CH_4, and N_2O—have been updated with GREET 2018 data. The upstream emission factors for the air toxics mentioned above were unchanged from the proposal. For the final rule, upstream emission factors cover the following analysis years, 2017, 2020, 2025, 2030, 2035, 2040, 2045, and 2050, and four distinct upstream processes:

- Petroleum Extraction,
- Petroleum Transportation,
- Petroleum Refining, and
- Fuel Transportation, Storage, and Distribution (TS&D).

These upstream emission factors for each fuel type and analysis year were generated by a process using emission factor values found in the GREET 2018 spreadsheet tool and adjustment factors where appropriate. Emission factors for the petroleum extraction process are the aggregation of different crude feedstock—such as crude oil, oil sands, and shale oil—emission factors multiplied by their associated adjustments for transportation to refineries losses, storage losses, and energy share by crude feedstock. Emission factors for the petroleum transportation process are emissions by crude feedstock sources—such as crude oil fields, surface and in-situ mining, and shale reserves—and multiplied the associated energy shares. Emission factors for the petroleum refining are the sum of the crude input, combustion, and non-combustion products multiplied by the transportation of blended fuel loss factors. The refining emission factors applies a non-ethanol energy content adjustment for gasoline, blended at E10. Diesel does not have any such ethanol content adjustment. Emission factors for the Fuel TS&D process are based on the blended fuel transportation and distribution emissions as well as an energy content factor for both the petroleum and ethanol portions of the fuels. Again, diesel does not have an ethanol adjustment.

The aggregated upstream emission factors used in the rule are aggregated across the four processes for each fuel type and analysis year. The aggregated upstream emission factor in the sum of the fuel TS&D emission factor, the petroleum refining emission factor multiplied by the share of fuel savings leading to reduced domestic refining, the pair of petroleum extraction and transportation emission factors multiplied by both the share of fuel savings and the share of reduced domestic refining from domestic crude. The upstream adjustments are replicated from the proposal.

Finally, the upstream emission factors for electricity are also updated with GREET 2018 data. Upstream electricity emissions factors are derived from electricity for transportation use feedstock and fuel emissions by analysis year. As the analysis supporting the proposal noted, there are three possible supply "pathways" for fuel consumed by the U.S. light-duty vehicle fleet:

1. Importing fuel that has been refined overseas into the U.S
2. Refining fuel in the U.S. from crude petroleum produced overseas and imported into the U.S.

3. Refining fuel in the U.S. from crude petroleum produced in the U.S.[2510]

The distribution of fuel consumed within the U.S. that is supplied via each of these pathways has important implications for domestic "upstream" emissions, because each pathway produces domestic emissions arising from a different combination of activities that occur within the U.S. For example, pathway 1 involves domestic emissions that occur during crude petroleum extraction, transportation of crude oil from production or nearby temporary storage facilities to domestic refineries, refining of crude petroleum to produce transportation fuels, and storage and distribution of refined fuels.[2511] In contrast, pathway 2 generates domestic emissions during transportation of crude petroleum from U.S. coastal ports to domestic refineries, as well as from fuel refining, storage, and distribution, while pathway 3 produces domestic emissions only from storage and distribution of refined fuel.

The analysis supporting the proposal made two central assumptions in estimating upstream emissions from fuel supply. First, 50 percent of any change in domestic fuel consumption by cars and light trucks operating on petroleum-based liquid fuels (gasoline and diesel) would be reflected in changes in imports of refined fuel, while the remaining 50 percent would be reflected in changes in the volume of those fuels refined domestically. Second, 90 percent of any change in the volume of fuel refined domestically was assumed to be reflected in changes in the volume of crude petroleum imported into the U.S, with the remaining 10 percent reflected in changes in the volume of crude petroleum produced within the U.S. The agencies developed these assumptions to analyze the environmental impacts of alternative CAFE and CO_2 standards for model years 2012-2016, and have continued to rely in their analyses supporting subsequent rules.

To illustrate the effect of these assumptions, for each increase in domestic fuel consumption of 100 gallons, 50 additional gallons would be supplied via pathway 1 (refined outside the U.S. and imported in already-refined form). Additional fuel supplied via pathway 2 (U.S. domestic refining of imported crude oil) would account for 90 percent of the remaining 50 gallons of increased consumption, or 45 gallons. Finally, the remaining 5 gallons of increased fuel consumed within the U.S. would be supplied via pathway 3 (domestic refining of crude oil produced within the U.S.). This same breakdown was applied to changes in fuel consumption estimated to occur throughout the analysis period used for the proposal, which extended from 2017 through 2050.

The agencies estimated the resulting changes in upstream emissions of criteria air pollutants and airborne toxics occurring within the U.S. by applying emission factors for the appropriate stages of the fuel supply chain (petroleum extraction, petroleum transportation to refineries, fuel refining, and fuel storage and distribution) to the changes in the total energy content of fuel supplied by each pathway, and summed the results.[2512] The energy content of fuel rather than its volume was used as the basis for estimating emissions,

[2510] The proposal assumed that all fuel refined outside the U.S. and then imported into the U.S. would be refined from petroleum that was also produced outside the U.S. Although some of it could be refined from crude petroleum produced in the U.S. and exported, the analysis assumed that the fraction supplied via this pathway is negligible.

[2511] By longstanding EPA convention, emissions that occur when vehicles are being refueled at retail stations or vehicle storage depots (such as buses) are ascribed to vehicle use, rather than to fuel supply.

[2512] Increases in upstream GHG emissions were calculated from the increase in U.S. domestic fuel consumption, without regard to whether they occurred within the U.S.

because emission factors are typically expressed in mass per unit of fuel energy supplied—for example, grams per million Btu—rather than per unit volume of fuel supplied.

In the proposal, the agencies made no explicit assumptions about the future mix of electric generating capacity that would be used to supply increased electricity consumed by BEVs and PHEVs. Instead, the agencies implicitly relied on the assumptions about future evolution of the nationwide mix of generation sources that were reflected in the U.S. average emission factors for electricity produced to power transportation vehicles, including cars and light trucks, which as described previously were drawn from the most recent version of Argonne National Laboratory's GREET model that was available at the time of the proposal. These assumptions were consistent with those made by EIA in its AEO 2017 Reference case analysis and publications.[2513]

While the agencies' use of these assumptions to estimate upstream emissions did not prompt widespread comments on their analyses in support of previous CAFE rulemakings, the more recent proposal did draw a large number of comments focusing on those same assumptions. Most commenters asserted that the entirety of any increase in consumption of petroleum-based fuels by cars and light trucks resulting from the proposal would be met via increased domestic refining, primarily from crude petroleum produced in the U.S., and would thus generate additional upstream emissions within the U.S. throughout the fuel supply process. Even some commenters who argued elsewhere that the U.S. would continue to be a large-scale importer of petroleum asserted that the entire increase in fuel consumption resulting from the proposal would be refined from additional domestically-produced petroleum.[2514]

As a consequence, most commenters argued that the agencies' analysis of the proposal significantly underestimated the increases in upstream emissions that were likely to result, with some also asserting that the increases in emissions of criteria air pollutants would cause potentially serious degradation of air quality in the areas surrounding U.S. refineries. For example, EDF stated, "NHTSA assumed that 50% of all the gasoline saved by more stringent CAFE and CO_2 standards would have been imported (i.e., refined overseas)…. It is difficult to see how this could be the case when the nation is producing enough crude oil to be a net exporter. It is also difficult to see how this could be the case when gasoline consumption is decreasing and sufficient domestic refining capacity exists to fulfill today's demand, let alone decreased demand in the future…. Assuming that 100% of the differences in gasoline consumption between control scenarios will be refined in the U.S. appears to be much more consistent with the available data. Likewise, it seems reasonable to assume that differences in the crude oil requirements of the various scenarios will also affect domestic production more so than imports."[2515]

However, one commenter did agree with the agencies' assessment of the proposal's likely impact on U.S. petroleum imports, noting that "Through 2050, there will only be a small increase in domestic oil production due to increased demand, well under 1%.... The vast majority (88% through 2050) of the additional petroleum that will be required to fuel light-duty vehicles in the proposed case will be imported.

[2513] https://greet.es.anl.gov/publication-greet-2017-summary.

[2514] For example, IPI notes that AEO 2019 shows the U.S. will continue to import crude petroleum through 2050, and will remain a net importer as measured by the energy content rather than the volume of U.S. petroleum exports and imports; *see* IPI, NHTSA-2018-0067-12213. Similarly, EDF argued that because U.S. petroleum imports have been declining and gasoline imports are currently low, the best assumption was that the entire increase in gasoline consumption resulting from the proposal would be supplied from increased domestic refining of U.S.-produced crude petroleum; *see* EDF, NHTSA-2018-0067-12108.

[2515] EDF, NHTSA-2018-0067-12108, p. 53. Others making similar assertions include IPI, NHTSA-2018-0067-12213, p. 5.

This assessment is not too far off of a single comment in the NPRM, 'Using NEMS, it was estimated that 50% of increased gasoline consumption would be supplied by increased domestic refining and that 90% of this additional refining would use imported crude petroleum.'"[2516]

The agencies note that there seems to be considerable confusion among commenters about the agencies' assumptions regarding import shares, and what they are attempting to measure. The agencies' assumptions are intended to measure the effects of *changes* in consumption of petroleum-derived transportation fuels by cars and light trucks that are attributable to this final rule on *changes* in U.S. production and imports of crude petroleum, in domestic refining of crude petroleum to produce transportation fuels, and in the volume of refined fuel distributed for domestic consumption. While recent data on U.S. fuel consumption, domestic production and imports of crude petroleum, and imports of refined petroleum products may be useful in estimating these desired measures, they are not themselves measures of the marginal impacts of changes in fuel consumption on the volumes of fuel supplied via each of the supply pathways described previously.

Instead, the agencies rely on two types of information to estimate the current and likely future values of the desired measures. First, they examine recent changes in domestic consumption of petroleum-based motor fuels—particularly gasoline, since it is the primary fuel used by vehicles that are subject to CAFE and CO_2 standards—and compare them to the accompanying changes in the three gasoline supply pathways, namely domestic petroleum production, U.S. imports of crude petroleum, and U.S. imports of refined gasoline (or components that are blended domestically to produce gasoline). Second, the agencies examine differences in forecasts of U.S. petroleum production, fuel refining, and imports of refined fuel under alternative future scenarios that were included in AEO 2018 whose projections of domestic fuel consumption differ in ways that include alternative CAFE standards. While this latter approach would ideally compare scenarios that differ only in their assumptions about the stringency of CAFE and CO_2 standards but are otherwise strictly comparable, such idealized comparisons are rarely possible because other factors almost always differ as well between the alternative scenarios being compared.

(i) Assumptions Used to Analyze Impacts of the Final Rule on Petroleum Imports and Emissions

In response to comments, the agencies conducted a detailed examination of recent changes in U.S. fuel consumption, domestic fuel refining, and U.S. imports and exports of crude petroleum as well as refined fuel (primarily gasoline). This included comparing changes in these variables at both the national aggregate level and for three separate regions of the U.S. In addition, they examined differences in the forecast values of these variables under alternative assumptions about fuel economy standards, although as indicated above these comparisons are complicated by the fact that factors other than CAFE and CO_2 standards also differ between these alternative scenarios.

The agencies also identified a fourth "pathway" to supply the increase in U.S. gasoline consumption anticipated to result from this final rule. The U.S. is now a net exporter of refined gasoline (and products that are blended to produce gasoline), and the volume of U.S gasoline exports is likely to increase for at least the next two decades. This introduces the possibility that some—and perhaps all—of the anticipated increase in domestic gasoline consumption will be met simply by redirecting U.S. gasoline exports to serve

[2516] David Gohlke, EPA-HQ-OAR-2018-0283-5082, p. 1.

domestic consumption. This additional source of supply would result in no increase in domestic refining activity, and thus no increase in emissions from refining of petroleum-based transportation fuels.[2517]

Throughout most of the past half-century, the nation has been a large net importer of crude petroleum, taking its price as determined in world markets and importing the volumes necessary to meet the difference between U.S. demand for refined petroleum products and domestic supplies. Throughout this period, the U.S. has also been largely self-sufficient in refining, meaning that the gap between domestic demand for refined products and the volumes refined from crude petroleum extracted within the U.S. was primarily met by domestic refining of imported crude petroleum, with only marginal volumes of gasoline and other products imported or exported. U.S. refinery capacity and output generally increased over this period in proportion to growth in domestic consumption of fuel and other products refined from petroleum.

In the past decade, however, this situation has changed dramatically. U.S. production of crude petroleum has more than doubled since 2008, making the nation one of the world's largest producers, while net imports of crude oil and refined products have declined by nearly 80 percent.[2518] Domestic gasoline consumption declined by more than 6 percent between 2007 and 2012, and recovered to its 2007 levels only as recently as 2016, remaining near or slightly below its 2016 level since then.[2519] As a consequence, the U.S. shifted from being a net importer of refined petroleum products to a net exporter in 2011, and has become a net exporter of gasoline and "blending stock" since 2016.[2520]

Over the past decade, increased availability of crude petroleum and other refinery feedstocks in combination with declining gasoline consumption has presented U.S. refiners with a choice between continuing to produce gasoline at or near their capacity while boosting exports, or cutting back on refinery output. U.S. refiners elected not to cut back on their production of gasoline; instead, they actually increased

---

[2517] Increased domestic emissions would only occur in this case to the extent that domestic distribution of gasoline entailed higher emissions than transporting it to U.S. coastal ports for export.

[2518] These and other petroleum statistics cited here were calculated from data available at EIA, Petroleum and Other Liquids, 2019, https://www.eia.gov/petroleum/data.php. U.S. production of crude petroleum rose from 1.83 billion barrels in 2008 to 4.01 billion barrels in 2018, or by 119%, During that same period, net U.S. imports of crude petroleum and refined products declined from 4.07 billion to 0.85 billion barrels, or by 79%. Net U.S. imports are the difference between the nation's total (or gross) imports from elsewhere in the world and the volumes it exports to other nations.

[2519] U.S. gasoline consumption declined from 3.39 billion barrels in 2007 to 3.18 billion barrels in 2012, or by 6.2 percent, rose to 3.41 billion barrels in 2016, and remained near that level through 2018.

[2520] In 2010, U.S. net imports of refined petroleum products were 98 million barrels, but by 2011 U.S. net *exports* were 160 million barrels. U.S. net exports of refined products then increased steadily through 2018, reaching 1.23 billion barrels in that year. In 2015, U.S. net imports of gasoline and blending components totaled 19 million barrels, but by 2016, U.S. net *exports* were 20 million barrels, and grew to 93 million barrels in 2018. Another recent change in petroleum markets has been the increasing production and trade in gasoline blendstock in domestic and international petroleum trade. While in earlier periods refineries normally produced finished gasoline and shipped it to local storage terminals for distribution and retailing, in recent years, refineries have increasingly shifted to producing standardized gasoline blendstocks, such as Reformulated Blendstock for Oxygenate Blending (or "RBOB"), which are then shipped and blended with ethanol or other additives to make finished gasoline that meets local regulatory requirements or customer specifications. Although this process has clear cost and operational advantages, particularly with extensive geographic and seasonal variation in gasoline formulations, it complicates the tabulation and comparison of petroleum statistics. In both EIA and most international trade statistics, finished gasoline and blendstocks are treated as separate products, and as reported in EIA statistics, large volumes of finished gasoline are now produced from blendstocks by local "blenders," rather than by more centralized "refiners." In addition, the volume of refinery production of gasoline and blendstock is now systematically lower than consumption of finished gasoline, because up to 10 percent of the volume of gasoline sold at retail can be made up of ethanol that is blended into gasoline after it leaves the refinery.

the volume they refined. U.S. production of finished gasoline increased by 9 percent between 2007 and 2018.

The excess of gasoline production resulting from increased refinery capacity and stable consumption has partly displaced previous gasoline and blendstock imports, with the remainder taking the form of increased U.S. exports. Thus, as Figure VI-166 below shows, the nation now has a capacity to produce gasoline that considerably exceeds its current domestic consumption. This surplus of gasoline appears likely to increase in coming few years, as EIA's *Annual Energy Outlook 2019* reference case (EIA, 2019) anticipates that domestic gasoline consumption will continue to decline until nearly 2040. Therefore, the U.S. seems likely to remain a net exporter of gasoline through the next three decades.

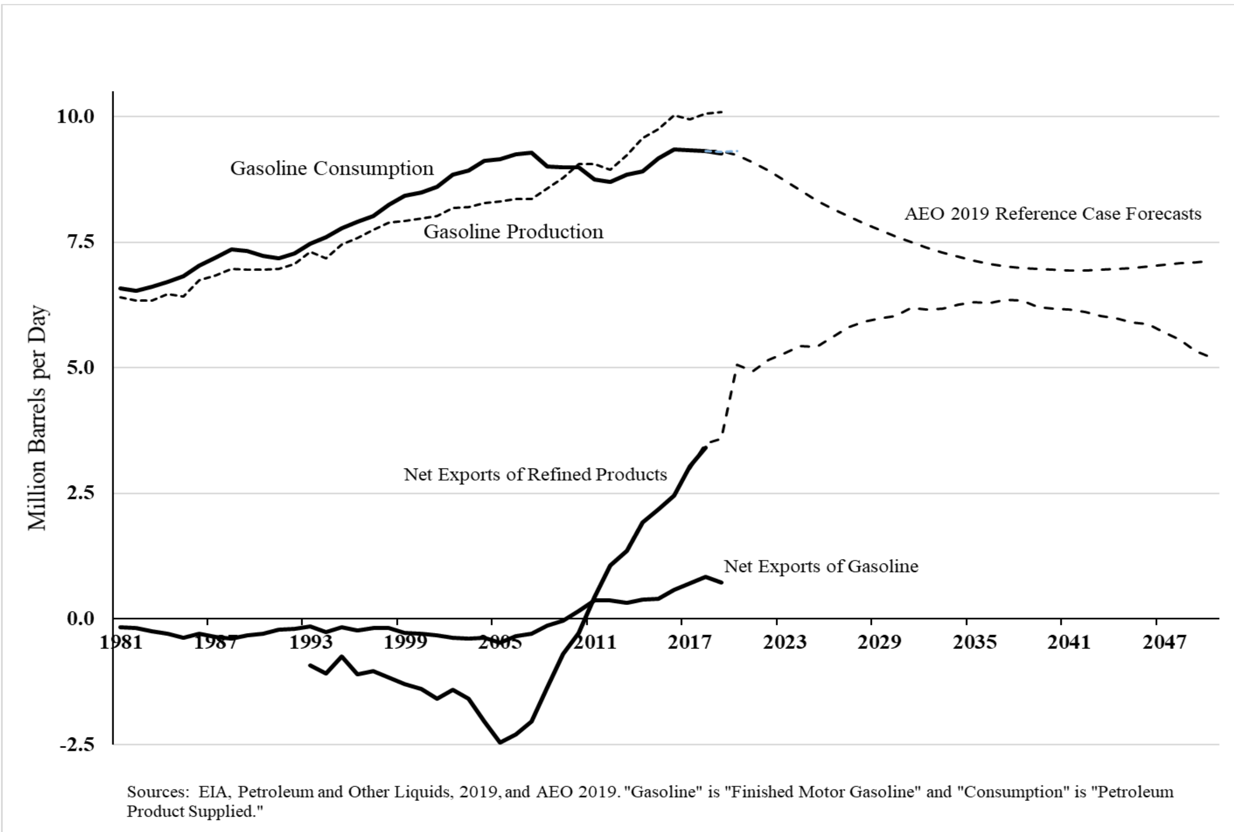

Figure VI-166 – U.S. Gasoline Consumption, Production, and Net Exports: Historical and Forecast

Although EIA's Annual Energy Outlook does not include separate forecasts of gasoline exports and imports, that same agency's *Short Term Energy Outlook* projects that U.S. gasoline exports will continue to rise through 2020 (EIA, 2019).[2521] Combined with EIA's reference case forecast in the AEO 2019, the forecasts of declining U.S. gasoline consumption and rising net exports of refined petroleum products suggest that the United States will remain a growing net exporter of refined petroleum products—including gasoline—through nearly 2040. In turn, this suggests that any increase in domestic gasoline consumption

[2521] AEO does not forecast gasoline refining, imports, or exports separately, instead reporting them as part of total refined petroleum products.

resulting from this final rule is likely to low anticipated growth in U.S. exports, rather than prompting growth in domestic refining and associated upstream emissions.

Regional patterns of U.S. gasoline consumption, refining, and trade also suggests that redirecting U.S. gasoline exports to domestic markets is likely to be an important source of additional supply to meet any increase in U.S. consumption stemming from this final rule. The nation's East Coast (which comprises the Energy Information Administration's Production and Distribution District 1, or PADD 1) currently accounts for about 32 percent of U.S. gasoline consumption, but has historically produced significantly less than gasoline than it consumes. As Figure VI-167 below shows, the gap between consumption and local supply within PADD1 has recently narrowed, as gasoline production along the East Coast has increased rapidly in recent years, while shipments into the region from the remainder of the U.S. and foreign imports (which come mostly from Canada) declined. In June 2019, however, press reports suggested that that one of the largest East Coast refineries (Philadelphia Energy Solutions, which represents some 28 percent of East Coast refining capacity) would be closed.[2522] At the same time, construction of new refineries continues to be hindered by the density of population concentrations and commercial development along the nation's East Coast, casting doubt on the potential for continued increases in local gasoline refining and supply within PADD 1.

[2522] Seba, E. (2019, July 5). Philadelphia refinery closing reverses two years of U.S. capacity gains. Retrieved September 19, 2019, from Reuters: https://www.reuters.com/article/us-usa-refinery-blast-capacity/philadelphia-refinery-closing-reverses-two-years-of-u-s-capacity-gains-idUSKCN1U0283.

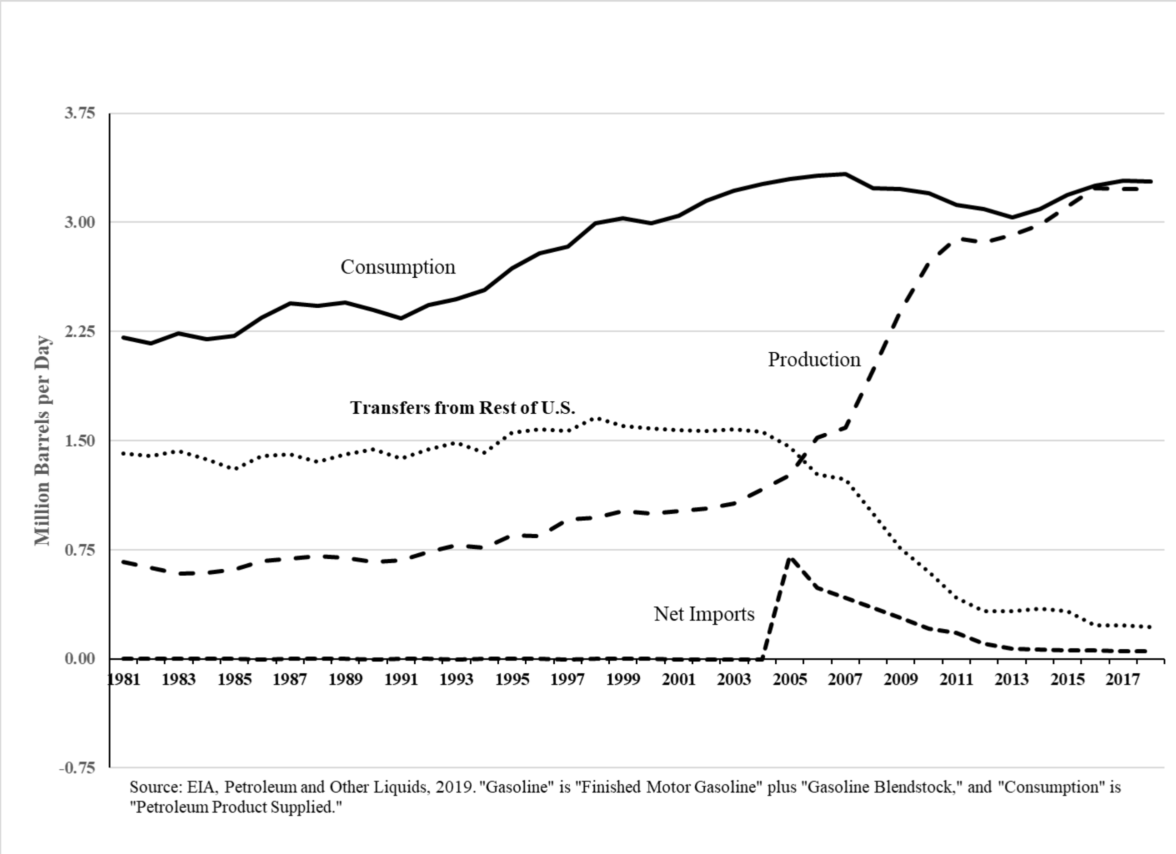

Figure VI-167 – U.S. East Coast (EIA PADD 1) Gasoline Production, Consumption, Transfers from Rest of U.S., and Net Exports

As a consequence, it seems likely that at least in the near term, any increase in gasoline consumption along the Nation's East Coast in response to this rule would be supplied primarily by Gulf Coast refineries or increased foreign imports, rather than from increased production in East Coast refineries. Pipelines available to transport refined petroleum products from Gulf Coast refineries to the East Coast may also face capacity limitations, in which case most of any increase in gasoline consumption there would need to be met by increased imports from abroad. Over the longer term, however, it is possible that increases in East Coast gasoline consumption could be met partly by expanded refining activity within the region.

The West Coast, which includes Nevada and Arizona (EIA's PADD 5), currently accounts for 168 percent of U.S. gasoline consumption. Almost all of the gasoline consumed in that region is also refined within it, although small volumes are shipped into Arizona from neighboring PADDs by pipeline, and small volumes are also exported to Latin America by tanker. The West Coast is relatively isolated from other U.S. sources of refined gasoline by long transportation distances and limited pipeline capacity, while import terminals for crude petroleum are relatively numerous, and it therefore appears more likely that marginal increases in gasoline consumption from the rule will be met from increases in local (i.e., within-PADD) refining. Figure VI-168 shows that this has been the case in recent decades, as growth in gasoline production within PADD 5 throughout that period has closely paralleled growth in local consumption, while net exports have remained minimal.

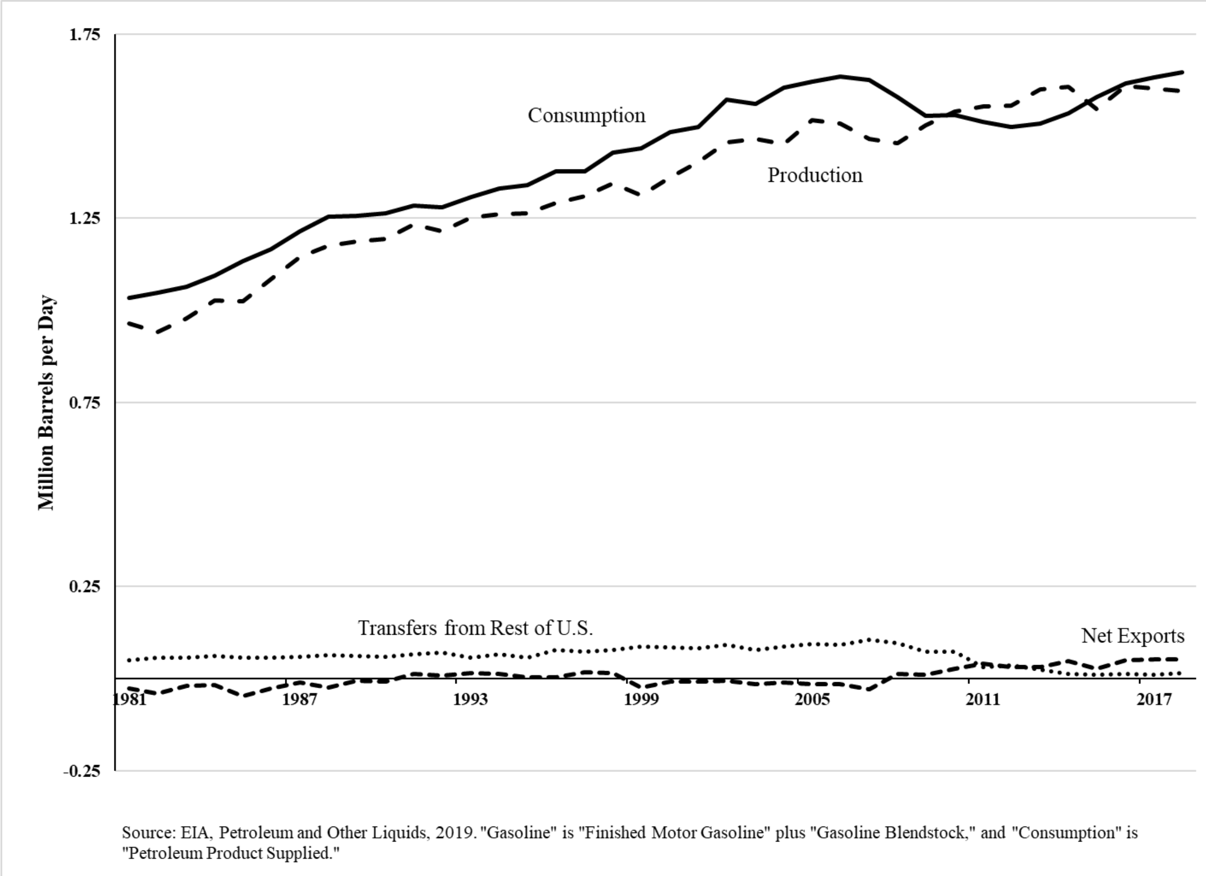

Figure VI-168 – U.S. West Coast (EIA PADD 5) Gasoline Production, Consumption, Transfers from Rest of U.S., and Net Exports

The central region of the United States (PADDs 2-4) accounts for the remaining 52 percent of current U.S. gasoline consumption, while producing about three-quarters of the nation's gasoline and blendstock. Although as Figure VI-169 shows the central region was a minor net exporter of gasoline as recently as 2007, it now exports some 800,000 barrels per day of gasoline and blendstock, and has accounted for virtually all of the recent growth in U.S. exports of these two categories of refined products. Recent press reports indicate that firms are currently making significant new investments to add refining capacity on the Gulf Coast to process the growing supply of U.S. shale oil (Douglas, 2019), and with the projected future decline in U.S. consumption, any additional gasoline refined there is likely to increase U.S. exports. Thus, future increases in gasoline consumption in the central region of the U.S. of the magnitude likely to result from adopting these final standards is expected to be met by diverting gasoline exports to domestic consumption, even in the absence of additional refinery investments.

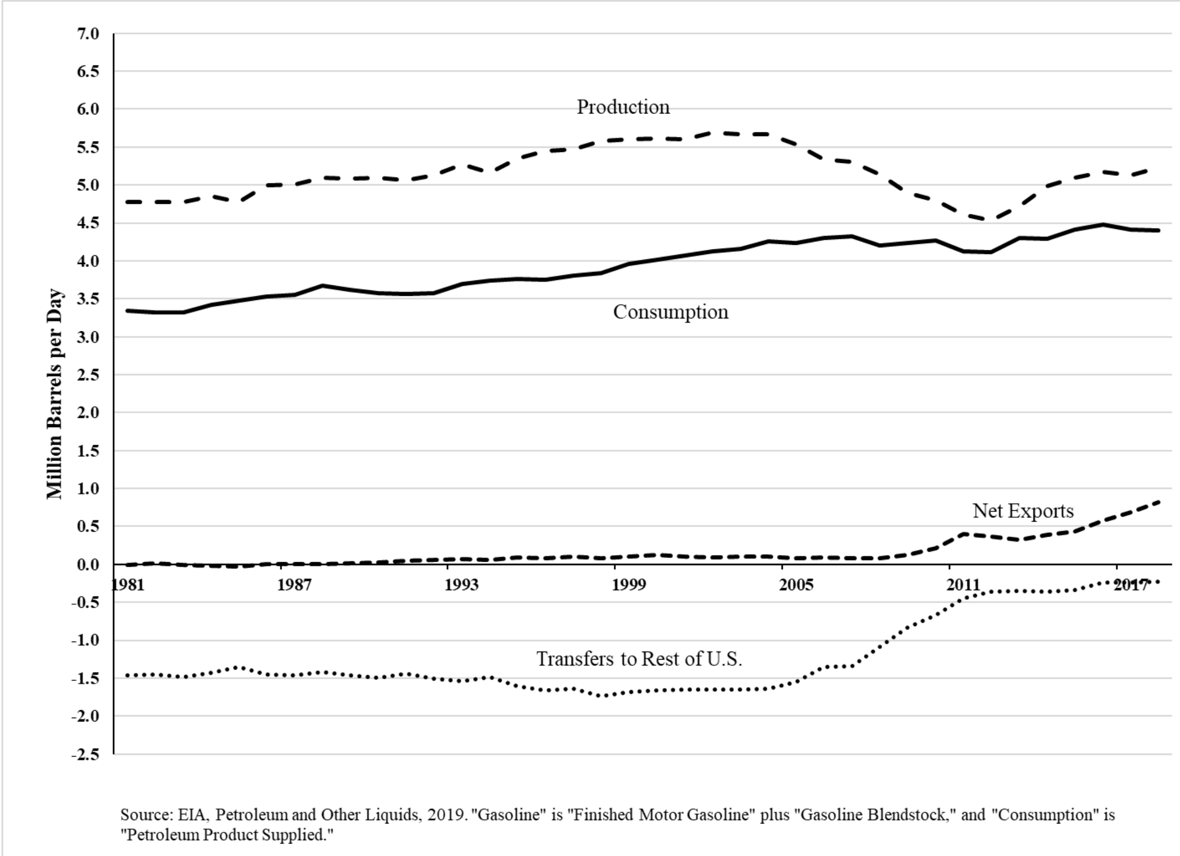

Figure VI-169 – U.S. Central Region (EIA PADDs 2-4) Gasoline Production, Consumption, Transfers to Rest of U.S., and Net Exports

Table VI-296 below compares recent changes in gasoline consumption and various sources of supply for these three U.S. regions during the recent period (2012-18) when gasoline consumption has generally increased. As it shows, recent increases in consumption along the U.S. East Coast have been supplied by increased production within the region. As noted previously, however, it appears likely that production capacity there will contract significantly in the near term, and that future increases in consumption will need to be met from foreign imports or shipments from other U.S. regions. As the table also shows, recent increases in gasoline production in the Midwest and Gulf Coast region have been adequate to supply increased consumption within the region as well as major increases in foreign exports and shipments to other U.S. regions. Finally, increased consumption on the Nation's West Coast appears to have been met via a combination of increased production within the region and drawdowns of previously accumulated inventories (not shown in the table).

At the national level, where net shipments among regions necessarily cancel one another (resulting in the zero entry for Net Receipts from Other PADDS shown in the table), recent increases in production have been sufficient to meet increased domestic consumption, while simultaneously enabling a major increase in exports. This suggests that from the nationwide aggregate perspective, incremental increases in domestic gasoline consumption resulting from this rule could be met by a reduction in U.S. exports of domestically-refined gasoline to other nations, accompanied by increases in shipments from the Midwest and Gulf Coast regions to the nation's East and West Coasts.

Table VI-296 – Recent Changes in Gasoline Consumption, Production, Imports and Exports by Region of the U.S.

Region	PADD	Gasoline Consumption, 2018		Changes, 2012-18 (000 Bbl.)				
		000 Bbl.	% of U.S. Total	Consumption	Production	Imports	Exports	Net Receipts from Other PADDs
East Coast	1	1,179,054	32%	67,206	134,201	225	1,227	-41,265
Midwest and Gulf Coast	2-4	1,910,047	52%	102,039	255,675	-787	165,069	48,389
West Coast	5	582,267	16%	54,573	14,470	805	8,575	-7,124
Entire U.S.	Total	3,671,368	100%	223,818	404,346	243	174,871	0

To summarize, based on changes in the various sources of supply that have accompanied recent changes in consumption within different regions of the U.S., the agencies anticipate that:

- Most of any marginal increases in U.S. gasoline consumption resulting from this rule that occur on the East Coast of the U.S. is likely to be met in the near term by increased transfers from other regions of the U.S. or higher foreign imports, and possibly by expanded refining activity in the longer term;
- Most of any marginal increases in U.S. gasoline consumption resulting from this rule that occur on the West Coast is likely to be supplied by increased gasoline refining within that region; and
- Most or all of any marginal increase in U.S. gasoline consumption resulting from this rule that occurs in the Central region is likely to be supplied by redirecting foreign exports to supply markets within that region.

With these expectations and acknowledging the uncertainty surrounding them, the agencies have concluded that assuming 50 percent of any increase in U.S. gasoline consumption will lead to increased domestic refining activity—and thus to increases in domestic refinery emissions—continues to be reasonable, and perhaps even overstates the expected increase in domestic refinery emissions. In particular, the agencies find that assuming 50 percent is more reasonable than assuming that either none or 100 percent of any change in gasoline consumption will be translated into changes in domestic gasoline refining. Thus, the agencies have elected to continue to employ the 50 percent assumption in their central analysis, and to examine the sensitivity of its results to varying this fraction over the entire possible range, from zero to 100 percent.

(ii) Changes in Crude Oil Supply to Domestic Refineries

The agencies also re-evaluated their assumption that 90 percent of the increase in crude petroleum refined in the U.S. to produce additional gasoline consumed as a result of this rule would be imported from abroad (thus resulting in increased emissions for its storage at import terminals, and transportation to domestic refineries), while the remaining 10 percent would be produced domestically (thus resulting in emissions from its extraction, local storage, and transportation to U.S. refineries). As discussed in more detail below, the agencies conclude that domestic petroleum production responds primarily to technological innovations, investments in exploration and development of new domestic sources of oil, and variation in the world price of petroleum, rather than to U.S. demand for refined products such as gasoline. As a consequence, they conclude that any increase in gasoline consumption attributable to this final rule is unlikely by itself to have a significant effect on domestic petroleum production, and that their previous assumption continues to be reasonable.

U.S. oil production is primarily a function of development opportunities identified during prior exploration programs, innovations in the technological for drilling and extracting crude petroleum, producer's expectations regarding future world petroleum prices, and the U.S. tax and regulatory situations surrounding petroleum exploration and production. Crude oil is a fungible, non-perishable commodity, and can usually be transported among local oil markets around the globe at some cost. As a consequence, the price of oil in a U.S. domestic market such as Texas is highly correlated with its price in markets located in Northern Europe, the Far East, and the Middle East.

In contrast, U.S. gasoline consumption depends on a broad array of factors that overlap only partially with the determinants of U.S. crude petroleum production. These include domestic economic growth and its consequences for transportation demand, current and future vehicle fuel economy, gasoline prices, excise and sales taxes levied on gasoline, technological and cultural changes, vehicle prices, and the evolution of transportation systems and the built environment.

As a consequence, changes in U.S. consumption and supply of petroleum products will primarily be reflected in changes the destinations of domestically produced and imported crude petroleum, rather than in changes in their production volumes. To the extent that changes in U.S. gasoline demand for lead to changes in the volume refined domestically (the subject of the previous analysis), increased refining activity is thus likely to be reflected in a shift in U.S. imports or exports of crude oil, rather than in a change in U.S. *production* of crude oil. Instead, any effect of this rule on U.S. crude oil production would arise primarily from the impact of increased domestic gasoline demand on global oil prices, which will be limited by the fact that U.S. gasoline demand accounts for a relatively small share of total global demand for petroleum products, and by the response of global supply to any upward pressure on prices. Thus, any effect of this rule on U.S. petroleum production is likely to be extremely modest.[2523]

Localized and temporary changes in domestic production might arise in response to capacity limitations or transportation bottlenecks associated with particular regions or refineries, which could temporarily create markets for higher-priced crude oil. However, these situations would normally be localized and prevail for only a limited time. At the same time, the effects of any change in domestic petroleum consumption on world oil prices would be attenuated, because as indicated previously the impact of increased domestic consumption would be felt on prices and volumes supplied in the much larger global petroleum market, rather than confined to the smaller U.S. market. Any resulting changes in global oil prices and petroleum production would inevitably be small when viewed on a world scale, and likely to prompt only minimal responses in U.S. petroleum supply.

As one indication of the likely minimal impacts of higher U.S. gasoline consumption on U.S. production of crude petroleum, EIA's *Annual Energy Outlook 2018* included a side case called "No New Efficiency Requirements," which included a freeze on U.S. fuel economy standards beginning in 2020. Although this scenario does not correspond exactly to either the agencies' earlier proposal or this final rule,

---

[2523] U.S. gasoline consumption currently accounts for about 9% of total global demand for refined petroleum products, and the AEO 2019 reference case projects that this will decline to 6% by the year 2035, and remain at that level through 2050. These figures are calculated from AEO 2019 Reference Case, Tables 11 and 21, available at https://www.eia.gov/outlooks/aeo/tables_ref.php.

comparing its results to those from the AEO 2018 reference case illustrates the insensitivity of domestic crude oil production to increases in gasoline consumption, as represented in EIA's National Energy Modeling System (NEMS).

Figure VI-170 below presents such a comparison, showing historical trends is U.S. gasoline consumption and petroleum production, and comparing their projected future trends in the AEO 2018 Reference Case and No New Efficiency Requirements alternative. As the figure illustrates, the large increase in U.S. gasoline consumption under the latter scenario relative to the Reference Case is accompanied by an almost indiscernible change in U.S. crude petroleum production, for exactly the reasons described above.

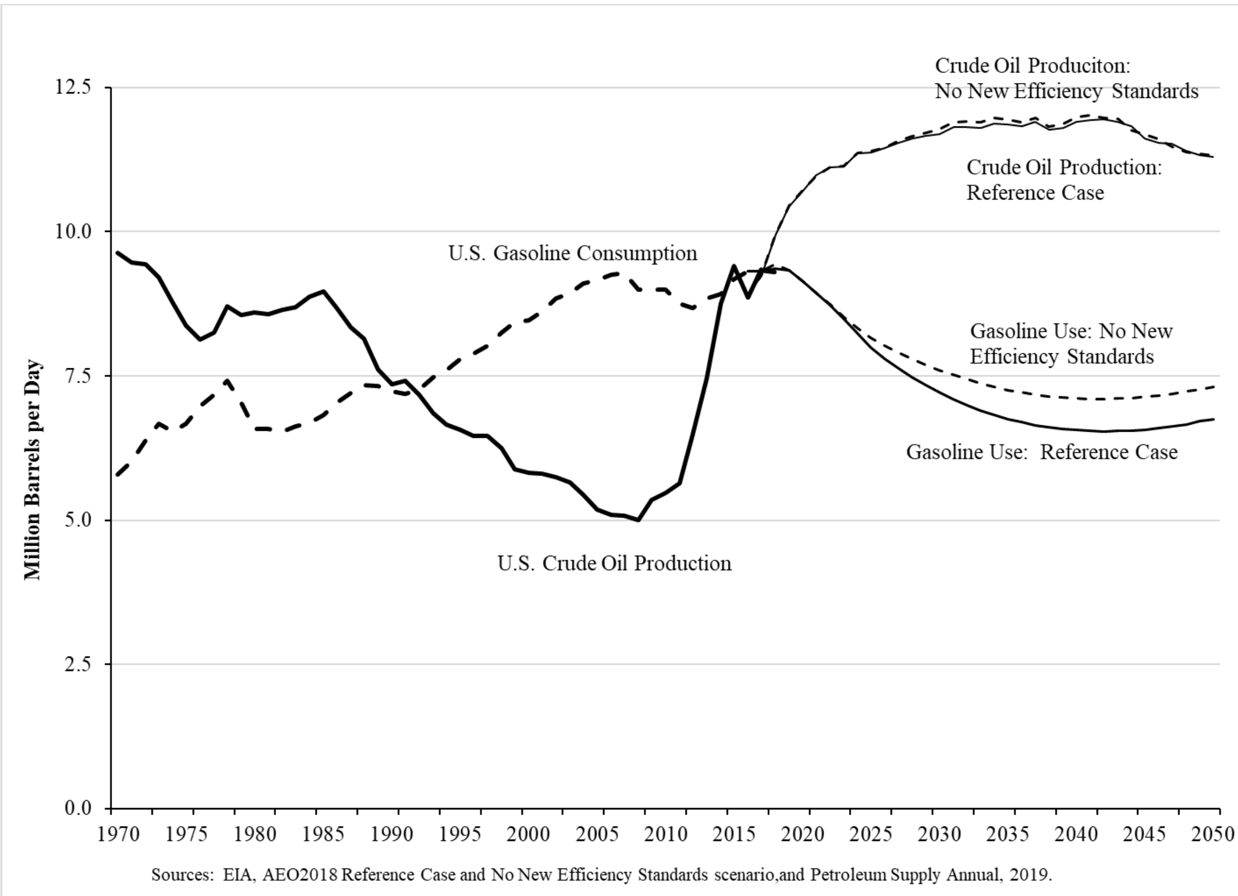

Figure VI-170 – Projected U.S. Gasoline Consumption and Crude Oil Production under AEO 2018 Reference and no New Efficiency Standards Scenario Cases

The agencies conclude that in the context of the current global petroleum market, increases in U.S. gasoline demand on the scale likely to result from this final rule are unlikely to produce changes in the market that prompt a significant increase in domestic petroleum production. Instead, they are likely to affect mainly the destinations and uses of crude petroleum—including refining gasoline within the U.S.—that is already being supplied to the global market. As a consequence, the agencies have elected to retain our previous assumption that any increase in domestic gasoline refining that occurs as a consequence of adopting this final rule is unlikely by itself to lead to a significant increase in domestic crude oil production or in the associated upstream emissions. Specifically, the agencies continue to assume that 10 percent of any increase in domestic gasoline refining would utilize increased U.S. production of crude petroleum.

The agencies chose to model upstream emissions in order to generate full fuel cycle emissions—using GREET for the upstream component and MOVES for the downstream component—because each alternative has varying levels of fuel consumption, and the specific gallons of gasoline, diesel, E85, and other fuels evaluated in today's rule will lead to different tailpipe and upstream emission outcomes.

While it may be fair to characterize MOVES and GREET as partial equilibrium models rather than general equilibrium models, the agencies did not make any modifications to the MOVES or GREET emission factors themselves. Changes in emission results were initiated through changes in fleet composition or activity, especially changes in vehicle miles travelled as well as vehicle sales and population. Other changes were made to average vehicle mass and road load coefficients such as aerodynamic drag and rolling resistance corresponding to the various regulatory alternatives. Each alternative consists of a package of technology changes, so a particular technology change was not modeled alone and would need to be evaluated separately to quantify incremental changes. Please consult the FRIA for quantified impacts for the technology packages laid out by alternative.

d) How did the agencies estimate and value health impacts from changes in air quality

The agencies' analyses estimates changes in the population-wide incidence of selected health impacts, as well as changes in the aggregate monetary value of those health impacts that may occur from the changes in emissions of criteria air pollutants projected to result from this final rule and the alternative that were considered. As with other estimated impacts of the final rule and alternatives, these changes are measured from a baseline that is represented by the adoption of the augural CAFE standards and the extension of EPA's CO_2 s updated estimates for these values, providing a more precise accounting of physical impacts and costs and benefits of the standards, and also directly responds to comments, as discussed below.[2524]

The agencies' analyses estimates changes in the population-wide incidence of selected health impacts, as well as changes in the aggregate value of health damage costs, likely to result from the changes in emissions of criteria air pollutants projected to result from this final rule and the alternative that were considered. As with other impacts of the final rule and alternatives, these are measured as changes from a baseline that is represented by the adoption of the Augural CAFE standards and the extension of EPA's CO_2 s updated estimates for these values, providing a more precise accounting of physical impacts and costs and benefits of the standards, and also directly responds to comments, as discussed below.[2525]

Many commenters expressed concern over the health impacts from increased GHG emissions and criteria pollutants. The American Lung Association et al. stated "Today, nearly 40 percent of Americans—more than 124 million—live in communities in nonattainment for ozone and particulate matter, with many residents impacted more severely by local pollution sources, including near-road pollution…. Near-road pollution has been found to increase asthma attacks in children, cardiovascular health impacts, impaired lung

[2524] *See* EPA, Office of Air and Radiation, Office of Air Quality Planning and Standards, *Technical Support Document, Estimating the Benefit per Ton of Reducing $PM_{2.5}$ Precursors from 17 Sectors*, February 2018, available at https://www.epa.gov/sites/production/files/2018-02/documents/sourceapportionmentbpttsd_2018.pdf.

[2525] *See* EPA, Office of Air and Radiation, Office of Air Quality Planning and Standards, *Technical Support Document, Estimating the Benefit per Ton of Reducing $PM_{2.5}$ Precursors from 17 Sectors*, February 2018, available at https://www.epa.gov/sites/production/files/2018-02/documents/sourceapportionmentbpttsd_2018.pdf.

function and premature death …. Reducing VOC emissions will help reduce the burden of these carcinogens on many communities, especially those living or working near these roadways."[2526] As discussed in this Section, the agencies agree with these statements and have considered health effects as part of the analysis for today's rule. The Institute for Policy Integrity stated "the agencies fixate on alleged on-road fatality effects while arbitrarily ignoring the mortalities, morbidities, and other welfare effects associated with emissions."[2527] As described in this Section, in the analysis for this rule, the agencies estimate both air quality-related fatalities and their costs, in addition to the agencies' analysis on vehicle-related fatalities. Many public commenters also expressed concern for health issues associated with increased pollutants and emissions over what was anticipated by the agencies' 2012 analysis. The agencies carefully considered these comments and provided additional analysis to consider health impacts, as described below.

The estimated health impacts reflect the nationwide baseline level of emissions of each pollutant, an assumed geographic distribution of increased emissions, the resulting changes in concentrations of criteria pollutants at various locations nationwide (some of which reflect accumulations of emissions, while others are chemical by-products formed in atmospheric reactions), increased exposure of the U.S. population to unhealthful concentrations of each pollutant, and the consequences of increased exposure for the aggregate frequency of each health impact. The agencies' analysis assumes that the increases in upstream and vehicle emissions are distributed in proportion to current emissions associated with fuel supply and vehicle use. This is consistent with the way EPA estimates health impacts and health damage costs for the refining and on-road mobile sources sectors, since those are estimated by assuming an increase in emissions from those sectors that is distributed in proportion to current emissions from each one, and estimating the resulting changes in accumulations of air pollutants, population exposure, health impacts, and associated monetary value. The accompanying estimates of per-ton damage costs apply unit values to the increased frequency of each health effect, representing the dollar costs or estimated willingness-to-pay to avoid its occurrence, and combine the results to estimate total damage costs.

EPA analysts utilize a large volume of underlying data, a number of intermediate calculations, and many simplifying assumptions to develop these estimates of health impacts and health damage costs per ton of additional emissions, and discussing these in detail is well beyond the scope of this rule. These underlying data, assumptions, and calculations are described in detail in the document that reports the values used for the agencies' analysis.[2528] EPA quantifies health impacts and damage costs for emissions from 17 separate sectors of U.S. economic activity, and reports values for increases in premature mortality and the combined costs of damages from premature mortality and various other health impacts per ton of $PM_{2.5}$, nitrate, and sulfate emissions.[2529] These values include high and low estimates of both premature mortality and health damage costs, which primarily reflect alternative published estimates of the premature mortality impact of $PM_{2.5}$ emissions.[2530] Alternative values are also reported for 3 percent and 7 percent discount rates;

[2528] *See* EPA, Office of Air and Radiation, Office of Air Quality Planning and Standards, *Technical Support Document, Estimating the Benefit per Ton of Reducing $PM_{2.5}$ Precursors from 17 Sectors*, February 2018, available at https://www.epa.gov/sites/production/files/2018-02/documents/sourceapportionmentbpttsd_2018.pdf.
[2529] Premature mortality includes deaths that are estimated to occur before the normally expected life span of persons with specified demographic characteristics.
[2530] Estimated willingness to pay to avoid premature death accounts for 98% of the total health damage costs included in these estimates; *see* EPA, p. 10.

discounting affects the values because of the delay (or "latency period") between exposure to air pollution and the development of some health impacts, most notably premature deaths.

The agencies' analysis uses those values for the petroleum refining sector (sector 15) to represent impacts resulting from emissions that occur during the fuel production and distribution process (upstream emissions), and those for the on-road mobile source sector (sector 13) to represent the impacts of emissions resulting from car and light truck use. The agencies apply EPA's estimates of per-ton increases in premature mortality and health damage costs for these sectors to their estimates of changes in nationwide total emissions of $PM_{2.5}$, nitrogen oxides (NOx), and sulfur dioxide (SO_2) from the fuel supply process and from car and light truck use.

Table VI-297 and Table VI-298 below report values the agencies used in the estimates of premature mortality impacts and total health damage costs per ton of emissions to analyze the consequences of this final rule. The results for this analysis are provided in Section VII of this rule. The dollar values reported in the tables below differ slightly from those reported in the underlying source, because they have been adjusted from the 2015$ used in that source to the 2018 dollars used throughout this analysis. Values for intervening years were interpolated from those shown in the tables, and values for the year 2030 shown in the tables were assumed to prevail for years beyond 2030. The agencies' central analysis of the rule uses averages of the low and high values shown in each table, while the low and high values themselves are used in the sensitivity analyses described in Section VII of this rule.

The valuation of premature mortality effects rely on the results of "benefits per ton" approach (BPT). This approach is a reduced form approach, which is less complex than full-scale air quality modeling, requiring less agency resources and time. Based on EPA's work to examine reduced form approach, the BPT may yield estimates of $PM_{2.5}$- benefits for the mobile sector that are as much as 10 percent greater than those estimated when using full air quality modeling.

The EPA is currently working on a systematic comparison of results from its BPT technique and other reduced-form techniques with results from full-form photochemical modelling. While this analysis employed photochemical modeling simulations, we acknowledge that the Agency has elsewhere applied reduced-form techniques. The summary report from the "Reduced Form Tool Evaluation Project", which has not yet been peer reviewed, is available on EPA's website at *https://www.epa.gov/benmap/reduced-form-evaluation-project-report*. Under the scenarios examined in that report, EPA's BPT approach in the 2012 rule (which was based off a 2005 inventory) may yield estimates of $PM_{2.5}$- benefits for the mobile sector that are as much as 10 percent greater than those estimated when using full air quality modeling. The estimate increases to 30 percent greater for the electricity sector. The EPA continues to work to develop refined reduced-form approaches for estimating $PM_{2.5}$ benefits.

In addition, considerable uncertainty surrounds many of the assumptions and other inputs used in the agencies' analysis of economic and environmental impacts likely to result from adopting the final standards, rather than ratifying the augural standards. Perhaps most notably, because fuel prices are inherently volatile and forecasts of their future level depend critically on developments in the often unstable and politicized global oil market, those forecasts are inherently uncertain, as evidenced by the fact that actual gasoline prices are well below those the agencies relied on in their 2012 analysis of CAFE and CO_2 standards for model years 2017-25. While the agencies' current analysis updates those projections to reflect EIA's 2019 Annual Energy Outlook, which now anticipates that future prices will remain well below those the agencies projected in their 2012 analysis, it remains possible that EIA's current forecast will continue to overestimate actual future prices (Of course, EIA's current forecast could also prove to be too low, although the recent record suggests a larger risk that the opposite will be the case.) Further, gasoline prices are only one of a number of assumptions about which the agencies have reason to be uncertain; others include the fuel economy and other features of car and light truck models that manufacturers will offer during future model years, how buyers will respond to changes in the features of competing models in the face of future fuel prices and economic conditions, and how much they (and subsequent owners) will ultimately drive the models they purchase over their lifetimes. Uncertainty about all of these factors is reflected in similar risks that the agencies' projections of changes in vehicle use and fuel consumption under the final standards will prove to be in error. Finally, uncertainty about the agencies' companion projections of those standards' impacts on PM emissions and premature mortality is compounded by the currently unknown effects of future control technologies and regulations on actual refinery and vehicle emissions, as well as by the sources of potential error in estimating the effects of changes in emissions on premature mortality discussed above. Although it may seem that the agencies' estimates of increases in premature mortality resulting from the final standards are more likely to be too high than too low, it is extremely difficult to anticipate whether this is actually the case.

Separately, the DEIS and FEIS accompanying this rule describe that the BPT estimates are subject to several assumptions and uncertainties that make it difficult to draw conclusions about the estimated monetary values.[2531] Non-exhaustively, these reasons include that estimates do not reflect local variability in

---

[2531] *See* DEIS and FEIS at Chapter 4, Air Quality - Health Impacts.

population density, meteorology, exposure, baseline health incidence rates, or other local factors that might lead to an overestimate or underestimate of the actual benefits of controlling fine particulates, and that the health impact studies include several sources of uncertainties, including: within-study variability (the precision with which a given study estimates the relationship between air quality changes and health impacts), across-study variation (different published studies of the same pollutant/health effect relationship typically do not report identical findings, and in some cases the differences are substantial), the application of concentration-response functions nationwide (does not account for any relationship between region and health impact to the extent that there is such a relationship), and extrapolation of impact functions across population (the agencies assumed that certain health impact functions applied to age ranges broader than those considered in the original epidemiological study).

Full-scale photochemical modeling provides the needed spatial and temporal detail to more precisely estimate changes in ambient levels of these pollutants and their associated impacts on human health and welfare. This modeling provides insight into the uncertainties associated with the use of benefit-per-ton estimates. The agencies conducted a photochemical modeling analysis for the Final EIS using the same methods as in the previous CAFE Final EISs[2532,2533] and the HD Fuel Efficiency Standards Phases 1 and 2 Final EISs.[2534,2535] The air quality modeling and health effects analysis focused on ozone and fine particulate matter equal to or less than 2.5 microns in diameter ($PM_{2.5}$). As indicated in the Draft EIS, the agencies performed photochemical air quality modeling based on the inputs and emissions forecasts used in the Draft EIS. Consistent with prior rulemakings and as described in the scoping notice, to accommodate the substantial time required to complete the air quality modeling analysis, NHTSA proposed to initiate air quality modeling before the inputs and emissions forecasts for the Final EIS were finalized.[2536] NHTSA received no public comments in response to the scoping notice addressing this analytical approach, and the agency proceeded accordingly. Therefore, NHTSA used the inputs and emissions forecasts for the Proposed Action and alternatives as stated in the Draft EIS for the analysis in this final rulemaking. For additional information on the scoping notice and comments received, *see* Section X.

Some stakeholders submitted comments about the agencies' use of underlying NPRM modeling to conduct the photochemical modeling; for example, NCDEQ recognized the agencies statement that there was not sufficient time to collect the modeling, but stated that they "strongly believe that the inputs and results should be readily available for public comment before the EIS and rulemaking are finalized."[2537] Those comments are addressed in Section X. As part of EDF's alternative examination of the CAFE model and inputs, EDF utilized the same EPA benefit-per-ton method the agencies utilized for the final rule (discussed further below) to estimate health effects due to criteria pollutant emissions, concluding that the proposal

would increase premature mortality due to increases in particulate matter emissions. EDF stated that these results indicated that the potential impacts of the rule are large, and accordingly, "NHTSA and EPA must conduct detailed and thorough emission, photochemical and health effects modeling to quantify the effect of this or any other proposal to relax the CAFE and CO_2 standards and increase upstream emissions."[2538]

The agencies estimated air quality changes and health-related benefits at the national scale based on a detailed analysis of air quality and health effects throughout the contiguous 48 states. Different regions of the country could experience either a net increase or a net decrease in emissions because of the rule, depending on the relative magnitude of the changes in emissions from decreased fuel economy, decreased vehicle use, and increased fuel production and distribution under each alternative. The EIS air quality analysis addresses regional differences using grid-based air quality modeling and analysis techniques, which account for local and regional differences in emissions and many of the other factors (such as meteorology and atmospheric processes) that affect air quality and the resulting health effects at any given location. This air quality modeling analysis is intended as a screening application of both the Community Multiscale Air Quality (CMAQ) model and the Environmental Benefits Mapping and Analysis Program (BenMAP) tool for the purposes of quantifying and comparing the air quality and health-related benefits.

To examine and quantify the air quality and health-related benefits associated with implementing the final CAFE standards for MY 2021–2026 light-duty vehicles, the agencies performed a national-scale photochemical air quality modeling and health benefit assessment with the following key steps:

- Preparing emission inventories
- Modeling air quality
- Assessing air quality–related health impacts

The following widely used tools were used for the air quality and health effects assessment:

- Sparse-Matrix Operator Kernel Emissions (SMOKE) processing tool (version 3.7) to prepare model-ready emissions.
- Community Multiscale Air Quality (CMAQ) model (version 5.2.1) to quantify air quality changes for the different fuel economy alternatives.
- Environmental Benefits Mapping and Analysis Program―Community Edition (BenMAP-CE) tool (version 1.4) to assess the health-related impacts of the simulated changes in air quality.

The national-scale modeling analysis employed the standard CMAQ continental modeling domain. The horizontal resolution of the grid for this modeling domain is 36 kilometers (22.4 miles). Air quality and health-related impacts were calculated for each grid cell in the entire contiguous United States (48 states). Although the modeling domain does not include all 50 states, nearly all of the affected emissions and population are included in the domain; therefore, the results are expected to represent those for a national-scale analysis. The agencies applied the CMAQ model for an annual simulation period using meteorological inputs for a base year of 2011.

The agencies performed modeling for 2035 (although the emission inputs represented a variety of different projection years, including 2030, 2035, and 2040, based on best available data). As in the Draft

[2538] Environmental Defense Fund, NHTSA-2018-0067-12108.

EIS, the agencies chose 2035 for analysis of the various fuel economy alternatives because a large proportion of vehicles in operation are expected to meet the level of the standards set forth by 2035. EPA provided up-to-date, projected, national-scale emissions data for 2040 for motor vehicles and for 2030 for all other sources. The emissions were processed for the 36-kilometer (22.4-mile) resolution modeling domain using SMOKE. The resulting model-ready inventories contain emissions for all criteria pollutants (as required for photochemical modeling) for multiple source categories (sectors), including on-road mobile sources, non-road mobile sources (e.g., construction equipment, locomotives, ships, and aircraft), electric generating unit (EGU) point sources, non-EGU point sources, area sources, and biogenic sources.

Following preparation of baseline emissions inventories, the baseline emissions for the light-duty vehicle portion of the on-road mobile emissions and the relevant upstream categories were replaced with data reflecting the alternatives analyzed in the Draft EIS. As discussed above, NHTSA calculated national estimates of on-road emissions for these vehicle classes for 2035, including both downstream and upstream emissions.

The agencies then applied CMAQ, using the emissions specific to each alternative. The simulated difference in air quality between the Draft EIS No Action Alternative and each action alternative represents the change in air quality associated with that alternative. Following the application of CMAQ, the agencies processed the CMAQ outputs for input to the BenMAP-CE health effects analysis tool, and used BenMAP-CE to estimate the health impacts and monetized health-related benefits associated with the changes in air quality simulated by CMAQ for each of the action alternatives. The BenMAP-CE tool includes health impact functions, which relate a change in the concentration of a pollutant with a change in the incidence of a health endpoint. BenMAP-CE also calculates the economic value of health impacts. For this study, the health effects analysis considered the effects of ozone and $PM_{2.5}$. The $PM_{2.5}$ analysis includes sulfate and nitrate particulates (secondary $PM_{2.5}$) formed from emissions of SO_2 (sulfur dioxide) and NO_X, respectively. BenMAP-CE does not estimate health impacts associated with changes in directly emitted sulfur dioxide (SO_2), carbon monoxide (CO), and other emissions. Health effects were calculated at the 36-kilometer scale (grid cell size) and aggregated nationally to determine overall impact.

Figure VI-171 shows the components of the air quality modeling and health-related benefits analysis. Note that both the emissions and meteorological inputs are used by SMOKE.

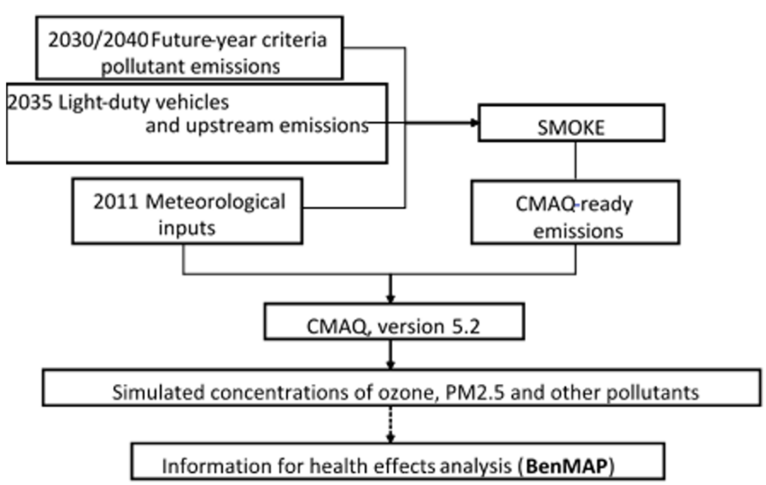

Figure VI-171 – Diagram of Air Quality Modeling and Health-Related Benefit Analysis

E. Compliance Example Walk-through

To illustrate the CAFE model's simulation of a manufacturer's potential response to fuel prices and new standards, the NPRM provided an example of how the preliminary version of the model showed, on a year-by-year basis, how GM could potentially respond to a set of CAFE standards, starting from MY 2016 (the latest year for which the agencies were able to develop a full and detailed characterization of the fleet of vehicles produced for sale in the U.S. at the time of publishing the NPRM). Although no analysis that does not rely heavily on a manufacturer's confidential product planning information can, with high fidelity, predict what that manufacturer *will* do, the CAFE model, by realistically reflecting product planning considerations in a detailed year-by-year context, can describe a course that manufacturer *could* realistically take. Indeed, when manufacturers provide information to the agencies, they often emphasize year-by-year plans. Although such information is typically considered confidential business information (CBI), public comments by the Alliance illustrate the concept for a hypothetical manufacturer. Although the illustration includes credit carry-back (aka borrowing) that most manufacturers have a history of avoiding, the illustration clearly demonstrates that the Alliance views product planning as a year-by-year exercise:

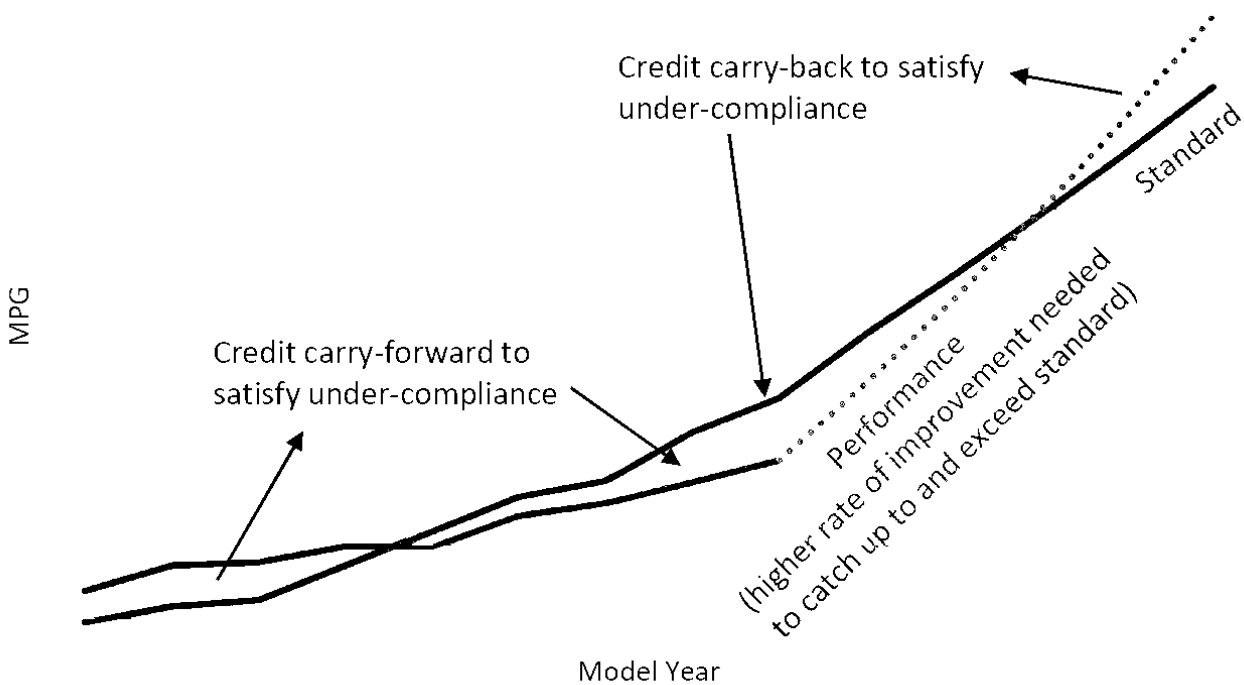

Figure VI-172 – Alliance Illustration of a Hypothetical OEM's Compliance Pathway[2539]

Like the peer reviewers who examined the model's simulation of technology application and compliance, automakers have been widely supportive of the CAFE model's approach of year-by-year analysis informed by product planning realities. For example, Toyota commented, "The preamble correctly notes that manufacturers try to keep costs down by applying most major changes mainly during vehicle redesigns and more modest changes during product refresh, and that redesign cycles for vehicle models can range from six to ten years, and eight to ten-years for powertrains… This appreciation for standard business

[2539] NHTSA-2018-0067-12073, at 28.

practice enables the modeling to capture more accurately the way vehicles share engines, transmissions, and platforms. There are now more realistic limits placed on the number of engines and transmissions in a powertrain portfolio which better recognizes manufacturers must manage limited engineering resources and control supplier, production, and service costs."[2540]

The CAFE model's year-by-year approach to estimating manufacturers' potential responses to standards and fuel prices is consistent with EPCA/EISA's requirement that CAFE standards be set at the maximum feasible levels for each fleet (passenger car and light truck) in each model year. Some commenters correctly observe that the CAA (which provides no direction regarding tailpipe CO_2 emissions standards) does not require such a year-by-year determination, but suggest, further, that EPA should refrain from making use of year-by-year analysis. In particular, CBD et. al. commented as follows:

> Furthermore, the Volpe model and association [sic] tools are not designed in accordance with EPA's independent statutory authority under Clean Air Act Section 202. The Volpe and OMEGA models have an overarching difference in their architecture—one where the Volpe modeling approach is designed to match NHTSA's statutory authority, but not EPA's. The EPCA requirements drive the design of the Volpe model, in that it performs a year-by-year analysis in order to demonstrate that NHTSA is meeting its EPCA obligations. As a result, the Volpe model attempts to simulate for each manufacturer, by year, their refresh and redesign cadence across their vehicle platforms and then predict a manufacturer's technology deployment decision-making process for each platform. But under the Clean Air Act, EPA is not required to demonstrate that standards are set at the maximum feasible level year-by-year, as EPCA explicitly requires for NHTSA.[2541]

Although CBD is correct that the CAA does not *require* a year-by-year determination or year-by-year analysis, CBD wrongly claims that the CAFE model's modeling approach is not "in accordance" with the CAA. CBD's claim is analogous to saying "just say you want to drive across the country; don't bother looking at a map." As the NPRM demonstrated, the CAFE model can be used to simulate compliance with CO_2 standards. That the model follows a year-by-year approach to doing so simply means that it takes greater pains to describe realistic pathways forward from a known model year. Manufacturers are by no means the only stakeholders to recognize that product planning is actually a year-by-year process. Supporting its comments on the agencies' proposal, CARB provided a study by Roush Industries, focusing on a potential design pathway for the Toyota RAV4.[2542] While this report, which was cited by CARB in its comments, asserted the agencies' modeling underestimated fuel consumption benefits and overestimated costs, Roush, like the Alliance, clearly interpreted the question of realism as a year-by-year question, as illustrated by the following chart in Roush's report:

[2540] NHTSA-2018-0067-12098, at 6.
[2541] NHTSA-2018-0067-12000, Appendix A, at 24-25.
[2542] Rogers, G., "Technical Review of: The Safer Affordable Fuel-Efficient (SAFE) Vehicles Rule for Model Years 2021-2026 Passenger Cars and Light Trucks, Final Report." Roush Industries. October 25, 2018. *See* CARB, NHTSA-2018-0067-11984.

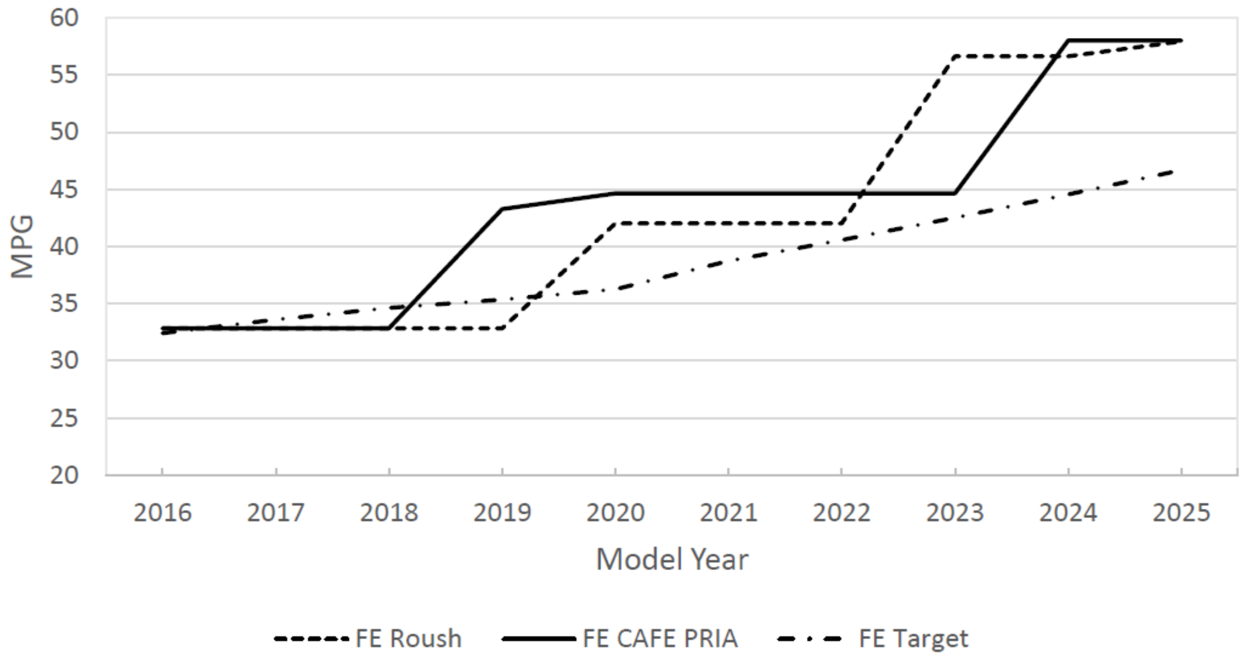

Figure VI-173 – Roush Industries Illustration (for CARB) of RAV4 Fuel Economy Pathway[2543]

While a year-by-year representation is essential to the estimation of pathways that individual manufacturers could realistically take to apply technologies to specific vehicle models, the CAFE model also accounts for a range of other important engineering and product planning considerations. For example, among specific vehicle models, engines and transmissions are often shared, and a given vehicle design platform may encompass a range of different specific vehicle models. This means not every configuration of every vehicle model can be as optimized for fuel economy as if each could be considered in isolation. This isn't to say that such optimization is technologically impossible, but rather to say that the resources involved in such optimization would be financially impracticable. Moreover, CAFE and CO_2 standards apply to fleets, not specific products. This means, for example, that if a given engine is shared among both passenger cars and light trucks, changes made to that engine in response to one fleet's standard will impact products in the other fleet. Consistent with the fact that CAFE and CO_2 compliance applies to fleets on a year-by-year basis, the CAFE model explicitly accounts for sharing among specific model/configurations when simulating year-by-year compliance. The Roush report's authors "have not performed a complete fleet-compliance simulation."[2544] Therefore, even notwithstanding differences in estimates of redesign schedules and technology efficacy and costs, Roush's analysis of the RAV4 is highly idealized. As discussed below, together with inputs based on Toyota's actual MY 2017 production, the CAFE model represents the RAV4 as encompassing multiple configurations, spanning both the passenger car and light truck regulatory classes, all on a common vehicle platform that includes several other vehicle models, and some RAV4s sharing engines with some Camrys. Compared to estimating the *potential* to apply technology to a handful of

[2543] Rogers, G., "Technical Review of: The Safer Affordable Fuel-Efficient (SAFE) Vehicles Rule for Model Years 2021-2026 Passenger Cars and Light Trucks, Final Report," at 26. Roush Industries. October 25, 2018. *See* CARB, NHTSA-2018-0067-11984.
[2544] *Ibid.* at 6.

specific model/configurations in isolation, analysis that accounts for manufacturers' *actual* production considerations produces more realistic results.

Nothing about the CAA discourages realism in regulatory analysis, and even if the CAA did so, the CAFE model can easily be run for isolated model years, or run in a manner that otherwise ignores practical limits on development and manufacturing complexity.[2545] EPA elected to use the CAFE model as designed because doing so produces a more realistic basis to estimate regulatory impacts. EPA considers its use of the CAFE model entirely consistent with all CAA and other statutory and other requirements governing the agency's development of motor vehicle CO_2 emissions standards which, unlike criteria pollutant standards, are specified on a year-by-year basis, and inherently involve the entirety of manufacturers' vehicles and fleets.

Of course, like any other model, the CAFE model used for the NPRM had room for improvement. As discussed above, the agencies have responded to public comments by making changes to some aspects of the CAFE model itself. Only a few such changes, all of which are discussed above in greater detail, impact the CAFE model's simulation of manufacturers' application of fuel-saving technologies. Among these, three are especially important: First, the model now uses a more "open" application of its technology "decision trees." While the primary objective of this change is to make the model's cost accounting more transparent (by recasting costs as absolute rather than incremental), it also makes the model somewhat more likely to identify and apply any highly cost-effective yet comparatively "advanced" combinations of technology. Second, the model introduces a "cost per credit" metric for comparing available opportunities to add specific technologies to specific vehicles.[2546] As discussed above and in the summary of the sensitivity analysis conducted for today's notice, changing from the NPRM's "effective cost" metric to this new "cost per credit" metric leads the model to, at least for the combination of inputs in today's central analysis, more frequently select less costly technology pathways than more costly pathways, at least when simulating compliance with CO_2 standards. Third, the CAFE model can now extend its explicit simulation of manufacturers' technology application well into the future. Today's analysis extends this explicit simulation through model year 2050. Because today's reference case input estimates include continued increases in fuel prices alongside continued ("learning"-related) reductions in technology costs, extending the explicit simulation shows manufacturers making significant voluntary improvement in the longer term (e.g., after MY 2035), even if CAFE and CO_2 remain unchanged.

The agencies have also revised most of the inputs to the CAFE model, both to respond to comments and to better reflect an ever-changing world. Sections appearing above discuss changes to model inputs, such as the analysis fleet, technology-related inputs, and fuel prices. Many of these changes are important to the model's simulated application of fuel-saving technology. Updating the analysis fleet from a MY 2016 to a MY 2017 basis ensures that fuel economy and CO_2 improvements manufacturers *actually* realized by adding technologies between those model years is accounted for, and ensures that changes in product offerings and production volumes between those model years are also accounted for. With this update, the agencies also more fully accounted for compliance credits accumulated prior to the MYs represented

[2545] Idealized simulation of compliance with a hypothetically isolated model year could be accomplished by, when running the model, setting the various "start" and "end" years to the same value. Sharing of engines and transmission among different model/configurations could be ignored by, in the CAFE model's "market" input file, assigning each engine, transmission, and vehicle platform to a single model/configuration (e.g., such that each of the six versions of the RAV4 is on its own vehicle platform, and uses a dedicated engine and transmission).
[2546] Notable comments on this metric appear at NHTSA-2018-0067-12039, Appendix, pp. 28-34, and at NHTSA-2018-0067-12108, Appendix B, pp. 66-70.

explicitly in today's analysis. Some manufacturers have accumulated large volumes of such credits, and are able to apply those credits well past MY 2016, and to trade them to other manufacturers. Updated vehicle simulations correct errors and make use of additional engine performance estimates (i.e., engine efficiency "maps"), and cost estimates for some technologies reflect additional data and consideration of comments. Also, fuel prices in the forecast used for today's analysis are somewhat higher than those used for the NPRM; by itself, this change makes the model tend to show larger and more widespread voluntary fuel economy increases and accompanying CO_2 emissions reductions, although this increased tendency is countered by the impact of changing to the "cost per credit" metric.

The following example will illustrate the model's behavior when simulating compliance with CO_2 standards. While the example focuses on the baseline CO_2 standards and on a specific manufacturer (Toyota), and highlights a specific vehicle model (the Toyota RAV4), results for other scenarios, manufacturers, and vehicle models reflect application of the same logic. Because this example begins with the MY 2017 fleet, and does not make use of manufacturers' product plans (which the agencies have historically treated as confidential business information, today's analysis cannot and does not fully reflect manufacturers' actual product design decisions, even in the short term. Nevertheless, the analysis yields a realistic and detailed characterization of a path each manufacturer could take in response to a given set of standards and other input estimates (e.g., of technology costs and fuel prices).

As discussed above, the model considers all models and model/configurations produced for sale in the U.S. by a given manufacturer. The Toyota Camry and Tundra are examples of specific Toyota passenger car and light truck models, Toyota produces a range of configurations (e.g., with different engines) of each of these vehicle models, and inputs to the CAFE model ensure that each such configuration is accounted for. CAFE model output files show the progressive application of technology to each model/configuration over time under each regulatory alternative. Here, focusing on different versions of one model, the RAV4, illustrates the process and results.

The RAV4 is one of the vehicle models included in a vehicle platform that also includes the Camry, Corolla, Prius, Lexus CT 200h, Lexus NX 200t, and Lexus NX 300h. As mentioned above, the CAFE model reflects the agencies' assumption that significant changes to vehicle structures or materials will most practicably be applied throughout a vehicle platform as models within the platform are redesigned. Within this platform, the CAFE model identifies the Corolla LE, at more than 180,000 units produced in MY 2017, as the most likely "leader" for such changes. Inputs to today's analysis also show that most of the RAV4s produced for the U.S. in MY 2017 shared a 2.5L naturally aspirated 4-cylinder gasoline engine with many Camrys. The CAFE model identifies the Camry as the leader for new versions of that engine. The same inputs show many RAV4s shared a 6-speed automatic transmission with a range of other vehicle models, including the Avalon, Camry, Lexus ES 350, Highlander, Lexus NX 200t, and the CAFE model identifies the Camry as the most likely leader for changes to this transmission. Model inputs also show other RAV4s shared a different 6-speed automatic transmission with the Lexus NX 200t, and the CAFE model identifies the RAV4 as the most likely leader for changes to this transmission. Finally, the MY2017 RAV4 also included two "strong" (power split) hybrid-electric versions (SE and XLE). Although these shared an engine with other Toyota hybrids (Avalon, Camry, Lexus ES 300h and NX 300h), the CAFE model reflects the agencies' assumption that it could be practicable to "split off" plug-in (or fuel cell) configurations rather than necessarily replace all strong hybrids sharing an engine with PHEVs, BEVs, or FCVs.

Inputs for today's analysis have Toyota redesigning the RAV4 every five years, starting with MY 2019, and freshening the model 2-3 years after each redesign. Given this design cycle, and all the other inputs to today's analysis, the CAFE model shows that under the baseline CO_2 standards, Toyota could potentially make changes to the RAV4 summarized in the table that follows. The first changes occur in 2019, with Toyota improving aerodynamics of the hybrid RAV4s, and with the conventional RAV4s inheriting a new high compression ratio (HCR) engine introduced with the MY 2018 redesign of the Camry, and also adding 8-speed automatic (A8) transmissions,[2547] improved accessories (IACC), and tires with reduced rolling resistance (ROLL20). With the MY 2024 redesign, all versions of the RAV4 receive further aerodynamic improvements (AERO20) and "Level 1" mass reduction, engine friction reduction (EFR) is applied to the HCR engine the non-hybrid versions share with the Camry, and secondary axle disconnect (SAX) is applied to the non-hybrid versions of the RAV4. With the MY 2027 freshening, Toyota applies low-drag brakes to all the RAV4s. The MY 2029 redesign does not make any powertrain changes, but applies more significant mass reduction (MR3) to all RAV4s. In MY 2039, Toyota replaces the hybrid RAV4 SE and XLE with 200-mile (BEV200) and 300-mile (BEV300) electric vehicle, respectively.

This progressive application of technology to the RAV4 produces a series of emission reductions shown in the following table (and, though not shown, corresponding fuel economy improvements). The table also shows the progression of CO_2 targets for these vehicles, reflecting the fact that targets are higher for the hybrid and conventional AWD versions of the RAV4, classified as light trucks, than for the FWD RAV4s classified as passenger cars. Also notably, the conventional RAV4s never achieve their respective CO_2 emissions targets. This merely reflects the fact that credits for reducing A/C refrigerant leakage apply at the fleet level rather than on a per-vehicle basis and, in any event, Toyota can respond by improving CO_2 levels enough among enough other vehicle models that Toyota's overall average CO_2 levels comply with Toyota's overall requirements, taking into account the potential application of compliance credits.

*Bold type indicates hybrid versions of RAV4 are replaced by BEV versions in 2039.

These CO_2 values could be converted to equivalent fuel economy levels by multiplying their reciprocals by 8887 grams per gallon (e.g., 8887 g/gal × 1/(144 g/mi) = 62 mpg), differences in compliance provisions are such that results would be offset from actual fuel economy levels under CAFE standards. When simulating compliance with CAFE or CO_2 standards, the CAFE model reports both fuel economy and CO_2 targets and achieved levels, even when the model is "enforcing" compliance with only one of these sets of standards. When simulating compliance with baseline CO_2 standards, results for the example discussed here show the following fuel economy targets and achieved levels for the RAV4.

Table VI-301 – Estimated RAV4 Target/Achieved FE Levels (mpg) under Modeled Response to Baseline CO_2 Standards

*Bold type indicates hybrid versions of RAV4 are replaced by BEV versions in 2039.

The progressive application of technology also produces increases (and some eventual decreases) in costs. For each RAV4 configuration, the following table shows costs beyond MY 2017 technology, in 2018 dollars. The conventional RAV4s incur a significant cost increase in MY 2019, primarily for the new HCR engine inherited from the Camry. Costs continue to increase through MY 2029 as additional technology accumulates, with another significant increase for MR4 in MY 2029. After MY 2029, technology costs for conventional RAV4s gradually decline through MY 2050, in response to ongoing learning. In MY 2039, the BEV200 RAV4 is *less* expensive than the HEV RAV4 it replaces, leading this version's cost to drop by about $500 between MY 2033 and MY 2034, and with learning, to fall quickly well below this version's MY *2017* cost. Conversely, the BEV300 RAV4 introduced in MY 2039 is about $950 more expensive than the MY 2038 hybrid RAV4 it replaces, and even with learning, the BEV300 remains more expensive through MY 2050 than the hybrid RAV4. These BEVs are not needed for compliance; the model shows Toyota could introduce them because, if battery costs continue to decline while gasoline prices continue to increase, BEVs could eventually become attractive on an economic basis.

Table-VI-302 – Estimated RAV4 Technology Costs (2018 Dollars) vs. MY 2017 under Baseline CO_2 Standards

*Bold type indicates hybrid versions of RAV4 are replaced by BEV versions in 2039.

As mentioned above, by making sufficient improvements to other vehicle models, Toyota could refrain from making the conventional RAV4s meet their CO_2 emissions targets. More broadly, Toyota can also use compliance credits to cover compliance gaps. The CAFE model accounts for the potential to transfer compliance credits between the passenger car (PC) and light truck (LT) fleets. The model also accounts for the potential to apply credits from prior model years (i.e., credits that have been "banked" or, equivalently, "carried forward"), including compliance credits earned prior to MY 2017. These aspects of the model interact with the model's accounting for multiyear planning—that is, the potential that a manufacturer, depending on its product design cadence and on the progression of standards, might apply "extra" technology in some model years in order to facilitate compliance in later model years. For example, if a manufacturer is only redesigning 15% of its fleet volume in MY 2025, that manufacturer might be best off—even setting aside credit banking—applying some "extra" technology (i.e., technology that leads to overcompliance) as part of vehicle redesigns planned for MYs 2018-2024, and carrying that technology forward into MY 2025 when there are fewer opportunities available to reduce CO_2 emissions in new models. As shown in Figure VI-174, in Toyota's case, the model shows that Toyota could offset its light truck compliance gaps during MY 2017-2019 by applying compliance credits earned for light trucks prior to MY 2017. The graph also shows Toyota applying extra technology to its passenger car fleet during MYs 2018-2024 in order to comply with the MY 2025 passenger car standard, but also to carry forward compliance credits and use those credits to offset large compliance gaps for Toyota's light truck fleet during MYs 2023-2027. After MY 2025, the model shows the effects of some technology continuing to be inherited (especially during MYs 2026-2030) from prior MYs, of Toyota continuing to make voluntary improvements where economically attractive (like the MY 2039 RAV4 EV mentioned above), and of Toyota continuing to transfer compliance credits from the passenger car to the light truck fleet.[2548]

[2548] While the fleets (PC and LT) are shown separately for compliance purposes in this example, the ability to utilize credits from either fleet toward total model year compliance (in the current year, without caps or limits) means that the fleets for a manufacturer comply jointly in each model year.

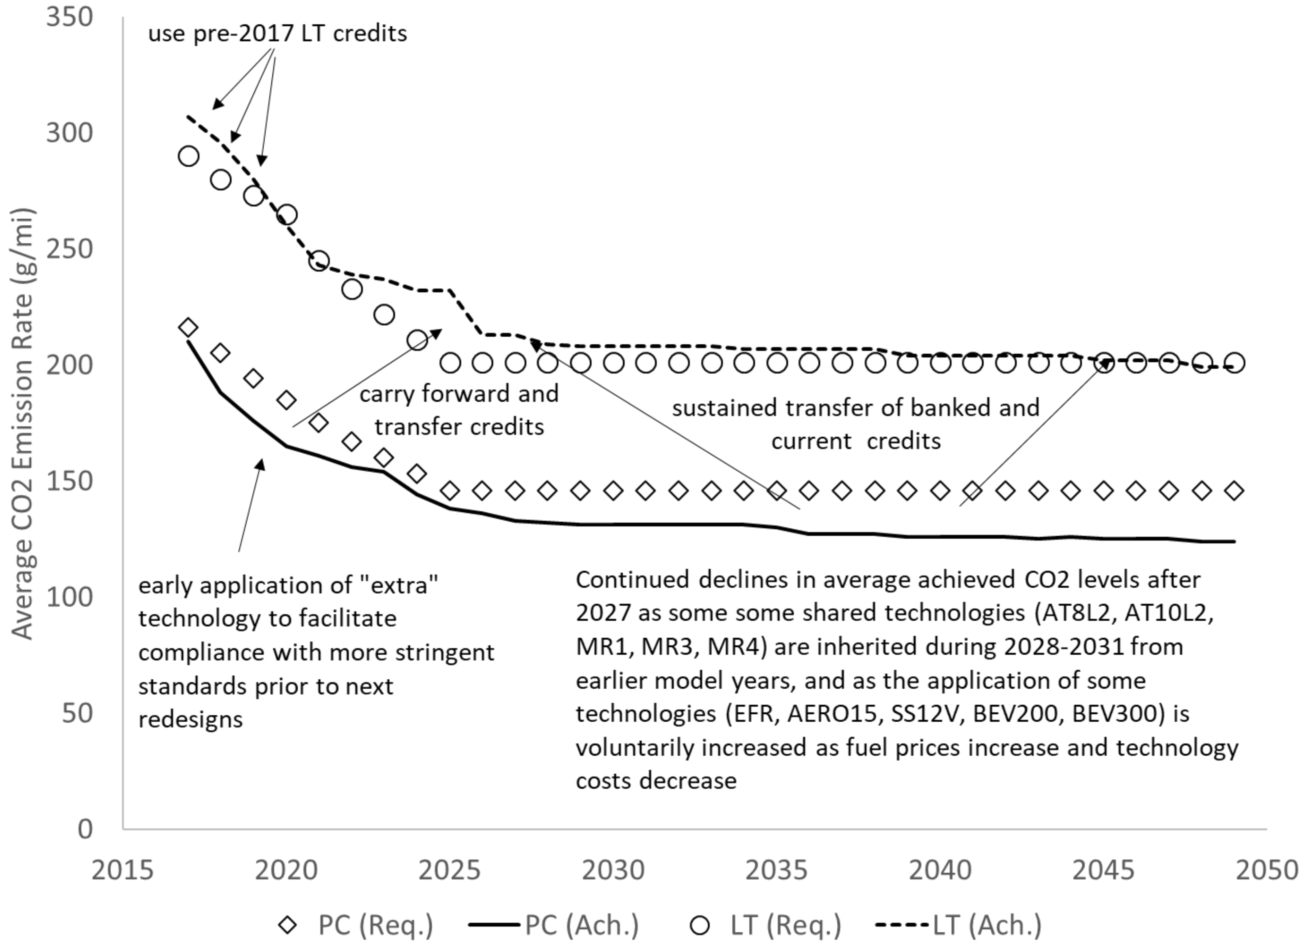

Figure VI-174 – Estimated CO_2 Requirements and Average Emission Rates for Toyota under Baseline CO_2 Standards

As the above figure shows, credit banking and transfers play an important role in Toyota's simulated response to the standards. If exercised in a manner that sets aside credit banking, the CAFE model shows Toyota increasing its application of fuel-saving technologies through MY 2025, and carrying those improvements forward, such that Toyota's overall average CO_2 emission rate is 16 g/mi lower in MY 2025 when credit banking is not accounted for, as illustrated by the next chart appearing below. Though not shown here, accounting for credit banking also impacts the simulation other OEMs' compliance pathways, because inputs to today's analysis assume that Toyota would likely not need to use all of its pre-2017 compliance credits before these credits expire in 2021, and that Toyota could therefore sell those older credits other manufacturers (e.g., FCA, VW). By accounting for credit banking, the CAFE model thereby avoids considerable potential understatement of future CO_2 emissions from light-duty vehicles.

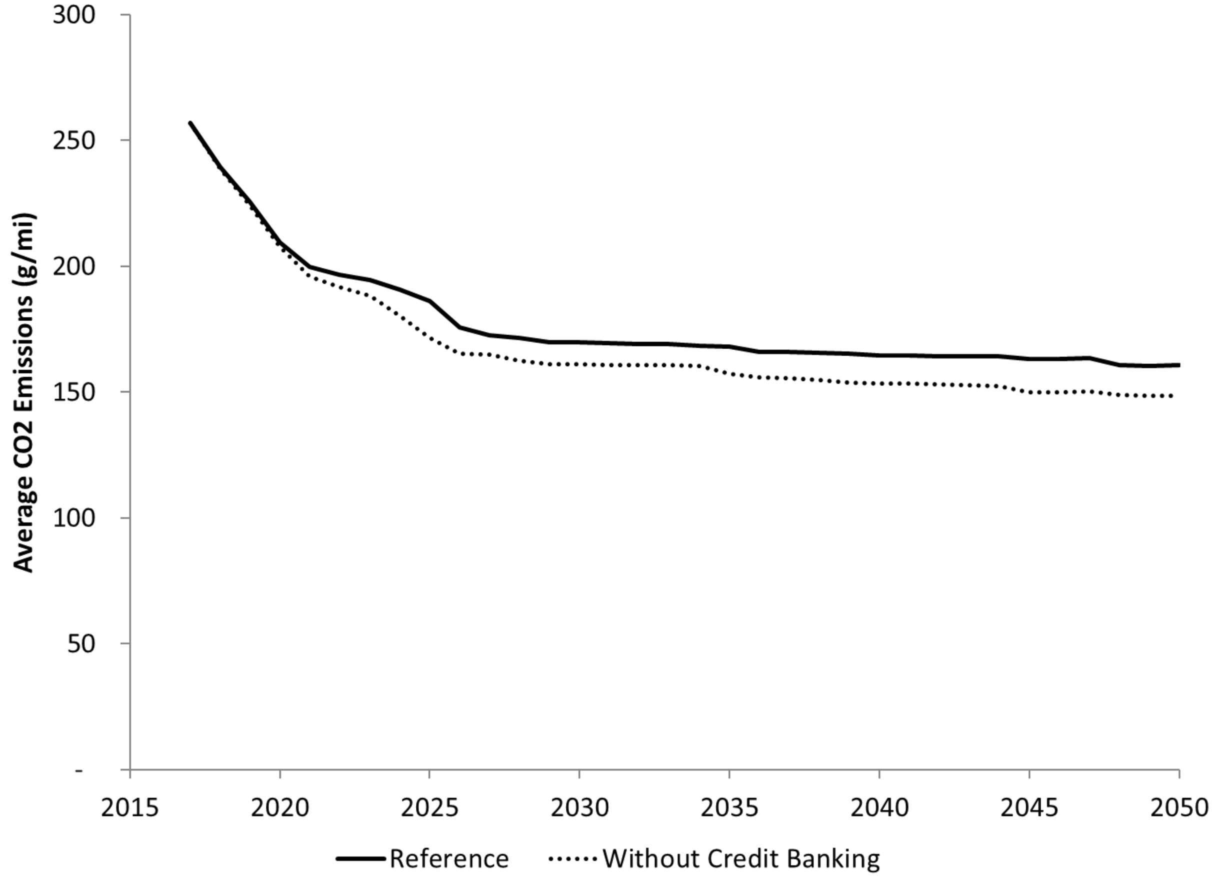

Figure VI-175 – Impact of Credit Banking on Estimated Toyota CO_2 Emission Rates under Baseline CO_2 Standards

As indicated by the following chart, a failure to account for credit banking would also increase Toyota's modeled per-vehicle costs by nearly $1,000 in MY 2025. By accounting for credit banking, the CAFE model thus avoids considerable potential overstatement of compliance costs. Though not shown here, accounting for credit banking while also applying inputs that reflect Toyota's ability to sell older credits to some other OEMs also enables the CAFE model to avoid overstatement of compliance costs for those OEMs.

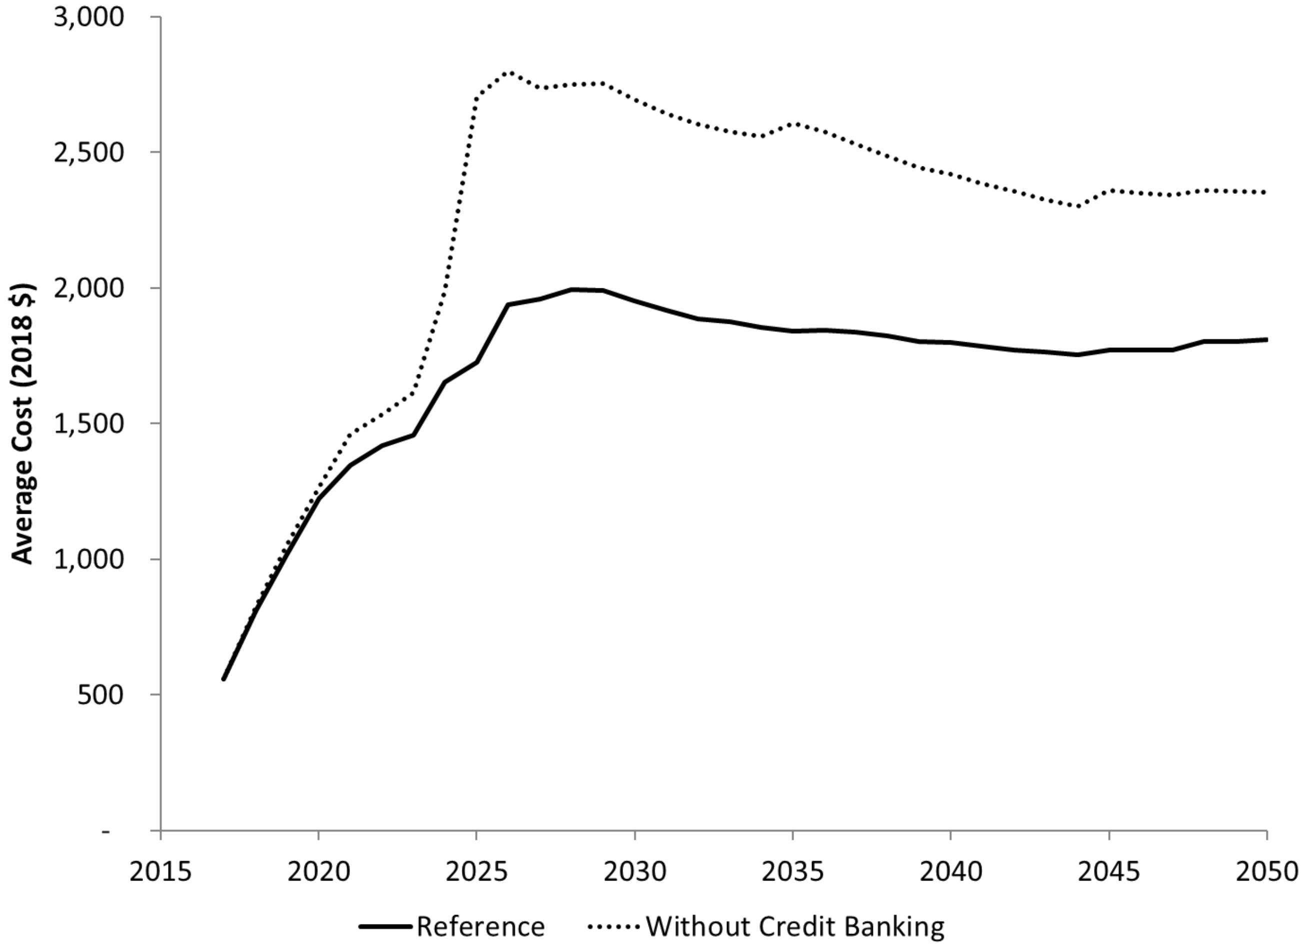

Figure VI-176 – Impact of Credit Banking on Estimated Toyota Per-Vehicle Costs under Baseline CO_2 Standards

While the model's simulation of manufacturers' potential responses to CAFE standards applies the same inputs and analytical methods, it does so accounting for several important statutory and regulatory differences between CO_2 standards and CAFE standards, and for specific statutory direction regarding how CAFE standards are to be considered for purposes of setting standards at the maximum feasible levels in each model year. EPCA places specific limits on the amount of credit that can be transferred between fleets, and requires that domestic passenger cars meet minimum standards without applying credits. EPCA also requires that the determination of maximum feasible stringency set aside the potential to apply compliance credits or introduce new alternative fuel vehicles (include BEVs and FCVs, but not including plug-in HEVs) during the model years under consideration. Especially with standards that continue to become more stringent, applying these statutory constraints to the analysis leads the model to tend to show greater overcompliance with standards in earlier model years, because even setting aside the potential to carry forward or transfer credits, Toyota is likely to find it more practicable to apply some "extra" technology when redesigning vehicles during MYs 2017-2024 than to attempt to address MY 2025 standards by working with only vehicles scheduled to be redesigned in MY 2025. The model also tends to show greater overcompliance in later model years, because some of that extra technology from years leading up to the last year of stringency increases takes time to carry forward to ensuing model years. These aspects of the CAFE "standard setting" analysis are evident in the model's solution for Toyota, shown in the following figure. With the use of credits set aside after MY 2020, Toyota overcomplies with light truck standards during MYs

2018-2023 in order to carry technology forward into MY 2025. Although Toyota only marginally overcomplies with MY 2025 standards, the inheritance of technology during MYs 2026-2029 contributes to increased overcompliance (which is to be expected given the degree of platform and powertrain sharing between the fleets). Continued increases in overcompliance after 2030 arise due to cost learning effects (especially for batteries) and increased fuel prices.

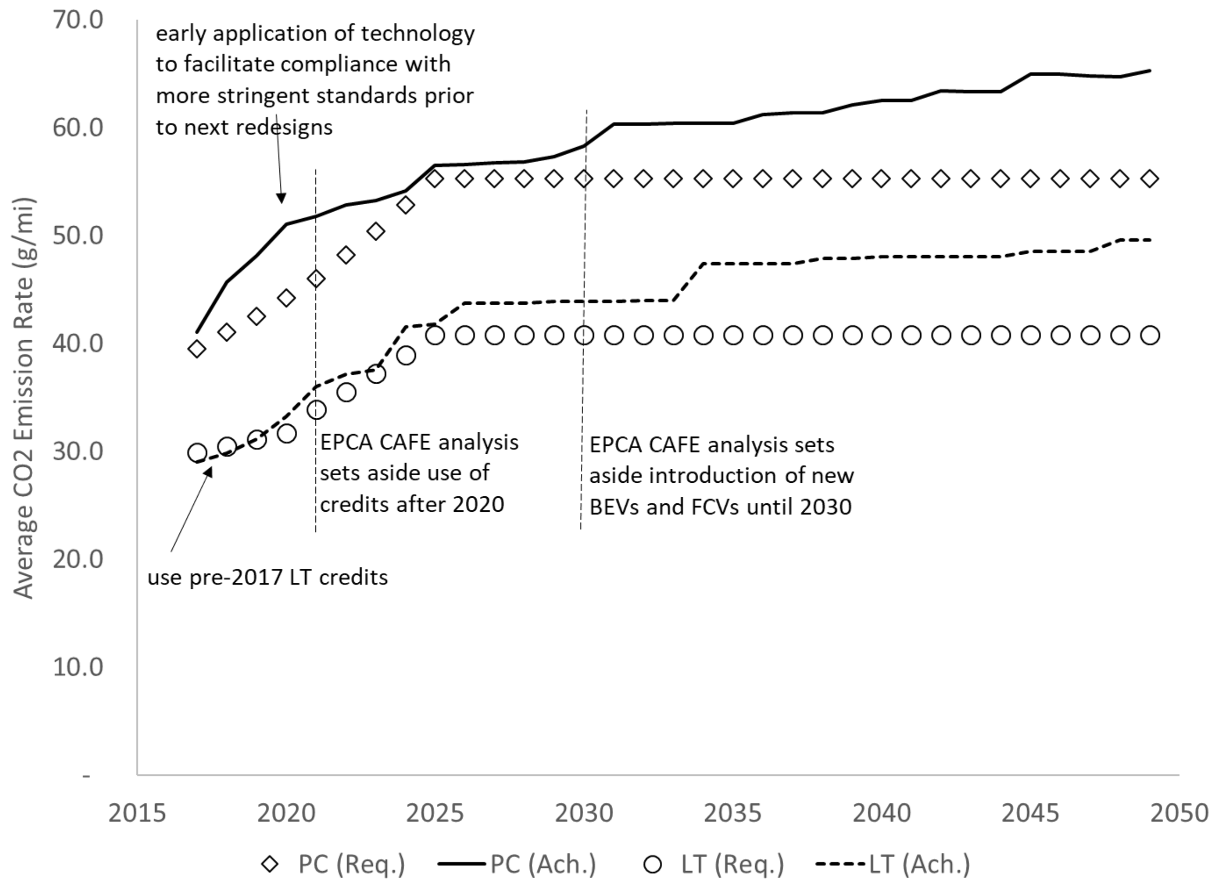

Figure VI-177 – Estimated CAFE Requirements and Levels for Toyota under Baseline CAFE Standards

VII. What Does the Analysis Show, and What Does It Mean?

A. Manufacturer CAFE and CO_2 Capabilities

1. Overview

New and amended CAFE and CO_2 standards will have a range of impacts. EPCA/EISA and NEPA require DOT to consider such impacts when making decisions about new CAFE standards, and the CAA requires EPA to do so when making decisions about new emissions standards. Like past rulemakings, today's final rule is supported by the analysis of many potential impacts of new and amended standards. Today's rule establishes new and amended standards through model year 2026, explicitly estimates manufacturers' responses to an hypothetical extension of these standards through model year 2029, and considers impacts throughout those vehicles' useful lives. It is not known today what would actually come to pass under the final standards or under any of the alternatives considered. The analysis is thus properly interpreted not as a forecast, but rather as an assessment—reflecting in some cases best judgments regarding different factors—of impacts that could occur.[2549] As discussed below, the analysis explores the sensitivity of this assessment to a variety of potential changes in key analytical inputs (e.g., fuel prices).

This section summarizes various impacts of the preferred alternative (i.e., the final standards) defined above in Section II.D and Section V.C.3.c). The no-action alternative defined in Section V.B provides the baseline relative to which all impacts are shown. Because the final standards (and other standards considered below), being of a "deregulatory" nature, are less stringent than the no-action alternative, all impacts are directionally opposite impacts reported in recent CAFE and CO_2 rulemakings. For example, while past rulemakings reported positive values for fuel consumption avoided under new standards, today's announcement reports negative values, as fuel consumption will be somewhat greater under today's final standards than under standards defining the baseline no-action alternative. Reported negative values for avoided fuel consumption could also be properly interpreted as simply "additional fuel consumption." Similarly, reported negative values for costs could be properly interpreted as "avoided costs" or "benefits," and reported negative values for benefits could be properly interpreted as "foregone benefits" or "costs." However, this analysis retains reporting conventions consistent with past rulemakings, anticipating that, compared to other options, doing so will facilitate review by most stakeholders.

This analysis presents individual model year results two different ways. The first way is similar to past rulemakings and shows how manufacturers could respond in each model year under the final standards and each alternative covering MYs 2022-2026. The second, expanding on the information provided in past rulemakings, evaluates incremental impacts of new standards for each model year, in turn. In past rulemaking analyses, NHTSA modeled year-by-year impacts under the aggregation of standards applied in all model years, and EPA modeled manufacturers' hypothetical compliance with a single model years' standards in that model year.

[2549] "Prediction is very difficult, especially if it's about the future." Attributed to Niels Bohr, Nobel laureate in Physics.

Especially considering multiyear planning effects, neither approach provides a clear basis to attribute impacts to specific standards first introduced in each of a series of model years. For example, of the technology manufacturers applied in MY 2016, some would have been applied even under the MY 2014 standards, and some was likely applied to position manufacturers toward compliance with (including credit banking to be used toward) MY 2018 standards. Therefore, of the impacts attributable to the model year 2016 fleet, only a portion can be properly attributed to the MY 2016 standards, and the impacts of the MY 2016 standards involve fleets leading up to and extending well beyond MY 2016. Considering this, the final standards were examined on an incremental basis, modeling each new model year's standards over the entire span of included model years, using those results as a baseline relative to which to measure impacts attributable to the next model year's standards. For example, incremental costs attributable to the standards finalized today for MY 2023 are calculated as follows -

$$COST_{Final,MY\ 2023} = (COST_{Final\_through\_MY\ 2023} - COST_{No\text{-}Action\_through\_MY\ 2023}) - (COST_{Final\_through\_MY\ 2022} - COST_{No\text{-}Action\_through\_MY\ 2022})$$

where

$COST_{Final,MY\ 2023}$ - Incremental technology cost during MYs 2017-2030 and attributable to the standards finalized for MY 2023.

$COST_{Final\_through\_MY\ 2022}$ - Technology cost for MYs 2017-2030 under standards finalized through MY 2022.

$COST_{Final\_through\_MY\ 2023}$ - Technology cost for MYs 2017-2030 under standards finalized through MY 2023.

$COST_{No\text{-}Action\_through\_MY\ 2022}$ - Technology cost for MYs 2017-2030 under no-action alternative standards through MY 2022.

$COST_{No\text{-}Action\_through\_MY\ 2023}$ - Technology cost for MYs 2017-2030 under no-action alternative standards through MY 2023.

Additionally, today's analysis includes impacts on new vehicle sales volumes and the use (i.e., survival) of vehicles of all model years, such that standards introduced in a model year produce impacts attributable to vehicles having been in operation for some time. For example, as modeled here, standards for MY 2021 will impact the prices of new vehicles starting in MY 2017, and those price impacts will affect the survival of all vehicles still in operation in calendar years 2017 and beyond (e.g., MY 2021 standards impact the operation of MY 2017 vehicles in calendar year 2027). Therefore, while past rulemaking analyses focused largely on impacts over the useful lives of the explicitly modeled fleets, much of today's analysis considers all model years through 2029, as operated throughout those vehicles' useful lives. For some impacts, such as on technology penetration rates, average vehicle prices, and average vehicle ownership costs, this analysis focused on the useful life of vehicles produced during MY 2030, as the simulation of manufacturers' technology application and credit use (when included in the analysis) continues to evolve after model year 2026, finally stabilizing by model year 2030.

The analysis evaluated effects from four perspectives - the social perspective, the manufacturer perspective, the private perspective, and the physical perspective. The social perspective focuses on economic benefits and costs, setting aside economic transfers such as fuel taxes but including economic externalities such as the social cost of CO_2 emissions. The manufacturer perspective focuses on average requirements and levels of performance (i.e., average fuel economy level and CO_2 emission rates), compliance costs, and degrees of technology application. The private perspective focuses on costs of vehicle purchase and ownership, including outlays for fuel (and fuel taxes). The physical perspective focuses on national-scale highway travel, fuel consumption, highway fatalities, and greenhouse gas and criteria pollutant emissions.

For the social perspective, the following effects for model years through 2029 as operated through calendar year 2068 are summarized:

- Technology Costs: Incremental cost, as expected to be paid by vehicle purchasers, of fuel-saving technology beyond that added under the no-action alternative.
- Welfare Loss: Loss of value to vehicle owners resulting from incremental increases in the numbers of strong and plug-in hybrid electric vehicles (strong HEVs or SHEVs, and PHEVs) and/or battery electric vehicles (BEVs), beyond increases occurring under the no-action alternative.[2550] The loss of value is a function of the factors that lead to different valuations for conventional and electric versions of similar-size vehicles (e.g., differences in: travel range, recharging time versus refueling time, performance, and comfort).
- Pre-tax Fuel Savings: Incremental savings, beyond those achieved under the no-action alternative, in outlays for fuel purchases, setting aside fuel taxes.
- Mobility Benefit: Value of incremental travel, beyond that occurring under the no-action alternative.
- Lost New Vehicle Consumer Surplus: Value of incremental savings to new vehicle buyers due to cheaper vehicle prices.
- Implicit Opportunity Cost:[2551] Value of other vehicle attributes forwent to apply technology to meet the standards.
- Refueling Benefit: Value of incremental reduction, compared to the no-action alternative, of time spent refueling vehicles.
- Non-Rebound Fatality Costs: Social value of additional fatalities, beyond those occurring under the no-action alternative, setting aside any additional travel attributable to the rebound effect.
- Rebound Fatality Costs: Social value of additional fatalities attributable to the rebound effect, beyond those occurring under the no-action alternative.

[2550] Through MY 2029, the "standard setting" analysis of CAFE standards sets aside the potential that manufacturers might by introduce new BEV (or FCV) vehicle models, but allows that the numbers of such vehicles produced might increase or decrease along with overall U.S. sales of new passenger cars and light trucks, and allows that additional BEV or FCV vehicle models might be intruded after MY 2029.
[2551] This value is set to "0" for the central analysis.

- Benefits Offsetting Rebound Fatality Costs: Assumed further value, offsetting rebound fatality costs internalized by drivers, of additional travel attributed to the rebound effect.
- Non-Rebound Non-Fatal Crash Costs: Social value of additional crash-related losses (other than fatalities), beyond those occurring under the no-action alternative, setting aside any additional travel attributable to the rebound effect.
- Rebound Non-Fatal Crash Costs: Social value of additional crash-related losses (other than fatalities) attributable to the rebound effect, beyond those occurring under the no-action alternative.
- Benefits Offsetting Rebound Non-Fatal Crash Costs: Assumed further value, offsetting rebound non-fatal crash costs internalized by drivers, of additional travel attributed to the rebound effect.
- Additional Congestion and Noise (Costs): Value of additional congestion and noise resulting from incremental travel, beyond that occurring under the no-action alternative.
- Energy Security Benefit: Value of avoided economic exposure to petroleum price "shocks," the avoided exposure resulting from incremental reduction of fuel consumption beyond that occurring under the no-action alternative.
- Avoided CO_2 Damages (Benefits): Social value of incremental reduction of CO_2 emissions, compared to emissions occurring under the no-action alternative.
- Other Avoided Pollutant Damages (Benefits): Social value of incremental reduction of criteria pollutant emissions, compared to emissions occurring under the no-action alternative.
- Total Costs: Sum of incremental technology costs, welfare loss, fatality costs, non-fatal crash costs, and additional congestion and noise costs.
- Total Benefits: Sum of pretax fuel savings, mobility benefits, refueling benefits, Benefits Offsetting Rebound Fatality Costs, Benefits Offsetting Rebound Non-Fatal Crash Costs, energy security benefits, and benefits from reducing emissions of CO_2, the CO_2 equivalent of other associated gases, and criteria pollutants.
- Net Benefits: Total benefits minus total costs.
- Retrievable Electrification Costs: The portion of HEV, PHEV, and BEV technology costs which can be passed onto consumers, using the willingness to pay analysis described above.
- Electrification Tax Credits: Estimates of the portion of HEV, PHEV, and BEV technology costs which are covered by Federal or State tax incentives.
- Irretrievable Electrification Costs: The portion of HEV, PHEV, and BEV technology costs OEM's must either absorb as a profit loss, or cross-subsidize with the prices of internal combustion engine (ICE) vehicles.
- Total Electrification Costs: Total incremental technology costs attributable to HEV, PHEV, or BEV vehicles.

For the manufacturer perspective, the following effects for the aggregation of model years 2017-2029 are summarized:

- Average Required Fuel Economy: Average of manufacturers' CAFE requirements for indicated fleet(s) and model year(s).

- Percent Change in Stringency from Baseline: Percentage difference between averages of fuel economy requirements under no-action and indicated alternatives.
- Average Required Fuel Economy: Industry-wide average of fuel economy levels achieved by indicated fleet(s) in indicated model year(s).
- Percent Change in Stringency from Baseline: Percentage difference between averages of fuel economy levels achieved under no-action and indicated alternatives.
- Total Technology Costs ($b): Cost of fuel-saving technology beyond that applied under no-action alternative.
- Total Civil Penalties ($b): Cost of civil penalties (for the CAFE program) beyond those levied under no-action alternative.
- Total Regulatory Costs ($b): Sum of technology costs and civil penalties
- Sales Change (millions): Change in number of vehicles produced for sale in U.S., relative to the number estimated to be produced under the no-action alternative.
- Revenue Change ($b): Change in total revenues from vehicle sales, relative to total revenues occurring under the no-action alternative.
- Curb Weight Reduction: Reduction of average curb weight, relative to MY 2017.
- Technology Penetration Rates: MY 2030 average technology penetration rate for indicated ten technologies (three engine technologies, advanced transmissions, and six degrees of electrification).
- Average Required CO_2: Average of manufacturers' CO_2 requirements for indicated fleet(s) and model year(s).
- Percent Change in Stringency from Baseline: Percentage difference between averages of CO_2 requirements under no-action and indicated alternatives.
- Average Achieved CO_2: Average of manufacturers' CO_2 emission rates for indicated fleet(s) and model year(s).

For the private perspective, the following effects for the MY 2030 fleet are summarized:

- Average Price Increase: Average increase in vehicle price, relative to the average occurring under the no-action alternative.
- Implicit Opportunity Cost: The lost benefit of vehicle attributes that consumers prefer, which are sacrificed by manufacturers to comply with the standards.
- Welfare Loss (Costs): Average loss of value to vehicle owners resulting from incremental increases in the numbers of strong HEVs, PHEVs) and/or BEVs, beyond increases occurring under the no-action alternative. The loss of value is a function of the factors that lead to different valuations for conventional and electric versions of similar-size vehicles (e.g., differences in: travel range, recharging time versus refueling time, performance, and comfort).
- Ownership Costs: Average increase in some other costs of vehicle ownership (taxes, fees, financing), beyond increase occurring under the no-action alternative.\
- Lost Consumer Surplus: Value of incremental savings to new vehicle buyers due to cheaper vehicle prices.
- Fuel Savings: Average of fuel outlays (including taxes) avoided over a vehicle's expected useful lives, compared to outlays occurring under the no-action alternative.
- Mobility Benefit: Average incremental value of additional travel over average vehicles' useful lives, compared to travel occurring under the no-action alternative.

- Refueling Benefit: Average incremental value of avoided time spent refueling over average vehicles' useful lives, compared to time spent refueling under the no-action alternative.
- Total Costs: Sum of average price increase, welfare loss, and ownership costs.
- Total Benefits: Sum of fuel savings, the mobility benefit, and the refueling benefit.
- Net Benefits: Total benefits minus total costs.

For the physical perspective, the following effects for model years through 2029 as operated through calendar year 2068 are summarized:

- Fuel Consumption, with rebound (billion gallons): Reduction of fuel consumption, relative to the no-action alternative, and including the rebound effect.
- Fuel Consumption, without rebound (billion gallons): Reduction of fuel consumption, relative to the no-action alternative, and excluding the rebound effect.
- Greenhouse Gases: Includes carbon dioxide (CO_2), methane (CH4), and nitrous oxide (N_2O), and values are reported separately for vehicles (tailpipe) and upstream processes (combining fuel production, distribution, and delivery) and shown as reductions in carbon dioxide or its equivalent relative to the no-action alternative.
- Criteria Pollutants: Includes carbon monoxide (CO), volatile organic compounds (VOC), nitrogen oxides (NO_X), sulfur dioxide (SO_2) and particulate matter (PM), and values are shown as reductions relative to the no-action alternative.
- Fuel Consumption: Aggregates all fuels, with electricity, hydrogen, and compressed natural gas (CNG) included on a gasoline-equivalent-gallon (GEG) basis, and values are shown as reductions relative to the no-action alternative.
- VMT, with rebound (billion miles): Increase in highway travel (as vehicle miles traveled), relative to the no-action alternative, and including the rebound effect.
- VMT, without rebound (billion miles): Increase in highway travel (as vehicle miles traveled), relative to the no-action alternative, and excluding the rebound effect.
- Fatalities, with rebound: Increase in highway fatalities, relative to the no-action alternative, and including the rebound effect.
- Fatalities, without rebound: Increase in highway fatalities, relative to the no-action alternative, and excluding the rebound effect.
- Health Effects: Increase in the occurrence of a variety of health effects of criteria pollutant emissions, relative to the no-action alternative, and reported separately for tailpipe and upstream emissions.

Below, this section tabulates results for each of these four perspectives and does so separately for the final CAFE and CO_2 standards. Additional and more detailed analysis of environmental impacts is provided for CAFE regulatory alternatives in the corresponding Environmental Impact Statement (EIS). Underlying CAFE Model output files are available (along with input files, model, source code, and documentation) on NHTSA's web site.[2552] Summarizing and tabulating results for presentation here involved considerable "off model"

[2552] https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system.

calculations (e.g., to combine results for selected model years and calendar years, and to combine various components of social and private costs and benefits); tools Volpe Center staff used to perform these calculations are also available on NHTSA's web site.[2553]

While the National Environmental Policy Act (NEPA) requires NHTSA to prepare an EIS documenting estimating environmental impacts of the regulatory alternatives under consideration in CAFE rulemakings, NEPA does not require EPA to do so for EPA rulemakings. CO2 standards for each regulatory alternative being harmonized as practical with corresponding CAFE standards, environmental impacts of CO2 standards should be directionally identical and similar in magnitude to those of CAFE standards. Results presented herein for the CAFE standards differ slightly from those presented in the EIS; while, as discussed above, EPCA/EISA requires that the Secretary determine the maximum feasible levels of CAFE standards in manner that, as presented here, sets aside the potential use of CAFE credits or application of alternative fuels toward compliance with new standards, NEPA does not impose such constraints on analysis presented corresponding EISs, and the EIS presents results of an "unconstrained" analysis that considers manufacturers' potential application of alternative fuels and use of CAFE credits.

In terms of all estimated impacts, including estimated costs and benefits, the results of today's analysis are different for CAFE and CO_2 standards. Differences arise because, even when the mathematical functions defining fuel economy and CO_2 targets are "harmonized", surrounding regulatory provisions may not be. For example, while both CAFE and CO_2 standards allow credits to be transferred between fleets and traded between manufacturers, EPCA/EISA places explicit and specific limits on the use of such credits, such as by requiring that each domestic passenger car fleet meet a minimum CAFE standard (as discussed above). The CAA provides no specific direction regarding CO_2 standards, and while EPA has adopted many regulatory provisions harmonized with specific EPCA/EISA provisions (e.g., separate standards for passenger cars and light trucks), EPA has not adopted all such provisions. For example, EPA has not adopted the EPCA/EISA provisions limiting transfers between regulated fleet or requiring separate compliance by domestic and imported passenger car fleets. Such differences introduce differences between impacts estimated under CAFE standards and under CO_2 standards. Also, as mentioned above, Congress has required that new CAFE standards be considered in a manner that sets aside the potential use of CAFE credits and the potential additional application of alternative fuel vehicles (such as electric vehicles) during the model years under consideration. Congress has provided no corresponding direction regarding the analysis of potential CO_2 standards, and today's analysis does consider these potential responses to CO_2 standards.

This analysis was conducted to examine the sensitivity of results to changes in key inputs.

[2553] These tools, available at the same location, are scripts executed using R, a free software environment for statistical computing. R is available through https://www.r-project.org/.

2. Impacts of Final Standards on Requirements, Performance, and Costs to Manufacturers in Specific Model Years

As mentioned above, this analysis presents impacts from two different perspectives for today's proposal. From either perspective, overall impacts are the same. The first perspective, following the approach taken by NHTSA in past CAFE rulemakings, examines impacts of the overall proposal — i.e., the entire series of year-by-year standards — on each model year. This perspective is especially relevant to understanding how the overall proposal may impact manufacturers in terms of year-by-year compliance, technology pathways, and costs. The second, presented below provides a clearer characterization of the incremental impacts attributable to standards introduced in each successive model year.

Part 1 below reviews estimates from the CAFE Model Table VII-1 and Table VII-2 which present estimated required and achieved fuel economy by manufacturer and model year under the baseline (no-action) and preferred alternatives. Table VII-3 and Table VII-4 present regulatory costs and average vehicle price increases, respectively, by manufacturer and model year. Table VII-5 provides summary estimates of impacts on technology costs, average vehicle prices, sales, and labor utilization.

Table VII-6 through Table VII-21 provide estimated technology penetration, with a focus on estimates by manufacturer. In Part 2, the analysis from Part 1 is repeated under EPA's CO_2 Program rather than the CAFE Model.

a) CAFE Standards

Table VII-1 – Required and Achieved CAFE Levels in MYs 2016-2029 under Baseline CAFE Standards (No-Action Alternative)

Manufacturer		**2017**	**2018**	**2019**	**2020**	**2021**	**2022**	**2023**	**2024**	**2025**	**2026**	**2027**	**2028**	**2029**
BMW	Required	35.6	36.8	38.0	39.4	41.3	43.2	45.3	47.4	49.6	49.6	49.6	49.6	49.6

*The change in vehicle prices (MSRP) may not match the change in technology costs reported in other tables. The change in MSRP noted here will include shifts in the average value of a vehicle, before technology application, due to the dynamic fleet share model (more light trucks are projected under the augural standards than the final standards, and light trucks are on average more expensive than passenger cars), in addition to the price changes from differential technology application and civil penalties, reported elsewhere.

*The change in vehicle prices (MSRP) may not match the change in technology costs reported in other tables. The change in MSRP noted here will include shifts in the average value of a vehicle, before technology application, due to the dynamic fleet share model (more light trucks are projected under the augural standards than the final standards, and light trucks are on average more expensive than passenger cars), in addition to the price changes from differential technology application and civil penalties, reported elsewhere.

3. Impacts on Producers of New Vehicles

Part 1 below presents estimates from the CAFE Model.

Table VII-48, Table VII-55, and Table VII-59 present estimated compliance impacts and cumulative industry costs under the preferred alternative, including changes in stringency, achieved fuel economy, technology costs, civil penalties, sales impacts and revenue impacts.

Table VII-52, Table VII-56 and Table VII-60 present estimated required fuel economy across fuel economy standards; Table VII-53, Table VII-57, and Table VII-61 present corresponding estimates of achieved fuel economy.

Table VII-54, Table VII-58, and Table VII-62 present estimated technology penetration rates for MY 2030 vehicles under the preferred alternative.

Table VII-63 through Table VII-66 detail impacts on the passenger car fleet, including separate estimates for domestic and imported vehicles.

Table VII-123 presents impacts on fuel economy, regulatory cost, average vehicle price, and technology use by manufacturer. In Part 2, the analysis from Part 1 is repeated under EPA's CO_2 Program rather than the CAFE Model.
